Figure 2-45B.—Nondegenerative parametric amplifier. ELECTRICAL EQUIVALENT.

The pump signal causes the capacitor in figure 2-45A to vary at a 12-gigahertz rate. The 3-gigahertz input signal enters via a four-port ferrite circulator, is developed in the signal cavity, and applied across the varactor. The nonlinear action of the varactor produces a 9-gigahertz difference frequency (fp-fs) with an energy-level higher than the original input signal.

The difference (idler) frequency is reapplied to the varactor to increase the gain and to produce an output signal of the correct frequency. The 9-gigahertz idler frequency recombines with the 12-gigahertz pump signal and produces a 3-gigahertz difference signal that has a much larger amplitude than the original 3-gigahertz input signal. The amplified signal is sent to the ferrite circulator for transfer to the next stage.

As with tunnel-diode amplifiers, the circulator improves stability by preventing reflection of the signal back into the amplifier. Reflections would be amplified and cause uncontrollable oscillations. The ferrite circulator also serves as an isolator to prevent source and load impedance changes from affecting gain.

Typically, the gain of a parametric amplifier is about 20 dB. The gain can be controlled with a variable attenuator that changes the amount of pump power applied to the varactor.

Parametric amplifiers are relatively simple in construction. The only component is a varactor diode placed in an arrangement of cavities and waveguides. The most elaborate feature of the amplifier is the mechanical tuning mechanism. Figure 2-46 illustrates an actual parametric amplifier.

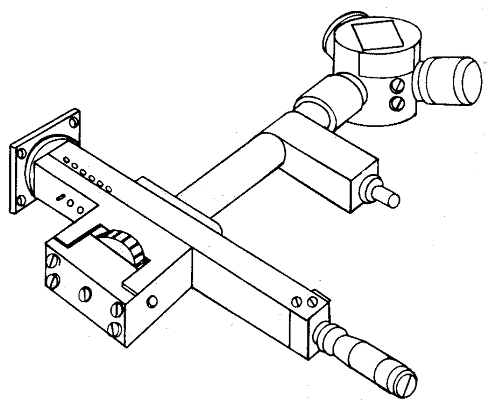

Figure 2-46.—Parametric amplifier.

PARAMETRIC FREQUENCY CONVERTERS.—Parametric frequency converters, using varactors, are of three basic types. The UPPER-SIDEBAND PARAMETRIC UP-CONVERTER produces an output frequency that is the SUM of the input frequency and the pump frequency. The LOWER-SIDEBAND PARAMETRIC DOWN-CONVERTER produces an output frequency that is the DIFFERENCE between the pump frequency and the input frequency. The DOUBLE-SIDEBAND PARAMETRIC UP-CONVERTER produces an output in which both the SUM and the DIFFERENCE of the pump and input frequencies are available.

Parametric frequency converters are very similar to parametric amplifiers in both construction and operation. Figure 2-47 is a functional diagram of a parametric down-converter.

The parametric frequency converter operates in the same manner as the parametric amplifier except that the sideband frequencies are not reapplied to the varactor. Therefore, the output is one or both of the sideband frequencies and is not the same as the input frequency. The output frequency is determined by the cavity used as an output. For example, the idler cavity in figure 2-47 could be replaced by a cavity that is resonant at the upper-sideband frequency (22 gigahertz) to produce an upper-sideband parametric up-converter. Since input and output signals are at different frequencies, the parametric frequency converter does not require a ferrite circulator. However, a ferrite isolator is used to isolate the converter from changes in source impedance.

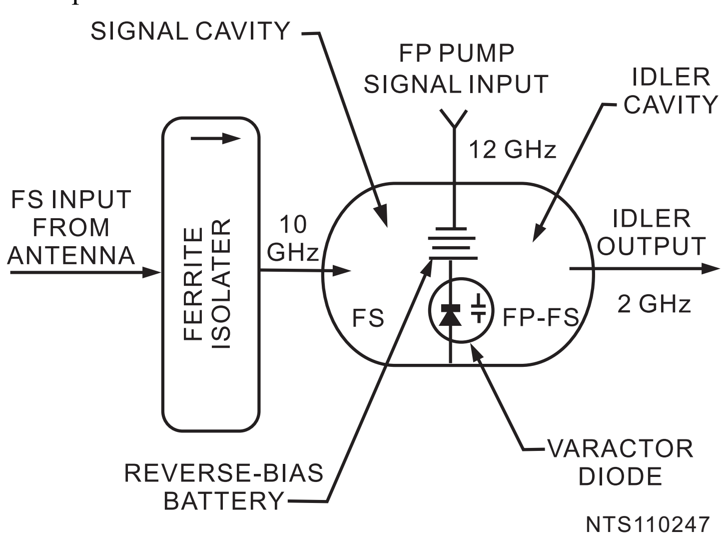

Figure 2-47.—Lower-sideband parametric down-converter.

Q-53. What limits the usefulness of high-gain, tunnel-diode frequency converters?

Q-54. The varactor is a pn junction that acts as what type of electronic device?

Q-55. The underlying principle of operation of the parametric amplifier is based on what property?

Q-56. What is the most important feature of the parametric amplifier?

Q-57. How is amplification achieved in the circuit shown in figure 2-43?

Q-58. What is the purpose of the pump in a parametric amplifier?

Q-59. The pump signal frequency must be of what value when compared to the input signal of a simple parametric amplifier?

Q-60. What is the primary difference between the pump signal of a simple parametric amplifier and the pump signal of a nondegenerative parametric amplifier?

Q-61. In a nondegenerative parametric amplifier the difference between the input frequency and the pump frequency is called what?

Bulk-Effect Semiconductors

BULK-EFFECT SEMICONDUCTORS are unlike normal pn-junction diodes in both construction and operation. Some types have no junctions and the processes necessary for operation occur in a solid block of semiconductor material. Other types have more than one junction but still use bulk-effect action. Bulk-effect devices are among the latest of developments in the field of microwave semiconductors and new applications are being developed rapidly. They seem destined to revolutionize the field of high-power, solid-state microwave generation because they can produce much larger microwave power outputs than any currently available pn-junction semiconductors.

Bulk-effect semiconductors are of two basic types: the transferred-electron devices and the avalanche transit-time devices.

TRANSFERRED-ELECTRON SEMICONDUCTORS.—The discovery that microwaves could be generated by applying a steady voltage across a chip of n-type gallium-arsenide (GaAs) crystal was made in 1963 by J.B. Gunn. The device is operated by raising electrons in the crystal to conduction-band energy levels that are higher than the level they normally occupy. The overall effect is called the transferred-electron effect.

In a gallium-arsenide semiconductor, empty electron conduction bands exist that are at a higher energy level than the conduction bands occupied by most of the electrons. Any electrons that do occupy the higher conduction band essentially have no mobility. If an electric field of sufficient intensity is applied to the semiconductor electrons, they will move from the low-energy conduction band to the high-energy conduction band and become essentially immobile. The immobile electrons no longer contribute to the current flow and the applied voltage progressively increases the rate at which the electrons move from the low band to the high band. As the curve in figure 2-48 shows, the maximum current rate is reached and begins to decrease even though the applied voltage continues to increase. The point at which the current on the curve begins to decrease is called the THRESHOLD. This point is the beginning of the negative-resistance region. Negative resistance is caused by electrons moving to the higher conduction band and becoming immobile.

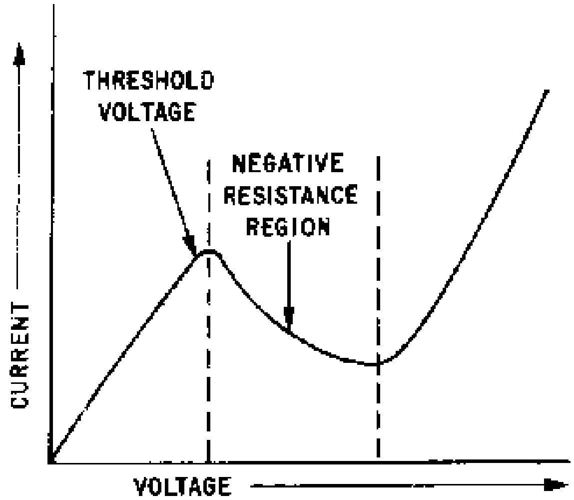

Figure 2-48.—Characteristic curve for a bulk-effect semiconductor.

If an increase in voltage is applied to a gallium-arsenide semiconductor, which is biased to operate in the negative-resistance region, it divides into regions of varying electric fields. A tiny region, known as a DOMAIN, forms that has an electric field of much greater intensity than the fields in the rest of the semiconductor. The applied voltage causes the domain to travel across the semiconductor chip from the cathode to the anode. The high field intensity of the domain is caused by the interaction of the slow electrons in the high-energy band and the faster electrons in the low-energy band. The electrons in the low-energy band travel faster than the moving domain and continually catch up during the transit from cathode to anode. When the fast electrons catch up to the domain, the high field intensity forces them into the higher band where they lose most of their mobility. This also causes them to fall behind the moving domain. Random scattering causes the electrons to lose some energy and drop back into the lower, faster, energy band and race again after the moving domain. The movement from the low-energy band to the high-energy band causes the electrons to bunch up at the back of the domain and to provide the electron-transfer energy that creates the high field intensity in the domain.

The domains form at or near the cathode and move across the semiconductor to the anode, as shown in figure 2-49. As the domain disappears at the anode, a new domain forms near the cathode and repeats the process.

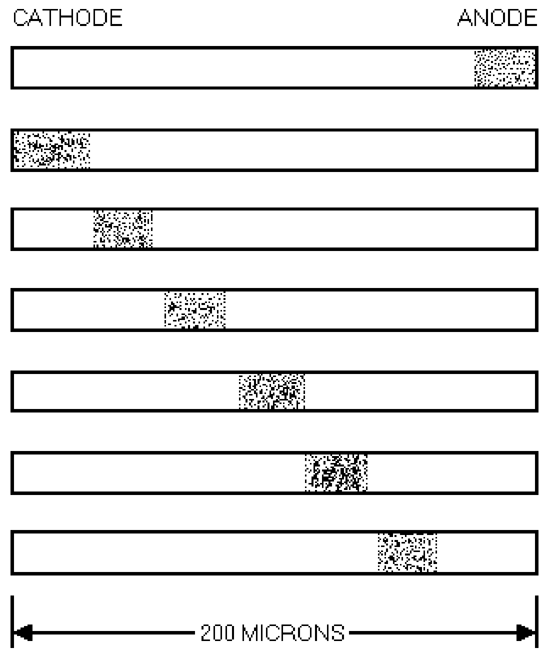

Figure 2-49.—Gallium-arsenide semiconductor domain movement.

The GUNN OSCILLATOR is a source of microwave energy that uses the bulk-effect, gallium-arsenide semiconductor. The basic frequency of a gunn oscillator is inversely proportional to the transit time of a domain across the semiconductor. The transit time is proportional to the length of semiconductor material, and to some extent, the voltage applied. Each domain causes a pulse of current at the output; thus, the output is a frequency determined by the physical length of the semiconductor chip.

The gunn oscillator can deliver continuous power up to about 65 milliwatts and pulsed outputs of up to about 200 watts peak. The power output of a solid chip is limited by the difficulty of removing heat from the small chip. Much higher power outputs have been achieved using wafers of gallium-arsenide as a single source.

AVALANCHE TRANSIT-TIME DIODES.—Avalanche transit-time diodes, also called IMPATT (Impact Avalanche and Transit-Time) diodes, are multilayer diodes of several different types used to generate microwave power. The earliest of the avalanche transit-time diodes consists of four layers in a pnin arrangement.The intrinsic (i) layer has neither p nor n properties.

The pn junction for the pnin diode, shown in figure 2-50, is strongly reverse biased to cause an avalanche in its depletion layer when the positive half cycle of a microwave signal is applied. The avalanche effect causes the electrons in the n region, which is very thin, to cross over to the intrinsic layer. The intrinsic layer is constructed so that the drift transit time causes the current to lag the signal voltage by more than 90 degrees at the desired frequency. Such a lag represents a negative resistance at the desired frequency. The pnin avalanche transit-time diode, when inserted in a microwave cavity with the proper dc bias, amplifies microwave signals introduced to the cavity.

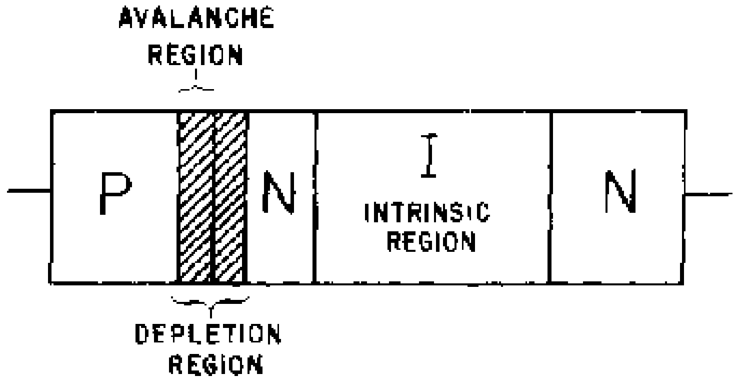

Figure 2-50.—Avalanche transit time for a pnin diode.

More recent research has shown that pin-junction diodes and simple pn-junction diodes can show negative resistance and amplification at microwave frequencies when they are reverse biased into an avalanche condition. The negative resistance in a simple pn-junction or pin diode is the result of a more complicated internal mechanism than in the pnin diode. The avalanche region and the drift region of the pnin diode are physically separate. Diodes of the pn and pin type must use the same physical region for both avalanche and drift-time control. In all types of avalanche transit-time diodes, the negative-resistance property causes dc bias energy to be absorbed by electrons in the avalanche process and given up to the applied microwave field.

Q-62. What is the output frequency of an upper-sideband parametric-frequency converter?

Q-63. What is the primary advantage of bulk-effect devices over normal pn-junction semiconductors?

Q-64. What happens to the electrons of a gallium-arsenide semiconductor when they move from the normal low-energy conduction band to the high-energy conduction band?

Q-65. The point on the current curve of a gallium-arsenide semiconductor at which it begins to exhibit negative resistance is called what?

Q-66. The domain in a gallium-arsenide semiconductor has what type of electrical field when compared to the other regions across the body of a semiconductor?

Q-67. What characteristic of a gunn oscillator is inversely proportional to the transit time of the domain across the semiconductor?

Q-68. What is the junction arrangement of the original avalanche transit-time diode?

Q-69. What causes dc bias energy to be absorbed by avalanche electrons and given up to the microwave field applied to an avalanche transit-time diode?

The Point-Contact Diode

POINT-CONTACT DIODES, commonly called CRYSTALS, are the oldest microwave semiconductor devices. They were developed during World War II for use in microwave receivers and are still in widespread use as receiver mixers and detectors.

Unlike the pn-junction diode, the point-contact diode depends on the pressure of contact between a point and a semiconductor crystal for its operation. Figure 2-51A and B, illustrate a point-contact diode. One section of the diode consists of a small rectangular crystal of n-type silicon. A fine beryllium-copper, bronze-phosphor, or tungsten wire called the CATWHISKER presses against the crystal and forms the other part of the diode. During the manufacture of the point contact diode, a relatively large current is passed from the catwhisker to the silicon crystal. The result of this large current is the formation of a small region of p-type material around the crystal in the vicinity of the point contact. Thus, a pn-junction is formed which behaves in the same way as a normal pn-junction.

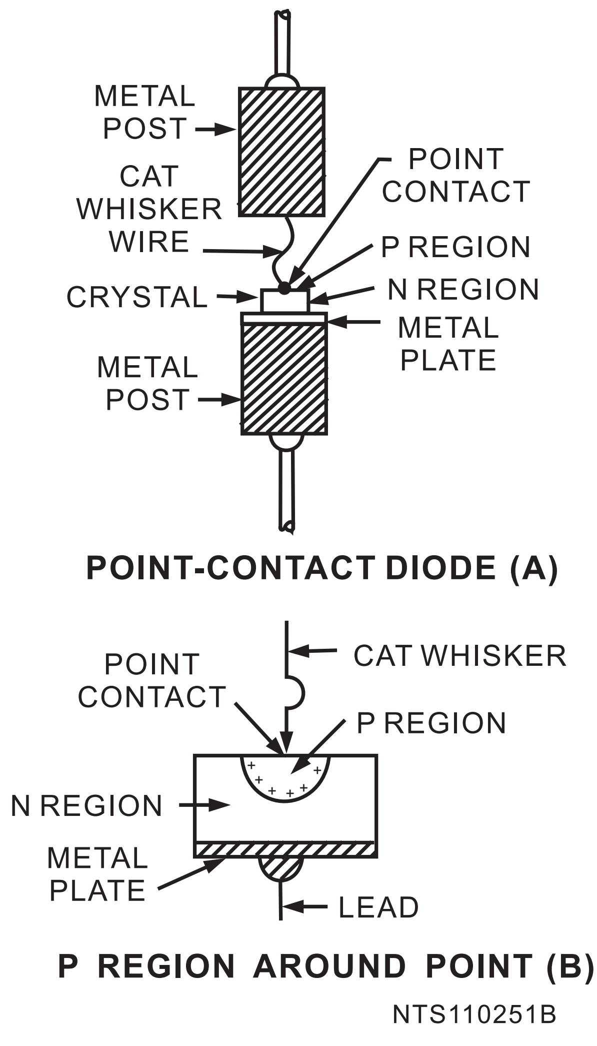

Figure 2-51A-B.—Point-contact diode. P REGION AROUND POINT.

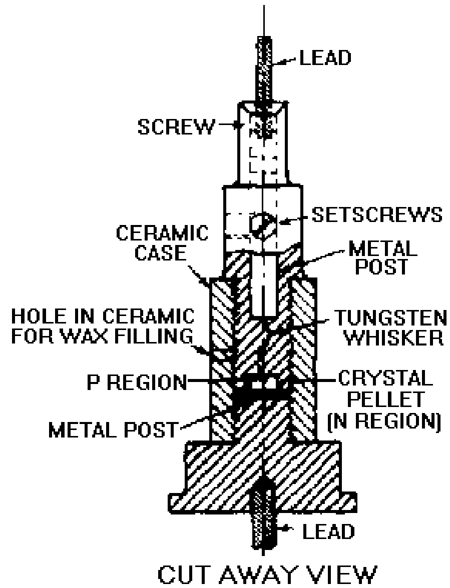

Figure 2-51C.—Point-contact diode. CUT AWAY VIEW.

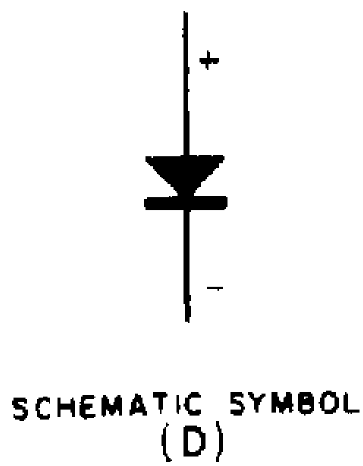

Figure 2-51D.—Point-contact diode. SCHEMATIC SYMBOL.

The pointed wire is used instead of a flat metal plate to produce a high-intensity electric field at the point contact without using a large external source voltage. It is not possible to apply large voltages across the average semiconductor because of the excessive heating.

The end of the catwhisker is one of the terminals of the diode. It has a low-resistance contact to the external circuit. A flat metal plate on which the crystal is mounted forms the lower contact of the diode with the external circuit. Both contacts with the external circuit are low-resistance contacts.

The characteristics of the point-contact diode under forward and reverse bias are somewhat different from those of the junction diode.

With forward bias, the resistance of the point-contact diode is higher than that of the junction diode. With reverse bias, the current flow through a point-contact diode is not as independent of the voltage applied to the crystal as it is in the junction diode. The point-contact diode has an advantage over the junction diode because the capacitance between the catwhisker and the crystal is less than the capacitance between the two sides of the junction diode. As such, the capacitive reactance existing across the point-contact diode is higher and the capacitive current that will flow in the circuit at high frequencies is smaller. A cutaway view of the entire point-contact diode is shown in figure 2-51C. The schematic symbol of a point-contact diode is shown in figure 2-51D.

Schottky Barrier Diode

The SCHOTTKY BARRIER DIODE is actually a variation of the point-contact diode in which the metal semiconductor junction is a surface rather than a point contact. The large contact area, or barrier, between the metal and the semiconductor in the Schottky barrier diode provides some advantages over the point-contact diode. Lower forward resistance and lower noise generation are the most important advantages of the Schottky barrier diode. The applications of the Schottky barrier diode are the same as those of the point-contact diode. The low noise level generated by Schottky diodes makes them especially suitable as microwave receiver detectors and mixers.

The Schottky barrier diode is sometimes called the HOT-ELECTRON or HOT-CARRIER DIODE because the electrons flowing from the semiconductor to the metal have a higher energy level than the electrons in the metal. The effect is the same as it would be if the metal were heated to a higher temperature than normal. Figure 2-52 is an illustration of the construction of a Schottky barrier diode.

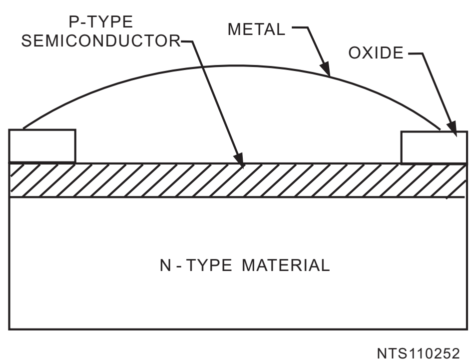

Figure 2-52.—Schottky-barrier diode.

PIN Diodes

The pin diode consists of two narrow, but highly doped, semiconductor regions separated by a thicker, lightly-doped material called the intrinsic region. As suggested in the name, pin, one of the heavily doped regions is p-type material and the other is n-type. The same semiconductor material, usually silicon, is used for all three areas. Silicon is used most often for its power-handling capability and because it provides a highly resistive intrinsic (i) region. The pin diode acts as an ordinary diode at frequencies up to about 100 megahertz, but above this frequency the operational characteristics change.

The large intrinsic region increases the transit time of electrons crossing the region. Above 100 megahertz, electrons begin to accumulate in the intrinsic region. The carrier storage in the intrinsic region causes the diode to stop acting as a rectifier and begin acting as a variable resistance. The equivalent circuit of a pin diode at microwave frequencies is shown in figure 2-53A. A resistance versus voltage characteristic curve is shown in figure 2-53B.

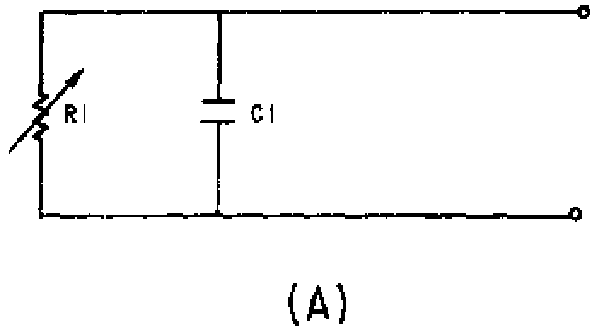

Figure 2-53A.—Diode equivalent circuit (pin).

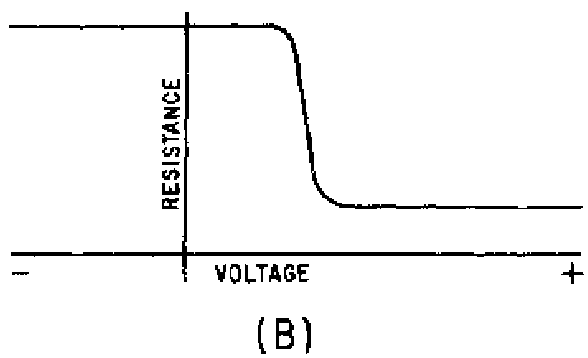

Figure 2-53B.—Diode equivalent circuit (pin).

When the bias on a pin diode is varied, the microwave resistance changes from a typical value of 6 kilohms under negative bias to about 5 ohms when the bias is positive. Thus when the diode is mounted across a transmission line or waveguide, the loading effect is insignificant while the diode is reverse biased, and the diode presents no interference to power flow. When the diode is forward biased, the resistance drops to approximately 5 ohms and most power is reflected. In other words, the diode acts as a switch when mounted in parallel with a transmission line or waveguide. Several diodes in parallel can switch power in excess of 150 kilowatts peak. The upper power limit is determined by the ability of the diode to dissipate power. The upper frequency limit is determined by the shunt capacitance of the pn junction, shown as C1 in figure 2-53A. Pin diodes with upper limit frequencies in excess of 30 gigahertz are available.

Q-70. During the manufacture of a point-contact diode, what is the purpose of passing a relatively large current from the catwhisker to the silicon crystal?

Q-71. What is the capacitive reactance across a point-contact diode as compared to a normal junction diode?

Q-72. What are the most important advantages of the Schottky barrier diode?

Q-73. At frequencies above 100 megahertz, the intrinsic (i) region causes a pin diode to act as what?

Q-74. The pin diode is primarily used for what purpose?

Microwave Transistors

Transistors, like vacuum tubes, have had a very limited application in the microwave range. Many of the same problems encountered with vacuum tubes, such as transit-time effects, also limit the upper frequency range of transistors. However, research in the area of microwave transistors, and especially MICROWAVE INTEGRATED CIRCUITS (ICs), is proceeding rapidly.

GALLIUM-ARSENIDE FET AMPLIFIERS have been developed which provide low-noise amplification up to about 30 dB in the 7- to 18-gigahertz range. The power output of many of these amplifiers is relatively low, approximately 20 to 200 milliwatts, but that is satisfactory for many microwave applications. Research has extended both the frequency range and the power output of gallium-arsenide FET amplifiers to frequencies as high as 26.5 gigahertz and power levels in excess of 1 watt in multistage amplifiers.

SILICON BIPOLAR-TRANSISTOR AMPLIFIERS in integrated circuit form have been developed that provide up to 40 watts peak power in the 1- to 1.5-gigahertz range. Other types of microwave transistor amplifiers combined into multistage modules are capable of providing power outputs approaching 100 watts.

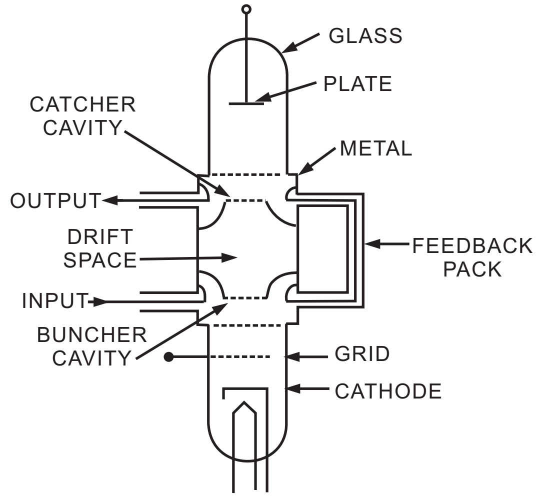
Microwave transistor amplifiers, because of their stability, light weight, and long life, are rapidly replacing microwave tubes in the first stages of high-powered radar and communications transmitters. In the future new systems will be almost completely solid state.

SUMMARY

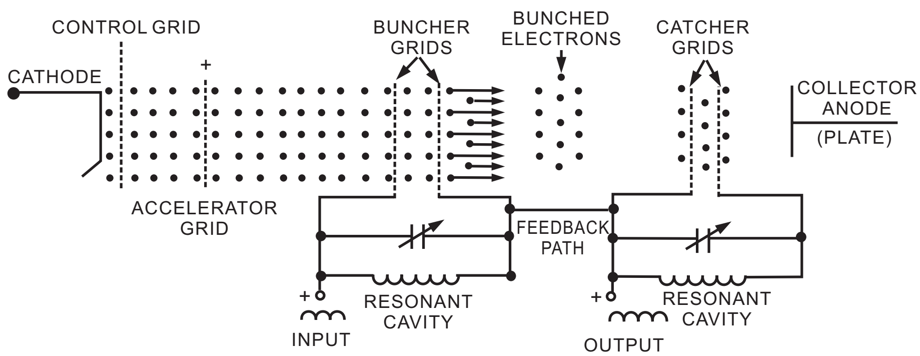
The information that follows summarizes the important points presented in this chapter.

The use of microwave frequencies forced the development of special tubes to offset the limitations caused by interelectrode capacitance, lead inductance, and electron transit-time effects in conventional tubes. Microwave tubes, such as the klystron and twt, take advantage of transit-time effects through the use of VELOCITY MODULATION to amplify and generate microwave energy.

The **KLYSTRON** is a velocity-modulated tube which may be used as an amplifier or oscillator. The klystron, when used as an amplifier, requires at least two resonant cavities, the buncher and the catcher. A diagram of a basic klystron is shown at the right.



A

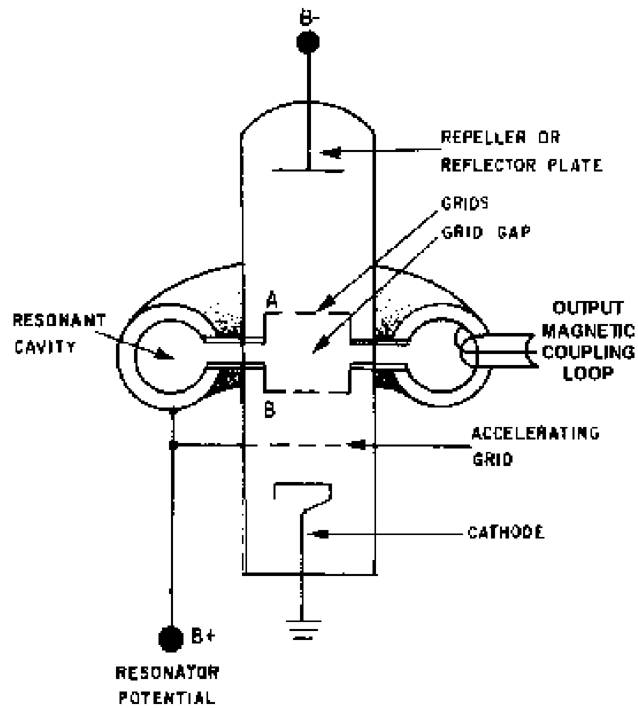


NOTE: RESONANT CAVITIES SHOWN AS CONVENTIONAL PARALLEL RESONANT CIRCUIT

B

NTS1102I-2

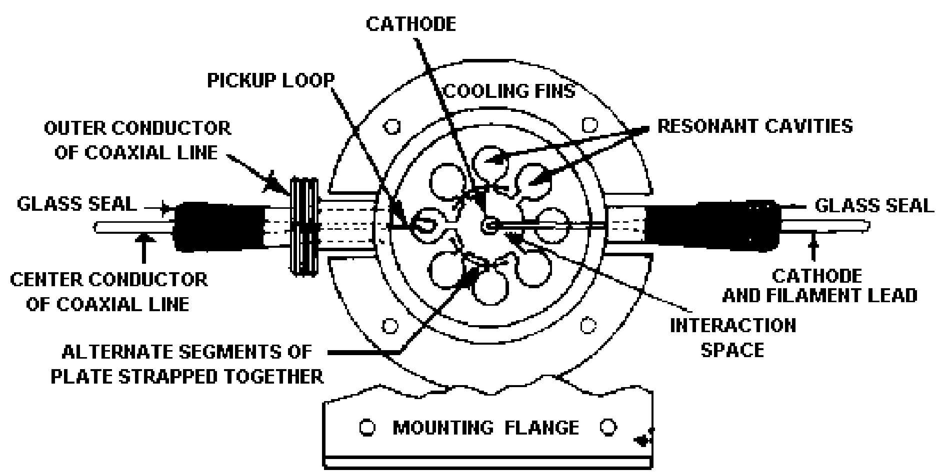
The **REFLEX KLYSTRON**, shown at the right, is used only as an oscillator and uses only one cavity to bunch and collect the electrons. The frequency is determined by the size and shape of the cavity. The reflex klystron has several possible modes of operation which are determined by electron transit time. Electron transit time is controlled by the REPELLER voltage.



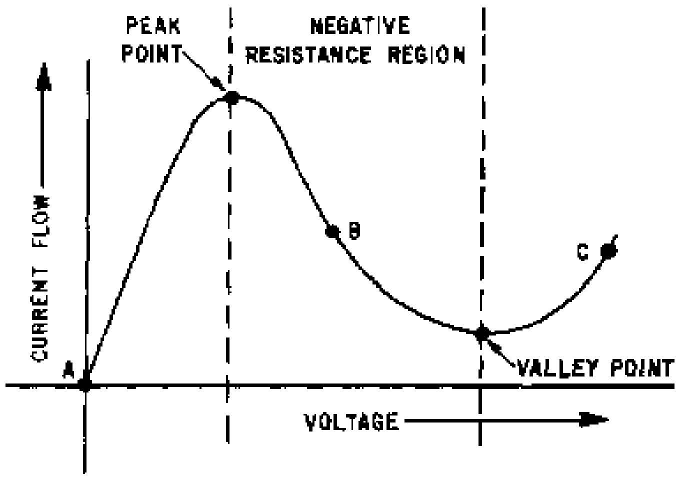
The **TWT** is a wide-bandwidth, velocity-modulated tube used primarily as an amplifier. The electron beam is bunched by a signal applied to the HELIX. The bunching causes an energy transfer from the electron beam to the traveling wave on the helix.

The **MAGNETRON** is a **DIODE OSCILLATOR** capable of delivering microwave energy at very high power levels. Three fields exist within a magnetron that influence operation: (1) the DC ELECTRIC FIELD between the anode and cathode; (2) the AC ELECTRIC FIELD produced by the oscillating resonant cavities and on the same plane as the dc field; and (3) the MAGNETIC FIELD produced by the permanent magnet which is perpendicular to the dc electric field.

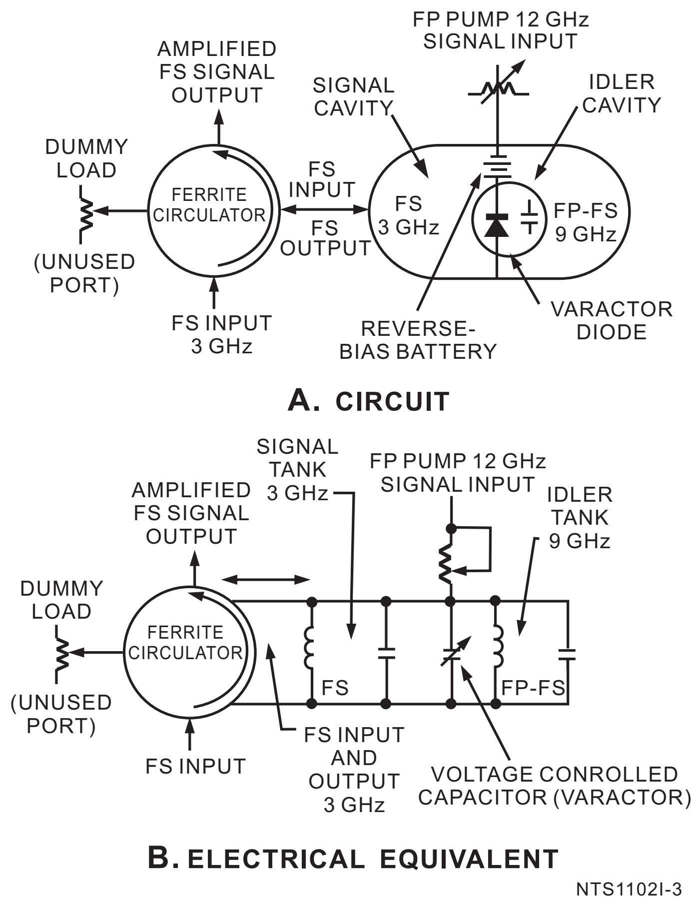
Magnetrons are of two basic types, the NEGATIVE-RESISTANCE MAGNETRON and the ELECTRON-RESONANCE MAGNETRON. A diagram of a magnetron is shown at the right.



SOLID-STATE MICROWAVE DEVICES are becoming increasingly widespread in microwave equipment with new developments almost daily. Most of the currently available solid-state devices are two-terminal diodes with the capability to generate or amplify microwave energy. Many of the solid-state devices, such as the TUNNEL DIODE and the BULK-EFFECT DIODE, apply the property of NEGATIVE RESISTANCE to amplify microwave signals or generate microwave energy. A characteristic curve illustrating the negative-resistance property of the tunnel diode is shown at the right.



The **VARACTOR** is a two-terminal diode that acts as a variable capacitance and is the active element of PARAMETRIC AMPLIFIERS. The parametric amplifier is a low-noise microwave amplifier that uses variable reactance to amplify microwave signals. The illustration shows an example of a NONDEGENERATIVE PARAMETRIC AMPLIFIER.



ANSWERS TO QUESTIONS Q1. THROUGH Q74.

A-1. *Impedance decreases.*

A-2. *Degenerative feedback.*

A-3. *Transit time causes the grid voltage and plate current to be out of phase.*

A-4. *Transit time.*

A-5. *Velocity.*

A-6. *The electron will be accelerated.*

A-7. *By alternately speeding up or slowing down the electrons.*

A-8. *The buncher grids.*

A-9. *There is no effect.*

A-10. *The frequency period of the buncher grid signal.*

A-11. *Velocity modulation.*

A-12. The accelerator grid and the buncher grids.

A-13. The catcher cavity.

A-14. Amplifier.

A-15. Intermediate cavities between the input and output cavities.

A-16. A large negative pulse is applied to the cathode.

A-17. The middle cavity.

A-18. The bandwidth decreases.

A-19. Stagger tuning.

A-20. The reflector or repeller.

A-21. Velocity.

A-22. Three-quarter cycle.

A-23. Mode 2.

A-24. Power is reduced.

A-25. The half-power points of the mode.

A-26. Voltage amplification.

A-27. Used to focus the electrons into a tight beam.

A-28. The directional couplers are not physically connected to the helix.

A-29. The traveling wave must have a forward velocity equal to or less than the speed of the electrons in the beam.

A-30. The helix.

A-31. Helix.

A-32. A magnetic field.

A-33. Anode or plate.

A-34. The resonant cavities.

A-35. The permanent magnet.

A-36. The critical value of field strength.

A-37. Circular.

A-38. The negative-resistance magnetron has a split plate.

A-39. The application of the proper magnetic field.

A-40. To reduce the effects of filament bombardment.

A-41. Rising-sun block.

A-71. Lower.

A-72. Lower forward resistance and low noise.

A-73. Variable resistance.

A-74. A switching device.

CHAPTER 3

MICROWAVE ANTENNAS

LEARNING OBJECTIVES

Upon completion of this section the student will be able to:

1. Explain the basic characteristics of coupling, directivity, reciprocity, and efficiency in microwave antennas.
2. Describe the construction and basic theory of operation of reflector antennas and horn radiators.
3. Explain construction and operation of microwave lens antennas.
4. Describe the construction and theory of operation of driven and parasitic antenna arrays.
5. Explain the basic operation and applications of frequency-sensitive antennas.

INTRODUCTION

In this chapter you will study the general characteristics of microwave antennas that are widely used in radar and communications applications. The basic principles of operation of microwave antennas are similar to those of antennas used at lower frequencies. You might want to review the principles presented in *NEETS*, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas*, at this time. Pay particular attention to basic antenna principles in chapter 4 for a review of microwave antennas.

Antennas are devices used to radiate electromagnetic energy into space. The characteristics of transmitting and receiving antennas are similar, so a good transmitting antenna is often a good receiving antenna. A single antenna performs both functions in many modern applications.

ANTENNA CHARACTERISTICS

Since the operating principles of low-frequency and microwave antennas are essentially the same, the electrical characteristics are also very similar. You will need a fundamental knowledge of radar and communications antenna electrical theory in your shipboard antenna maintenance work. Antenna theory is primarily a design consideration of antenna size and shape requirements that depend on the frequency used. A brief description of antenna electrical characteristics is sufficient for the needs of most students of electronics.

Antenna Efficiency

The effectiveness of an antenna depends upon its ability to couple or radiate energy into the air. An efficient antenna is one which wastes very little energy during the radiation process. The efficiency of an antenna is usually referred to as the POWER GAIN or POWER RATIO as compared to a standard reference antenna. The power gain of an antenna is a ratio of the radiated power to that of the reference antenna, which is usually a basic dipole. Both antennas must be fed rf energy in the same manner and must be in the same position when the energy is radiated. The power gain of a single dipole without a reflector is unity (one). An array of several dipoles in the same position as the single dipole, and fed with the same line, has a power gain of more than one.

The effectiveness of an entire transmitting/ receiving system depends largely on impedance matching between the elements of the system. Impedance matching is particularly critical at the antenna connection. If a good impedance match is maintained between the system and the antenna throughout the operating frequency band, power transfer to and from the antenna is always maximum. The transmission line or waveguide used to transport energy to and from the antenna should have a characteristic impedance equal to that of the antenna. A proper impedance match allows all available power to be absorbed and radiated by the antenna without reflections back down the line.

If you have a transmission line or waveguide with an impedance mismatch at the termination, standing waves are set up by the reflections. Standing waves cause losses in the form of unwanted radiations, heat losses in transmission lines, and arcing in waveguides.

The STANDING-WAVE RATIO, abbreviated swr, is a way to measure the degree of mismatch between the transmission line and its load. The swr can be expressed as a ratio of the maximum and minimum values of the current or voltage in the standing waves that are set up on the lines as follows:

$$vswr = \frac{E_{max}}{E_{min}}$$

or

$$iswr = \frac{I_{max}}{I_{min}}$$

A transmission line or waveguide approaches a perfectly matched condition when the swr approaches a value of 1. A ratio that is a little higher than 1 is usually acceptable in practical applications.

Measurement of swr is the only practical method of detecting an impedance mismatch between a transmitting/receiving system and its antenna. As such, the system swr is an important indication of the overall efficiency of the system during operation.

The line impedance can usually be matched to the antenna at only one frequency. However, the swr will NOT become too high if the antenna is used over a small range of frequencies and the line is matched to the center frequency.

Antenna Directivity

You can divide antennas into two general classes based on directivity, omnidirectional and directional. OMNIDIRECTIONAL antennas radiate and receive energy from all directions at once (SPHERICAL WAVEFRONT). They are seldom used in modern radar systems as the primary antenna, but are commonly used in radio equipment and iff (identification friend or foe) receivers. DIRECTIONAL antennas radiate energy in LOBES (or BEAMS) that extend outward from the antenna in either one or two directions. The radiation pattern contains small minor lobes, but these lobes are weak and normally have little effect on the main radiation pattern. Directional antennas also receive energy efficiently from only one or two directions, depending upon whether it is unidirectional or bidirectional.

Directional antennas have two characteristics that are important to you in radar and communications systems. One is DIRECTIVITY and the other is POWER GAIN. The directivity of an antenna refers to the NARROWNESS of the radiated beam. If the beam is NARROW in either the horizontal or vertical plane, the antenna has a high degree of directivity in that plane. An antenna may be designed for high directivity in one plane only or in both planes, depending on the application. The power gain of an antenna increases as the degree of directivity increases because the power is concentrated into a narrow beam and less power is required to cover the same distance.

Since microwave antennas are predominantly unidirectional, the examples you will study in this chapter are all of the unidirectional type.

Reciprocity

You read in this chapter that an antenna is able to both transmit and receive electromagnetic energy. This is known as RECIPROCITY. Antenna reciprocity is possible because antenna characteristics are essentially the same regardless of whether an antenna is transmitting or receiving electromagnetic energy. Reciprocity allows most radar and communications systems to operate with only one antenna. An automatic switch, called a DUPLEXER, connects either the transmitter or the receiver to the antenna at the proper time. Duplexer operation will be explained in later *NEETS* modules dealing with radar and communications systems. Because of the reciprocity of antennas, this chapter will discuss antennas from the viewpoint of the transmitting cycle. However, you should understand that the same principles apply on the receiving cycle.

Radar Fundamentals

Radio, television, radar, and the human eye have much in common because they all process the same type of electromagnetic energy. The major difference between the light processed by the human eye and the radio-frequency energy processed by radio and radar is frequency. For example, radio transmitters send out signals in all directions. These signals can be detected by receivers tuned to the same frequency. Radar works somewhat differently because it uses reflected energy (echo) instead of directly transmitted energy. The echo, as it relates to sound, is a familiar concept to most of us. An experienced person can estimate the distance and general direction of an object causing a sound echo. Radar uses microwave electromagnetic energy in much the same way.

Radar transmits microwave energy that reflects off an object and returns to the radar. The returned portion of the energy is called an ECHO, as it is in sound terminology. It is used to determine the direction and distance of the object causing the reflection. Determination of direction and distance to an object is the primary function of most radar systems.

Telescopes and radars, in terms of locating objects in space, have many common problems. Both have a limited field of view and both require a geographic reference system to describe the position of an object (target). The position of an object viewed with a telescope is usually described by relating it to a familiar object with a known position. Radar uses a standard system of reference coordinates to describe the position of an object in relation to the position of the radar. Normally ANGULAR measurements are made from true north in an imaginary flat plane called the HORIZONTAL PLANE. All angles in the UP direction are measured in a second imaginary plane perpendicular to the horizontal plane called the VERTICAL PLANE. The center of the coordinate system is the radar location. As shown in figure 3-1, the target position with respect to the radar is defined as 60 degrees true, 10 degrees up, and 10 miles distant. The line directly from the radar to the target is called the LINE OF SIGHT. The distance from point 1 to point 2, measured along the line of sight, is called TARGET RANGE. The angle between the horizontal plane and the line of sight is known as the ELEVATION ANGLE. The angle measured in a clockwise direction in the horizontal plane between true north and the line of sight is known as BEARING (sometimes referred to as AZIMUTH). These three coordinates of range, bearing, and elevation determine the location of the target with respect to the radar.

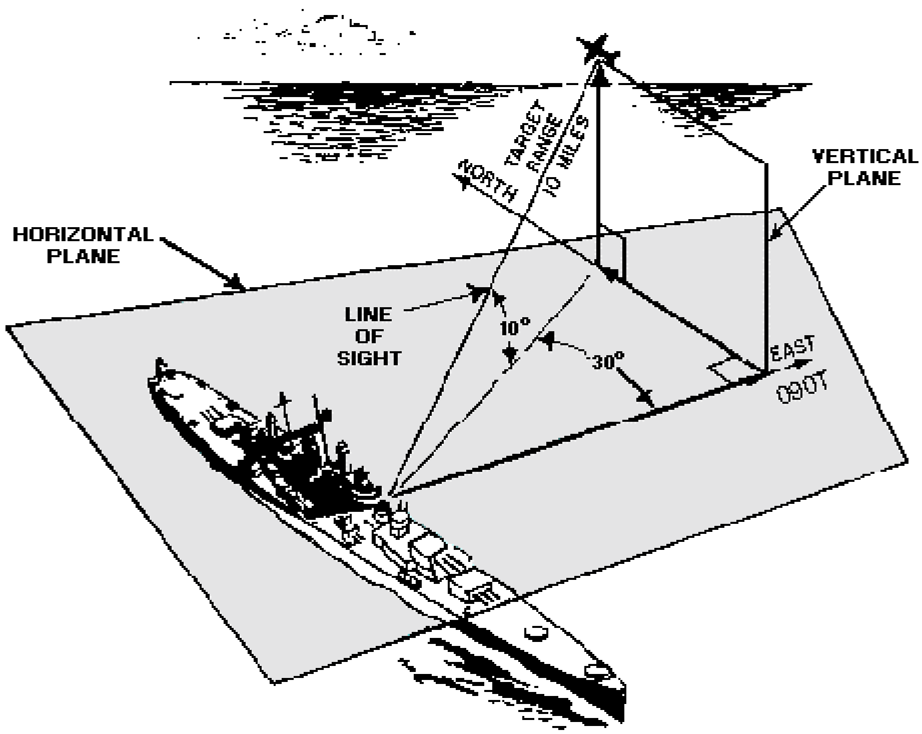

Figure 3-1.—Radar target position.

Bearing and elevation angles are determined by measuring the angular position of the radar antenna (the transmitted beam) when it is pointing directly at the target. Range is more difficult to determine because it cannot be directly measured. The radar system is designed to measure range as a function of time. Since the speed of electromagnetic energy is the same as the speed of light, range is determined by measuring the time required for a pulse of energy to reach the target and return to the radar. Because the speed of the pulse is known, the two-way distance can be determined by multiplying the time by the speed of travel. The total must be divided by two to obtain the one-way range because the time value used initially is the time required for the pulse to travel to the target and return.

The discussion of microwave antennas in this chapter requires only the most basic understanding of radar concepts! Radar fundamentals will be discussed in more detail in a later *NEETS* module.

Q-1. Microwave antennas and low-frequency antennas are similar in what ways?

Q-2. What term is used to express the efficiency of an antenna?

Q-3. What term is used to express the measurement of the degree of mismatch between a line and its load?

Q-4. What type of antenna radiates in and receives energy from all directions at once?

Q-5. What is the term that is used to describe narrowness in the radiated beam of an antenna?

Q-6. What characteristic allows the same antenna to both transmit and receive?

REFLECTOR ANTENNAS

A spherical wavefront (one in which the energy spreads out in all directions) spreads out as it travels away from the antenna and produces a pattern that is not very directional. A wavefront that exists in only one plane does not spread because all of the wavefront moves forward in the same direction. For an antenna to be highly directive, it must change the normally spherical wavefront into a plane wavefront. Many highly directive microwave antennas produce a plane wavefront by using a reflector to focus the radiated energy. The PARABOLIC REFLECTOR is most often used for high directivity.

Microwaves travel in straight lines as do light rays. They can also be focused and reflected just as light rays can, as illustrated by the antenna shown in figure 3-2. A microwave source is placed at focal point F. The field leaves this antenna as a spherical wavefront. As each part of the wavefront reaches the reflecting surface, it is phase-shifted 180 degrees. Each part is then sent outward at an angle that results in all parts of the field traveling in parallel paths. Because of the special shape of a parabolic surface, all paths from F to the reflector and back to line XY are the same length. Therefore, when the parts of the field are reflected from the parabolic surface, they travel to line XY in the same amount of time.

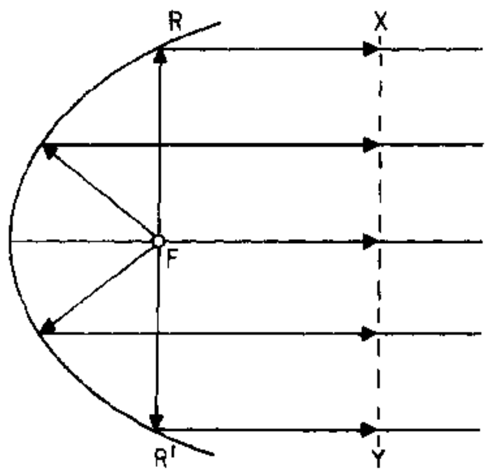

Figure 3-2.—Parabolic reflector radiation.

If a dipole is used as the source of transmission, energy will be radiated from the antenna into space as well as toward the reflector. Energy which is not directed toward the paraboloid has a wide-beam characteristic which will destroy the narrow pattern of the parabolic reflector. However, a HEMISPHERICAL SHIELD (not shown) may be used to direct most of the radiation toward the parabolic surface and thus prevent the destruction of the narrow pattern. Direct radiation into space is eliminated, the beam is made sharper, and more power is concentrated in the beam. Without the shield, some of the radiated field would leave the radiator directly. Since this part of the field that would leave the radiator would not be reflected, it would not become a part of the main beam and could serve no useful purpose.

In figure 3-3 the radiation pattern of a paraboloid reflector contains a major lobe and several minor lobes. The major lobe is directed along the axis of revolution. Very narrow beams are possible with this type of reflector. Figure 3-4 illustrates the basic paraboloid reflector.

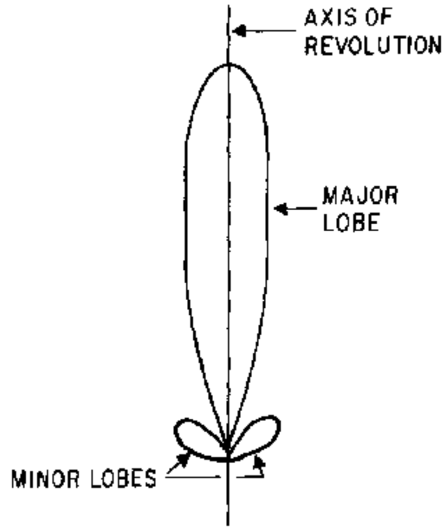

Figure 3-3.—Parabolic radiation pattern.

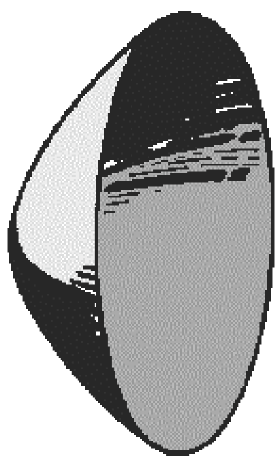

Figure 3-4.—Basic paraboloid reflector.

You may see several variations of the basic paraboloid reflector used to produce different beam shapes required by special applications. The basic characteristics of the most commonly used paraboloids are presented in the following paragraphs.

Truncated Paraboloid

Figure 3-5A, shows a TRUNCATED PARABOLOID. Since the reflector is parabolic in the horizontal plane, the energy is focused into a narrow beam. With the reflector TRUNCATED (cut) so that it is shortened vertically, the beam spreads out vertically instead of being focused. This fan-shaped beam is used in radar detection applications for the accurate determination of bearing. Since the beam is spread vertically, it will detect aircraft at different altitudes without changing the tilt of the antenna. The truncated paraboloid also works well for surface search radar applications to compensate for the pitch and roll of the ship.

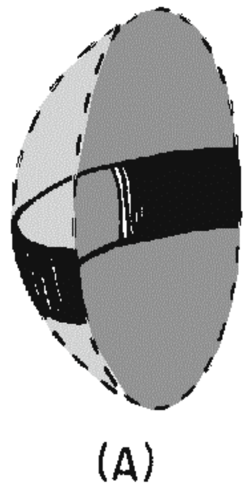

Figure 3-5A.—Truncated paraboloid.

The truncated paraboloid may be used in target height-finding systems if the reflector is rotated 90 degrees, as shown in figure 3-5B. Since the reflector is now parabolic in the vertical plane, the energy is focused vertically into a narrow beam. If the reflector is truncated, or cut, so that it is shortened horizontally, the beam will spread out horizontally instead of being focused. Such a fan-shaped beam is used to accurately determine elevation.

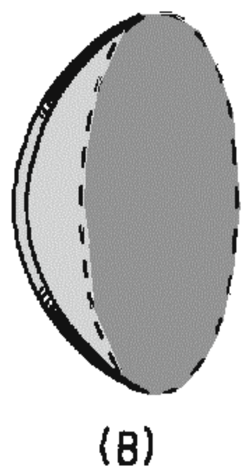

Figure 3-5B.—Truncated paraboloid.

Orange-Peel Paraboloid

A section of a complete circular paraboloid, often called an ORANGE-PEEL REFLECTOR because of its orange-peel shape, is shown in figure 3-6. Since the reflector is narrow in the horizontal plane and wide in the vertical plane, it produces a beam that is wide in the horizontal plane and narrow in the vertical plane. In shape, the beam resembles a huge beaver tail. The microwave energy is sent into the parabolic reflector by a horn radiator (not shown) which is fed by a waveguide. The horn radiation pattern covers nearly the entire shape of the reflector, so almost all of the microwave energy strikes the reflector and very little escapes at the sides. Antenna systems which use orange-peel paraboloids are often used in height-finding equipment.

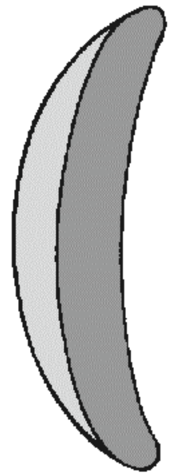

Figure 3-6.—Orange-peel paraboloid.

Cylindrical Paraboloid

When a beam of radiated energy that is noticeably wider in one cross-sectional dimension than in another is desired, a cylindrical paraboloidal section which approximates a rectangle can be used. Figure 3-7 illustrates such an antenna. A PARABOLIC CYLINDER has a parabolic cross section in just one dimension which causes the reflector to be directive in one plane only. The cylindrical paraboloid reflector is fed either by a linear array of dipoles, a slit in the side of a waveguide, or by a thin waveguide radiator. It also has a series of focal points forming a straight line rather than a single focal point. Placing the radiator, or radiators, along this focal line produces a directed beam of energy. As the width of the parabolic section is changed, different beam shapes are obtained. You may see this type of antenna system used in search radar systems and in ground control approach (gca) radar systems.

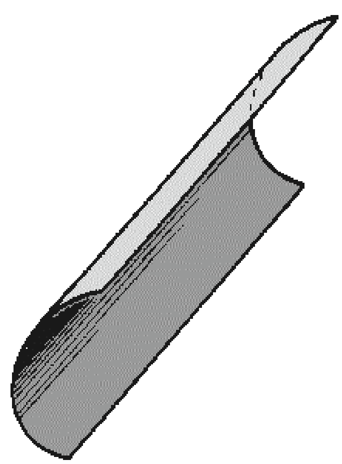

Figure 3-7.—Cylindrical paraboloid.

Corner Reflector

The CORNER-REFLECTOR ANTENNA consists of two flat conducting sheets that meet at an angle to form a corner, as shown in figure 3-8. The corner reflector is normally driven by a HALF-WAVE RADIATOR located on a line which bisects the angle formed by the sheet reflectors.

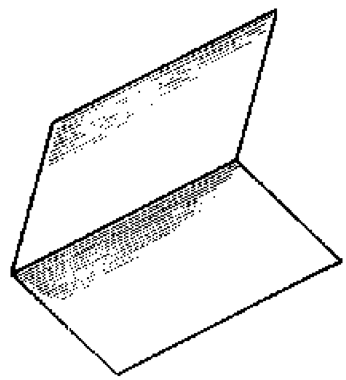

Figure 3-8.—Corner reflector.

Q-7. What type of reflector is most often used in directive antennas?

Q-8. Microwaves can be focused and reflected in the same way as what other type of waves?

Q-9. How many major lobes are radiated by a parabolic reflector?

Q-10. A horizontally truncated paraboloid antenna is used for what purpose?

Q-11. The beam from a horizontally positioned cylindrical paraboloid is narrow in what plane?

HORN RADIATORS

Like parabolic reflectors, you can use HORN RADIATORS to obtain directive radiation at microwave frequencies. Because they do not use resonant elements, horns have the advantage of being useful over a wide frequency band.

The operation of a horn as an rf radiating device is similar to that of an automobile horn radiating sound waves. However, the throat of an automobile horn usually is sized much smaller than the sound wavelengths for which it is used. The throat of the rf radiating horn is sized to be comparable to the wavelength being used.

Horn radiators are used with waveguides because they serve both as an impedance-matching device and as a directional radiator. Horn radiators may be fed by coaxial and other types of lines.

Horn radiators are constructed in a variety of shapes, as illustrated in figure 3-9. The shape of the horn determines the shape of the field pattern. The ratio of the horn length to the size of its mouth determines the beam angle and directivity. In general, the larger the mouth of the horn, the more directive is the field pattern.

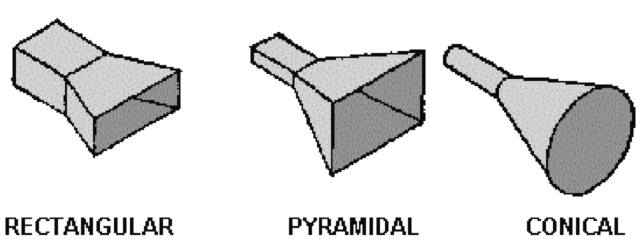

Figure 3-9.—Horn radiators.

LENS ANTENNAS

With a LENS ANTENNA you can convert spherically radiated microwave energy into a plane wave (in a given direction) by using a point source (open end of the waveguide) with a COLLIMATING LENS. A collimating lens forces all radial segments of the spherical wavefront into parallel paths. The point source can be regarded as a gun which shoots the microwave energy toward the lens. The point source is often a horn radiator or a simple dipole antenna.

Waveguide Type

The WAVEGUIDE-TYPE LENS is sometimes referred to as a conducting-type. It consists of several parallel concave metallic strips which are placed parallel to the electric field of the radiated energy fed to the lens, as shown in figure 3-10A and 3-10B. These strips act as waveguides in parallel for the incident (radiated) wave. The strips are placed slightly more than a half wavelength apart.

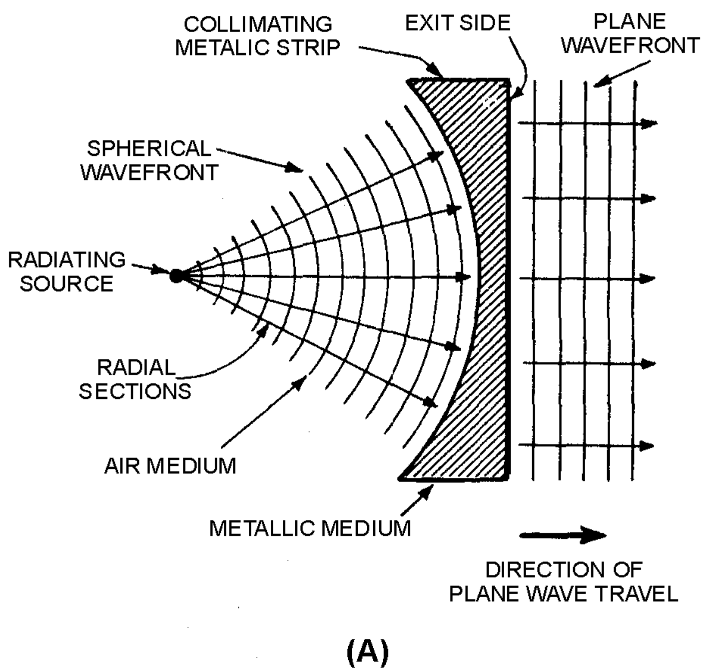

Figure 3-10A.—Waveguide lens.

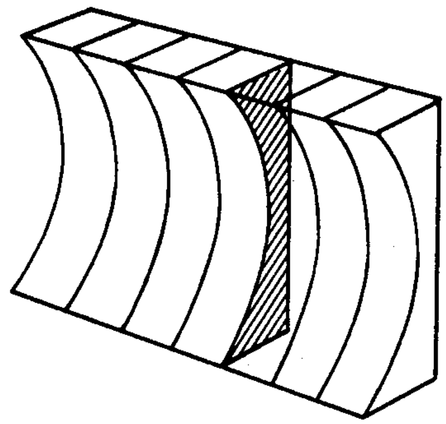

THREE DIMENSIONAL VIEW OF PARALLEL-PLATE LENS

(B)

Figure 3-10B.—Waveguide lens.

The radiated energy consists of an infinite number of RADIAL SECTIONS (RAYS). Each of the radial sections contains mutually perpendicular E and H lines and both are perpendicular to the direction of travel. Because each of the radial sections travels in a different direction, the point source, in itself, has poor directivity. The purpose of the lens is to convert the input spherical microwave segment (which consists of all of the radial sections) into parallel (collimated) lines in a given direction at the exit side of the lens. The focusing action of the lens is accomplished by the refracting qualities of the metallic strips. The collimating effect of the lens is possible because the velocity of electromagnetic energy propagation through metals is greater than its velocity through air. Because of the concave construction of the lens, wavefronts arriving near the ends of the lens travel farther in the same amount of time than do those at the center. Thus, the wavefront emerging from the exit side of the lens appears as a plane wave. It consists of an infinite number of parallel sections (with both the E field and H field components) mutually perpendicular to the direction of travel.

Delay lens

Another type of lens that you may see is the DIELECTRIC or METALLIC DELAY LENS shown in figure 3-11. The delay lens, as its name implies, slows down the phase propagation (velocity) as the wave passes through the lens. The delay lens is convex and is constructed of dielectric material. The delay in the phase of the wave passing through the lens is determined by the DIELECTRIC CONSTANT (REFRACTIVE INDEX) of the material. In most cases, artificial dielectrics, consisting of conducting rods or spheres that are small compared to the wavelength, are used. (Artificial dielectrics are of three-dimensional construction and act as a dielectric to electromagnetic waves.) In this case the inner portion of the transmitted wave is decelerated for a longer interval of time than the outer portions. The delay causes the radiated wave to be collimated.

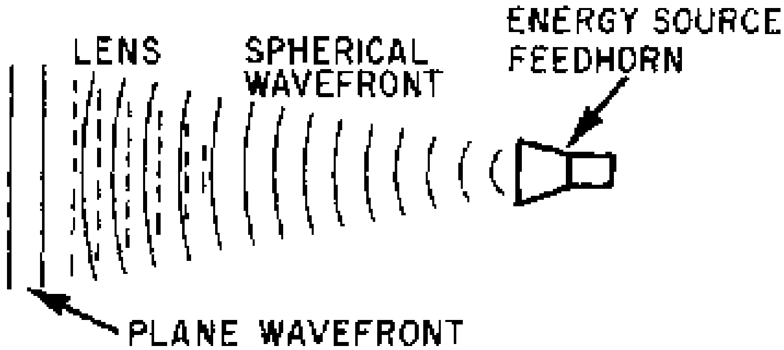

Figure 3-11.—Delay-type lens.

Loaded Microwave Lens

The LOADED MICROWAVE LENS, shown in figure 3-12, is a multi-cellular array of thousands of cells. Each cell contains a slow-wave (delayed), serrated-metal, plastic-supported waveguide element which acts as a phase-controlling device. A loaded lens can focus microwave energy in much the same way as the waveguide type. The reason is that the speed of propagation is higher in the region between parallel plates than in free space. The parallel plates support the cells.

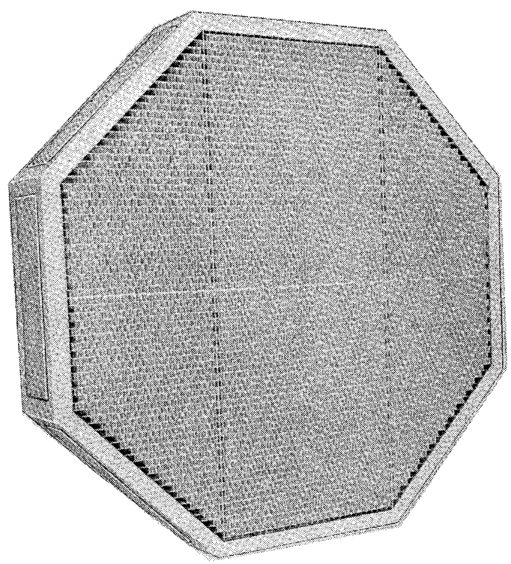

Figure 3-12.—Loaded lens.

The lens shown in figure 3-12 has an egg-crate appearance because it is really two lenses occupying the same volume. Vertical plates make up a lens that focuses a vertically polarized beam, and horizontal plates handle beams which are horizontally polarized. In other words, this type of construction can be used in multiple-beam applications where the polarization of the beams is different.

Q-12. What is the purpose of a collimating lens?

Q-13. How does a waveguide-type lens focus spherical wavefront microwave energy?

Q-14. What type of lens decelerates a portion of a spherical wavefront?

ANTENNA ARRAYS

Sharply directive antennas can be constructed from two or more simple half-wave dipole elements. They must be positioned so that the fields from the elements add in some directions and cancel in others. Such a set of antenna elements is called an ANTENNA ARRAY. When a reflector is placed behind the dipole array, radiation occurs in one direction with a pattern similar to the one shown in figure 3-13.

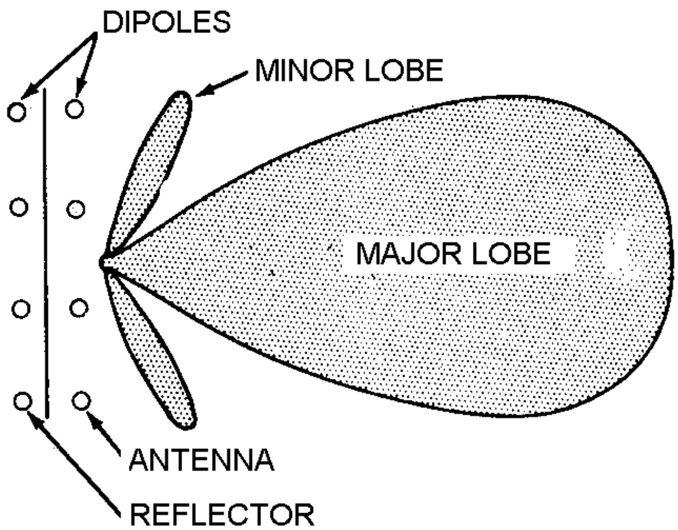

Figure 3-13.—Field pattern of an antenna array.

You will encounter two basic types of antenna arrays, PARASITIC and DRIVEN. Both types of antenna arrays were explained in *NEETS*, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas*. Only a brief review is presented in this chapter.

The parabolic reflector antennas previously discussed and the antenna shown in figure 3-13 are examples of parasitic arrays. Notice that the reflector in figure 3-13 is not directly connected to the energy source. Driven arrays, in which all the radiating elements are connected to the energy source, have smaller losses than parasitic arrays while retaining some of the narrow-beam characteristics. Parasitic arrays, such as the parabolic reflector, are used primarily as antennas in fire control radars and other installations, such as microwave communication systems, that require very accurate (narrow) beams. Driven arrays are used primarily as search-radar antennas because extremely narrow beams are less critical than low losses.

If you position a number of driven half-wave antenna elements with respect to each other so that energy from the individual elements will add in certain directions and cancel in other directions, then the antenna system is directional.

Signals from a number of different sources may contribute to or subtract from the overall effect. By properly phasing the energy fed to the antenna elements, and by properly locating the elements, you can control the direction of the energy. You can cause the energy to add in the desired direction and to be out of phase (cancel) in the undesired direction.

Driven arrays are usually made up of a number of half-wave dipoles positioned and phased so that the desired directional pattern will be achieved. Figure 3-14, view (A), shows a simple antenna array consisting of two horizontally mounted elements, each a half wavelength long and fed in phase. The resulting radiation pattern is in a direction at right angles to the plane containing the antenna conductor.

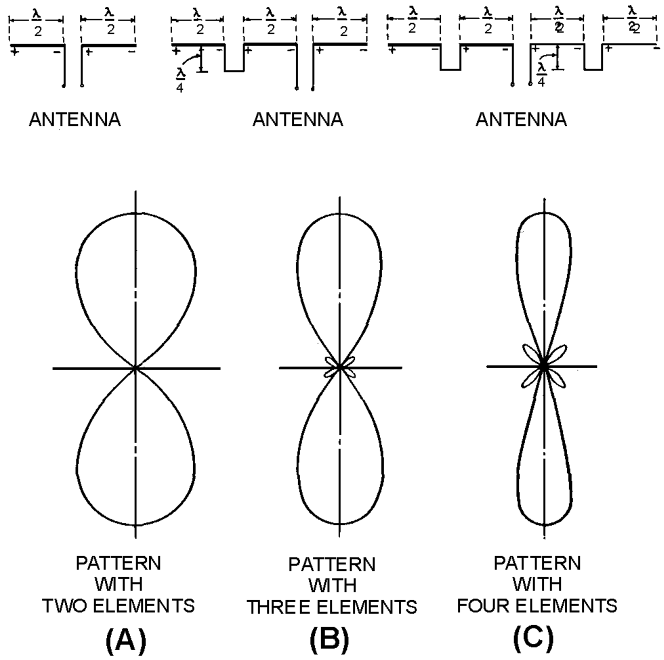

Figure 3-14.—Horizontal array field patterns.

Three- and four-element arrays are shown in figure 3-14, views (B) and (C), respectively. The field pattern of each array is shown beneath it. Note that the beam becomes sharper as the number of elements is increased. If a still-narrower beam is desired, you may add additional elements. The field patterns of the antennas in the figure are bidirectional. Unidirectional patterns may be obtained with a parasitic reflector mounted behind the driven antenna elements.

The BEDSPRING ARRAY (figure 3-15), so called because of its resemblance to a bedspring, is an example of a unidirectional antenna. It consists of a stacked dipole array with an untuned reflector. The more dipoles that are used or stacked in one dimension (horizontal, for example), the more narrow the beam of radiated energy becomes in that plane. Consequently, the size of the antenna is not the same for all installations. Antennas such as the bedspring array are commonly used in TWO-DIMENSIONAL SEARCH RADARS that obtain the range and bearing information of a target.

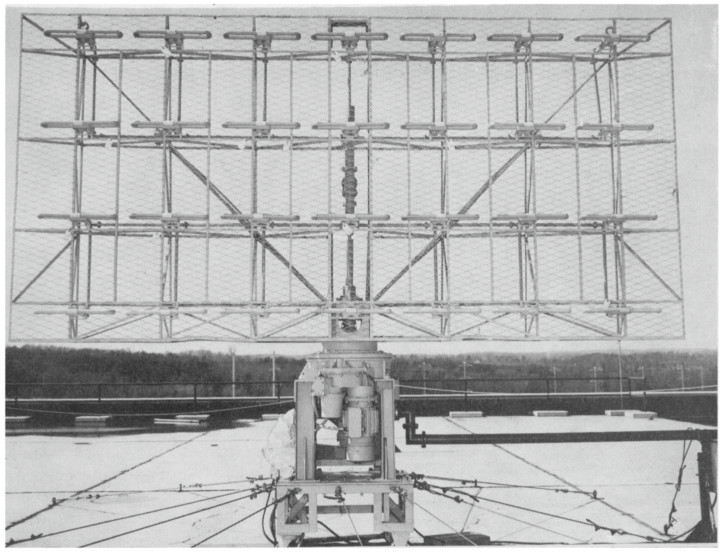

Figure 3-15.—Bedspring array.

FREQUENCY-SENSITIVE ANTENNA

The radar antenna in figure 3-16 uses a feed section to drive horizontally stacked array sections which radiate the applied rf pulses. The same array sections receive the target returns. Each array contains slots cut to radiate and receive a particular frequency. Bearing data is obtained by mechanically rotating the antenna 360 degrees. Elevation data is obtained by electronic scanning of the beam in elevation. The radar antenna is frequency sensitive and radiates pulses at an elevation angle determined by the applied frequency. When the frequency is increased, the beam elevation angle decreases. Conversely, when the applied frequency is decreased, the beam elevation angle increases. The beam elevation angle is therefore selected by the application of a frequency corresponding to the desired angle of elevation. The physical length of the antenna feed section, called the SERPENTINE SECTION (figure 3-17), in relation to the wavelength of the applied energy determines the direction of the radiated beam. You may understand this more clearly if you consider how the beam is shifted. The shift occurs with a change in frequency because the positive and negative peaks of the energy arrive at adjacent slotted arrays at different times. The change in the field pattern is such that the angle of departure (angle at which the radiated beam leaves the antenna) of the beam is changed. Note that a change in phase of the applied rf energy would cause the same effect.

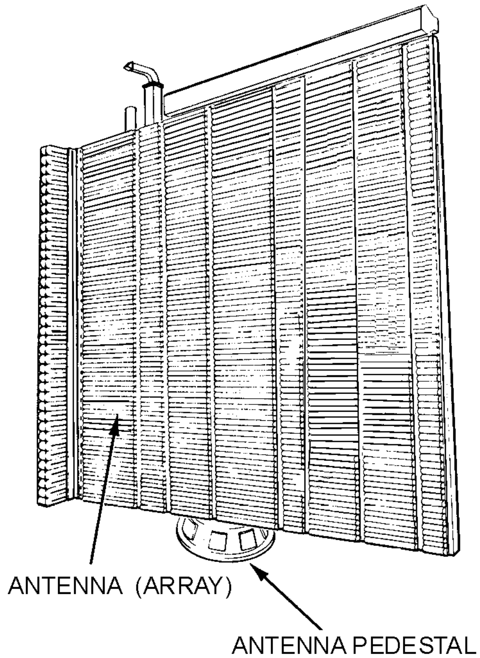

Figure 3-16.—Frequency-sensitive antenna.

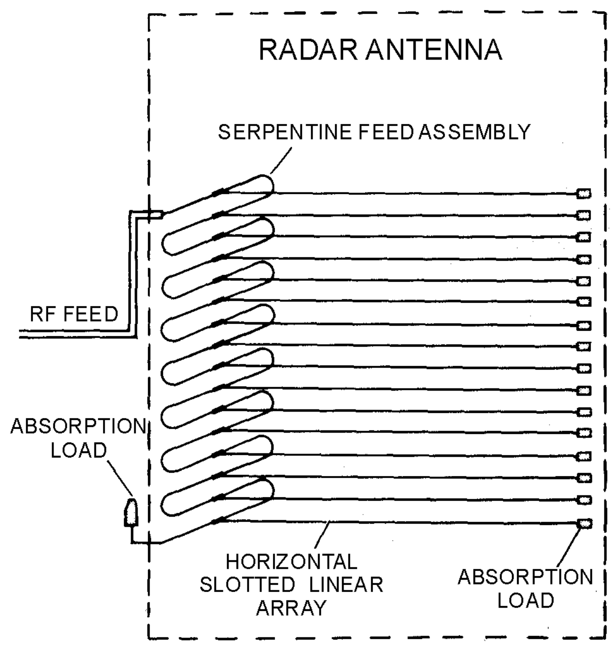

Figure 3-17.—Serpentine feed.

A SLOT ANTENNA exhibits many of the characteristics of a conventional dipole antenna. When arranged in arrays, a high degree of directivity can be obtained. Also, the beam can be caused to scan a volume of space by changing either the frequency or phase of the energy driving the antenna elements.

Basic Slot Antenna and Its Complementary Dipole

The slot antenna consists of a radiator formed by cutting a narrow slot in a large metal surface. Such an antenna is shown in figure 3-18. The slot length is a half wavelength at the desired frequency and the width is a small fraction of a wavelength. The antenna is frequently compared to a conventional half-wave dipole consisting of two flat metal strips. The physical dimensions of the metal strips are such that they would just fit into the slot cut out of the large metal sheet.

This type of antenna is called the COMPLEMENTARY DIPOLE.

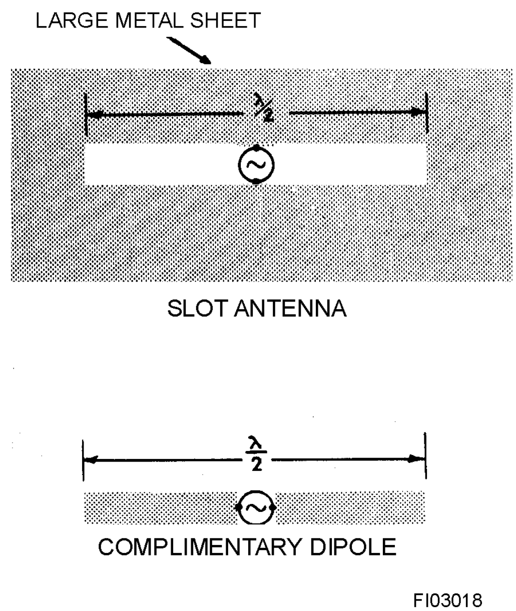

Figure 3-18.—Slot antenna and complementary dipole.

The slot antenna is compared to its complementary dipole to illustrate that the radiation patterns produced by a slot antenna cut into an infinitely large metal sheet and that of the complementary dipole antenna are the same.

Several important differences exist between the slot antenna and its complementary antenna. First, the electric and magnetic fields are interchanged. In the case of the dipole antenna shown in figure 3-18, the electric lines are horizontal while the magnetic lines form loops in the vertical plane. With the slot antenna, the magnetic lines are horizontal and the electric lines are vertical. The electric lines are built up across the narrow dimensions of the slot. As a result, the polarization of the radiation produced by a horizontal slot is vertical. If a vertical slot is used, the polarization is horizontal.

A second difference between the slot antenna and its complementary dipole is that the direction of the lines of electric and magnetic force abruptly reverse from one side of the metal sheet to the other. In the case of the dipole, the electric lines have the same general direction while the magnetic lines form continuous closed loops.

When energy is applied to the slot antenna, currents flow in the metal sheet. These currents are not confined to the edges of the slot but rather spread out over the sheet. Radiation then takes place from both sides of the sheet. In the case of the complementary dipole, however, the currents are more confined; so a much greater magnitude of current is required to produce a given power output using the dipole antenna.

The current distribution of the dipole resembles the voltage distribution of the slot. The edges on the slot have a high voltage concentration and relatively low current distribution; the complementary dipole has a high current concentration and relatively low voltage.

Slot antennas are adaptable for the vhf and uhf ranges. One of their practical advantages is that the feed section which energizes the slot may be placed below the large metal surface in which the slot is cut. Thus, nothing needs to extend from the surface. In addition, the slot itself may be covered by a section of insulating material to provide a seal so that the antenna can be pressurized with dry air. Dry air pressurization reduces moisture in the waveguide and prevents arcing.

Many of the new radar systems reaching the fleet over the next few years will use frequency- or phase-sensitive antennas. Some of the new radars will use antennas that electronically scan the azimuth as well as elevation, eliminating the moving antenna.

Q-15. What is a set of antenna elements called?

Q-16. What type of antenna has all elements connected to the same energy source?

Q-17. What determines the beam elevation angle of an antenna that is electronically scanned in elevation?

Q-18. What is the polarization of the energy radiated by a vertical slot?

SUMMARY

This chapter has presented information on the characteristics of microwave antennas. The information that follows summarizes the important points of this chapter.

The **ANTENNA CHARACTERISTICS** of microwave and low-frequency antennas are essentially the same. The efficiency of an antenna is expressed as a POWER GAIN or POWER RATIO as compared to a standard reference antenna.

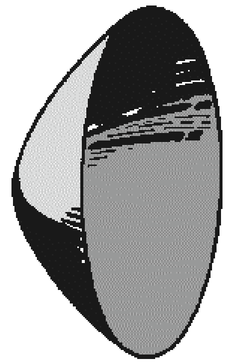
The **STANDING WAVE RATIO (swr)** is a measurement of the impedance mismatch between a transmission line and its load and is an indicator of overall system efficiency.

DIRECTIVITY refers to the direction in which an antenna radiates and the narrowness of the radiated beam in DIRECTIONAL ANTENNAS.

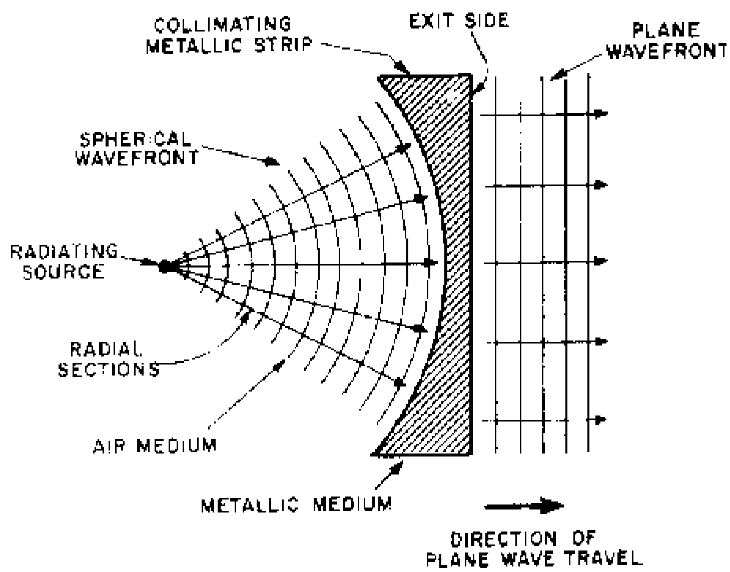
OMNIDIRECTIONAL ANTENNAS radiate and receive in all directions at once.

RECIPROCITY is the ability of an antenna to both transmit and receive electromagnetic energy.

REFLECTOR ANTENNAS are antennas that use a reflector to focus electromagnetic energy into a beam that is directional in either the vertical plane, the horizontal plane, or both planes at once. The basic PARABOLIC REFLECTOR shown in the illustration, or one of its variations, is most often used.



LENS ANTENNAS use a **COLLIMATING LENS** to force the spherical components of a wavefront into parallel (focused) paths by delaying or accelerating portions of the wavefronts, as shown in the illustration.



An **ANTENNA ARRAY** is a set of antenna elements and may be one of two basic types, the DRIVEN ARRAY or the PARASITIC ARRAY.

FREQUENCY-SENSITIVE ANTENNAS use frequency-sensitive slots as radiation sources to achieve directivity. The angle at which the radiated beam leaves the antenna is determined by the frequency of the radiated energy. Currently the most common frequency-sensitive antennas use this feature to achieve elevation coverage while azimuth coverage is achieved by rotating the antennas. New systems will use stationary frequency-sensitive antennas to achieve both azimuth and elevation coverage.

ANSWERS TO QUESTIONS Q1. THROUGH Q18.

A-1. Operating principles and electrical characteristics.

A-2. Power gain or power ratio.

A-3. Standing-wave ratio (swr).

A-4. Omnidirectional.

A-5. Antenna directivity.

A-6. Reciprocity.

A-7. Parabolic.

A-8. Light waves.

A-9. One.

A-10. Determine elevation.

A-11. Vertical.

A-12. Forces the radial segments of a wavefront into parallel paths.

A-13. Some wavefronts are accelerated so that all wavefronts exit the lens at the same time.

A-14. Delay lens.

A-15. Antenna Array.

A-16. Driven Array.

A-17. Frequency or phase of radiated energy.

A-18. Horizontal.

APPENDIX I

GLOSSARY

APERTURE—See slot.

BOUNDARY CONDITIONS—The two conditions that the E-field and H-field within a waveguide must meet before energy will travel down the waveguide. The E-field must be perpendicular to the walls and the H-field must be in closed loops, parallel to the walls, and perpendicular to the E-field.

BEARING—An angular measurement that indicates the direction of an object in degrees from true north. Also called azimuth.

BUNCHER CAVITY—The input resonant cavity in a conventional klystron oscillator.

BUNCHER GRID—In a velocity-modulated tube, the grid which concentrates the electrons in the electron beam into bunches.

CATCHER GRID—In a velocity-modulated tube, a grid on which the spaced electron groups induce a signal. The output of the tube is taken from the catcher grid.

CAVITY RESONATOR—A space totally enclosed by a metallic conductor and supplied with energy in such a way that it becomes a source of electromagnetic oscillations. The size and shape of the enclosure determine the resonant frequency.

CHOKE JOINT—A joint between two sections of waveguide that provides a good electrical connection without power losses or reflections.

COOKIE-CUTTER TUNER—Mechanical magnetron tuning device that changes the frequency by changing the capacitance of the anode cavities.

COPPER LOSS—Power loss in copper conductors caused by the internal resistance of the conductors to current flow. Also called I^2R loss.

CROWN-OF-THORNS TUNER—See Sprocket Tuner.

CUTOFF FREQUENCY—The frequency at which the attenuation of a waveguide increases sharply and below which a traveling wave in a given mode cannot be maintained. A frequency with a half wavelength that is greater than the wide dimension of a waveguide.

DIELECTRIC CONSTANT—The ratio of a given dielectric to the dielectric value of a vacuum.

DIELECTRIC LOSSES—The electric energy that is converted to heat in a dielectric subjected to a varying electric field.

DIRECTIONAL COUPLER—A device that samples the energy traveling in a waveguide for use in another circuit.

DIRECTIVITY—The narrowness of the radiated beam from an antenna.

DOMINANT MODE—The easiest mode to produce in a waveguide, and also, the most efficient mode in terms of energy transfer.

DRIFT SPACE—In an electron tube, a region free of external fields in which relative electron position depends on velocity.

DUMMY LOAD—A device used at the end of a transmission line or waveguide to convert transmitted energy into heat so no energy is radiated outward or reflected back.

E-FIELD—Electric field that exists when a difference in electrical potential causes a stress in the dielectric between two points.

E-TYPE T-JUNCTION—A waveguide junction in which the junction arm extends from the main waveguide in the same direction as the E-field in the waveguide.

ELECTRIC FIELD—See E-field.

ELECTRONIC TUNING—In a reflex klystron, changing the frequency and output power of the tube by altering the repeller voltage.

ELECTROLYSIS—Chemical changes produced by passing an electrical current from one substance (electrode) to another (electrolyte).

ELECTRON ORBITAL MOVEMENT—The movement of an electron around the nucleus of an atom.

ELECTRON SPIN—The movement of an electron around its axis.

ELEVATION ANGLE—The angle between the line of sight to an object and the horizontal plane.

FARADAY ROTATION—The rotation of the plane of polarization of electromagnetic energy when it passes through a substance influenced by a magnetic field that has a component in the direction of propagation.

FERRITE—A powdered and compressed ferric oxide material that has both magnetic properties and resistance to current flow.

FERRITE SWITCH—A ferrite device that blocks the flow of energy through a waveguide by rotating the electric field 90 degrees. The rotated energy is then reflected or absorbed.

GRID-GAP TUNING—A method of changing the center frequency of a resonant cavity by physically changing the distance between the cavity grids.

GROUP VELOCITY—The forward progress velocity of a wave front in a waveguide.

H-FIELD—Any space or region in which a magnetic force is exerted. The magnetic field may be produced by a current-carrying coil or conductor, by a permanent magnet, or by the earth itself.

H-TYPE T-JUNCTION—A waveguide junction in which the junction arm is parallel to the magnetic lines of force in the main waveguide.

HELIX—A spirally wound transmission line used in a traveling-wave tube to delay the forward progress of the input traveling wave.

HORIZONTAL PLANE—An imaginary plane tangent to and touching the Earth's surface as established by a stable element, such as a gyroscope.

HORN—A funnel-shaped section of waveguide used as a termination device and as a radiating antenna.

HOT CARRIER—A current carrier, which may be either a hole or an electron, that has relatively high energy with respect to the current carriers normally found in majority-carrier devices.

HOT-CARRIER DIODE—A semiconductor diode in which hot carriers are emitted from a semiconductor layer into the metal base. Also called a hot-electron diode. An example is the Schottky-Barrier diode.

HYBRID JUNCTION—A waveguide junction that combines two or more basic T-junctions.

HYBRID RING—A hybrid-waveguide junction that combines a series of E-type T-junctions in a ring configuration.

IDLER FREQUENCY—In a parametric amplifier, the difference between the input signal and the pump signal frequency. Also called the lower-sideband frequency.

INTERACTION SPACE—The region in an electron tube where the electrons interact with an alternating electromagnetic field.

INTERELECTRODE CAPACITANCE—The capacitance between the electrodes of an electron tube.

I^2R LOSS—See Copper Loss.

IRIS—A metal plate with an opening through which electromagnetic waves may pass. Used as an impedance matching device in waveguides.

LEAD INDUCTANCE—The inductance of the lead wires connecting the internal components of an electron tube.

LOAD ISOLATOR—A passive attenuator in which the loss in one direction is much greater than that in the opposite direction. An example is a ferrite isolator for waveguides that allows energy to travel in only one direction.

LOOP—A curved conductor that connects the ends of a coaxial cable or other transmission line and projects into a waveguide or resonant cavity for the purpose of injecting or extracting energy.

LOOSE COUPLING—Inefficient coupling of energy from one circuit to another that is desirable in some applications. Also called weak coupling.

MAGIC-T JUNCTION—A combination of the H-type and E-type T-junctions.

MAGNETIC FIELD—See H-field.

METALLIC INSULATOR—A shorted quarter-wave section of transmission line.

MICROWAVE REGION—The portion of the electromagnetic spectrum from 1,000 megahertz to 100,000 megahertz.

MODULATOR—A device that produces modulation; i.e., varies the amplitude, frequency, or phase of an ac signal.

NEGATIVE-RESISTANCE ELEMENT—A component having an operating region in which an increase in the applied voltage increases the resistance and produces a proportional decrease in current. Examples include tunnel diodes and silicon unijunction transistors.

NONDEGENERATIVE-PARAMETRIC AMPLIFIER—A parametric amplifier that uses a pump signal frequency that is higher than twice the frequency of the input signal.

PHASE SHIFTER—A device used to change the phase relationship between two ac signals.

POWER GAIN—The ratio of the radiated power of an antenna compared to the output power of a standard antenna. A measure of antenna efficiency usually expressed in decibels. Also referred to as POWER RATIO.

POWER RATIO—See Power Gain.

PROBE—A metal rod that projects into, but is insulated from, a waveguide or resonant cavity and used to inject or extract energy.

PUMP—Electrical source of the energy required to vary the capacitance of a parametric amplifier.

RANGE—Distance, as measured from a point of reference, such as a radar, to a target or other object.

REACTANCE AMPLIFIER—A low-noise amplifier that uses a nonlinear variable reactance as the active element instead of a variable resistance. Also called a parametric amplifier.

RECIPROCITY—The ability of an antenna to both transmit and receive electromagnetic energy.

REFLEX KLYSTRON—A klystron with a reflector (repeller) electrode in place of a second resonant cavity to redirect the velocity-modulated electrons back through the cavity which produced the modulation.

REFRACTIVE INDEX—The ratio of the phase velocity of a wave in free space to the phase velocity of the wave in a given substance (dielectric).

REPELLER—Sometimes called a reflector. An electrode in a reflex klystron with the primary purpose of reversing the direction of the electron beam.

ROTATING JOINT—A joint that permits one section of a transmission line or waveguide to rotate continuously with respect to another while passing energy through the joint. Also called a rotary coupler.

SKIN EFFECT—The tendency for alternating current to concentrate in the surface layer of a conductor. The effect increases with frequency and serves to increase the effective resistance of the conductor.

SLOT—Narrow opening in a waveguide wall used to couple energy in or out of the waveguide. Also called an aperture or a window.

SPROCKET TUNER—Mechanical tuning device for magnetron tubes that changes the frequency of the cavities by changing the inductance. Also called a crown-of-thorns tuner.

STAGGER TUNING—A method of klystron tuning in which the resonant cavities are tuned to slightly different frequencies to increase the bandwidth of the amplifier.

STANDING WAVE RATIO—The ratio of the maximum to the minimum amplitudes of corresponding components of a field, voltage, or current along a transmission line or waveguide in the direction of propagation measured at a given frequency.

SYNCHRONOUS TUNING—In a klystron amplifier, a method of tuning which tunes all the resonant cavities to the same frequency. High gain is achieved, but the bandwidth is narrow.

TRANSIT TIME—The time an electron takes to cross the distance between the cathode and anode.

TRANSVERSE ELECTRIC MODE—The entire electric field in a waveguide is perpendicular to the wide dimension and the magnetic field is parallel to the length. Also called the TE mode.

TRANSVERSE MAGNETIC MODE—The entire magnetic field in a waveguide is perpendicular to the wide dimension ("a" wall) and some portion of the electric field is parallel to the length. Also called the TM mode.

TUNNELING—The piercing of a potential barrier in a semiconductor by a particle (current carrier) that does not have sufficient energy to go over the barrier.

TUNNEL DIODE—A heavily doped junction diode that has negative resistance in the forward direction over a portion of its operating range. See NEGATIVE-RESISTANCE ELEMENT.

VARACTOR—A pn-junction semiconductor designed for microwave frequencies in which the capacitance varies with the applied bias voltage.

VARIABLE ATTENUATOR—An attenuator for reducing the strength of an ac signal either continuously or in steps, without causing signal distortion.

VELOCITY MODULATION—Modification of the velocity of an electron beam by the alternate acceleration and deceleration of electrons.

VERTICAL PLANE—An imaginary plane that is perpendicular to the horizontal plane.

WAVEGUIDE—A rectangular, circular, or elliptical metal pipe designed to transport electromagnetic waves through its interior.

WAVEGUIDE MODE OF OPERATION—Particular field configuration in a waveguide that satisfies the boundary conditions. Usually divided into two broad types: the transverse electric (TE) and the transverse magnetic (TM).

WAVEGUIDE POSTS—A rod of conductive material used as impedance-changing devices in waveguides.

WAVEGUIDE SCREW—A screw that projects into a waveguide for the purpose of changing the impedance.

WINDOW—See Slot.

WOBBLE FREQUENCY—The frequency at which an electron wobbles on its axis under the influence of an external magnetic field of a given strength.

MODULE 11 INDEX

W

ASSIGNMENT 1

Textbook assignment: Chapter 1, "Waveguide Theory and Applications," pages 1-1 through 1-68.

1-1. The portion of the electromagnetic spectrum which falls between 1,000 and 100,000 megahertz is referred to as which of the following regions?

1. X-ray
2. Infrared
3. Microwave
4. Ultra-violet

1-2. Microwave theory is based on the action of which of the following fields?

1. Electric field only
2. Magnetic field only
3. Electromagnetic field

1-3. Coaxial lines are more efficient than two-wire lines at microwave frequencies for which of the following reasons?

1. Because electromagnetic fields are completely confined in coaxial lines
2. Because electromagnetic fields are not completely confined in coaxial lines
3. Because coaxial lines have less resistance to current flow than two-wire transmission lines
4. Each of the above

1-4. The most efficient transfer of electromagnetic energy can be provided by which of the following mediums?

1. Waveguides
2. Twin-lead flat lines
3. Single-conductor lines
4. Coaxial transmission lines

1-5. Copper (I^2R) losses are reduced by what physical property of waveguides?

1. Small surface area
2. Large surface area
3. Shape of the waveguide
4. Waveguide material used

1-6. In a coaxial line, the current-carrying area of the inner conductor is restricted to a small surface layer because of which of the following properties?

1. Skin effect
2. Copper loss
3. Conductor density
4. Temperature effect

1-7. Which of the following dielectrics is used in waveguides?

1. Air
2. Mica
3. Insulating oil
4. Insulating foam

1-8. Which of the following characteristics of a waveguide causes the lower-frequency limitation?

1. I^2R loss
2. Physical size
3. Wall thickness
4. Dielectric loss

1-9. At very high frequencies, ordinary insulators in a two-wire transmission line display the characteristics of what electrical component?

1. An inductor
2. A resistor
3. A capacitor
4. A transformer

1-10. At very high frequencies, which of the following devices works best as an insulator?

1. Open half-wave section
2. Open quarter-wave section
3. Shorted half-wave section
4. Shorted quarter-wave section

1-11. The range of operating frequencies is determined by which of the following wave-guide dimensions?

1. The widest
2. The longest
3. The shortest
4. The narrowest

1-12. If frequency is decreased, what change, if any, will be required in the dimensions of the wave-guide bus bar?

1. Decrease in dimensions
2. Increase in dimensions
3. None

1-13. The cutoff frequency for a wave-guide is controlled by the physical dimensions of the wave-guide and is defined as the frequency at which two quarter-wavelengths are

1. shorter than the "a" dimension
2. shorter than the "b" dimension
3. longer than the "b" dimension
4. longer than the "a" dimension

1-14. In practical applications, which of the following dimensions describes the wide dimension of the wave-guide at the operating frequency?

1. 0.1 wavelength
2. 0.2 wavelength
3. 0.5 wavelength
4. 0.7 wavelength

1-15. Which of the following fields is/are present in wave guides?

1. E field only
2. H field only
3. E and H fields
4. Stationary field

1-16. A difference in potential across a dielectric causes which of the following fields to develop?

1. Electric field only
2. Magnetic field only
3. Electromagnetic field

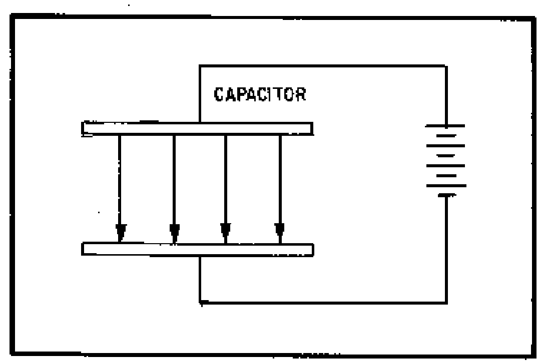

Figure 1A.—Electric field.

IN ANSWERING QUESTION 1-17, REFER TO FIGURE 1A.

1-17. What information is indicated by the number of arrows between the plates of the capacitor?

1. The amount of capacitance
2. The amount of current flow
3. The strength of the electric field
4. The strength of the magnetic field

1-18. H lines have which of the following distinctive characteristics?

1. They are continuous straight lines
2. They are generated by voltage
3. They form closed loops
4. They form only in the wave-guide

1-19. What minimum number of boundary conditions must be satisfied for energy to travel down a waveguide?

1. One
2. Two
3. Three
4. Four

1-20. For an electric field to exist at the surface of a conductor, the field must have what angular relationship to the conductor?

1. 0 degrees
2. 30 degrees
3. 45 degrees
4. 90 degrees

1-21. What, if anything, happens to the amplitude of the wavefronts within a waveguide that DO NOT meet boundary conditions?

1. They Increase rapidly to maximum
2. They decrease slowly to the half-power point
3. They decrease rapidly to zero
4. Nothing

1-22. If the wall of a wave-guide is perfectly flat, the angle of reflection is equal to which of the following angles?

1. Angle of cutoff
2. Angle of incidence
3. Angle of refraction
4. Angle of penetration

1-23. THIS QUESTION HAS BEEN DELETED.

1-24. How does the group velocity of an electromagnetic field in a waveguide compare to the velocity of a wavefront through free space?

1. Group velocity is faster
2. Group velocity is slower
3. Their velocities are the same

1-25. The group velocity of a wavefront in a waveguide may be increased by which of the following actions?

1. Decreasing the frequency of the input energy
2. Increasing the frequency of the input energy
3. Increasing the power of the input energy
4. Decreasing the power of the input energy

1-26. The various field configurations that can exist in a waveguide are referred to as

1. wavefronts
2. modes of operation
3. fields of operation
4. fields of distribution

1-27. The most efficient transfer of energy occurs in a waveguide in the what mode?

1. Sine
2. Dominant
3. Transverse
4. Time-phase

1-28. How is the cutoff wavelength for a circular waveguide figured?

1. 1.17 times the radius of the waveguide
2. 1.17 times the diameter of the waveguide
3. 1.71 times the diameter of the waveguide
4. 1.71 times the radius of the waveguide

1-29. The field configuration in waveguides is divided into what two categories?

1. Half-sine and dominant
2. Transverse electric and transverse magnetic
3. Transverse electric and dominant
4. Transverse magnetic and half-sine

1-30. With a mode description of $TE_{1,0}$, what maximum number of half-wave patterns exist across the "a" dimension of a waveguide?

1. One
2. Two
3. Three
4. Four

1-31. With the mode description, $TE_{1,1}$, what maximum number of half-wave patterns exist across the diameter of a circular waveguide?

1. One
2. Two
3. Three
4. Four

1-32. To inject or remove energy from a waveguide, which of the following devices could you use?

1. Slot
2. Loop
3. Probe
4. Each of the above

1-33. Loose coupling is a method used to reduce the amount of energy being transferred from a waveguide. How is loose coupling achieved when using a probe?

1. By doubling the size of the probe
2. By increasing the length of the probe
3. By decreasing the length of the probe
4. By placing the probe directly in the center of energy field

1-34. Loop coupling is most efficient when the loop is placed at what point in which of the following fields?

1. At the point of maximum electric field
2. At the point of minimum electric field
3. At the point of minimum magnetic field
4. At the point of maximum magnetic field

1-35. Increasing the size of the loop wire increases which of the following loop capabilities?

1. Efficiency
2. Bandwidth coverage
3. Power-handling capability
4. Each of the above

1-36. A waveguide which is not perfectly impedance matched to its load is not efficient. Which of the following conditions in a waveguide causes this inefficiency?

1. Sine waves
2. Dominant waves
3. Standing waves
4. Transverse waves

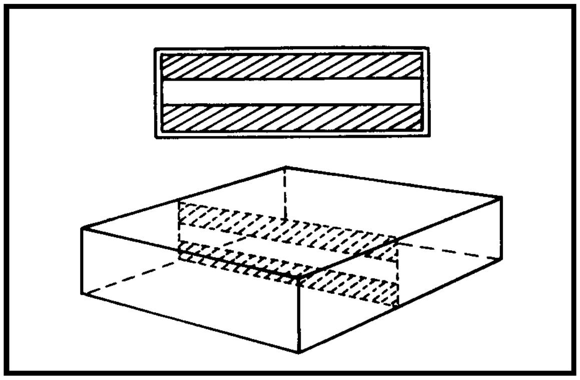

Figure 1B.—Waveguide iris.

IN ANSWERING QUESTION 1-37, REFER TO FIGURE 1B.

1-37. The iris shown in the figure has what type of equivalent circuit?

1. Parallel-LC
2. Shunt-resistive
3. Shunt-inductive
4. Shunt-capacitive

1-38. A waveguide iris that covers part of both the electric and magnetic planes acts as what type of equivalent circuit at the resonant frequency?

1. As a shunt inductive reactance
2. As a shunt resistance
3. As a shunt capacitive reactance
4. Each of the above

1-39. A horn can be used as a waveguide termination device because it provides which of the following electrical functions?

1. A reflective load
2. An absorptive load
3. An abrupt change in impedance
4. A gradual change in impedance

1-40. For a waveguide to be terminated with a resistive load, that load must be matched to which of the following properties of the waveguide?

1. The bandwidth
2. The frequency
3. The inductance
4. The characteristic impedance

1-41. A resistive device with the sole purpose of absorbing all the energy in a waveguide without causing reflections is a/an

1. iris
2. horn
3. antenna
4. dummy load

1-42. A resistive load most often dissipates energy in which of the following forms?

1. Heat
2. Light
3. Magnetic
4. Electrical

1-43. Reflections will be caused by an abrupt change in which of the following waveguide physical characteristics?

1. Size
2. Shape
3. Dielectric material
4. Each of the above

1-44. A waveguide bend which is in the E or H plane must be greater than two wavelengths to prevent

1. cracking
2. reflections
3. energy gaps
4. electrolysis

1-45. A flexible waveguide is used in short sections because of the power-loss disadvantages. What is the cause of this power loss?

1. Walls are not smooth
2. E and H fields are not perpendicular
3. Cannot be terminated in its characteristics impedance
4. Wall size cannot be kept consistent

1-46. The choke joint is used for what purpose in a waveguide?

1. To reduce standing waves
2. To restrict the volume of electron flow
3. To prevent the field from rotating
4. To provide a temporary joint in a waveguide during maintenance or repair

1-47. A circular waveguide is normally used in a rotating joint because rotating a rectangular waveguide would cause which of the following unwanted conditions?

1. Oscillation
2. Large power loss
3. Decrease in bandwidth
4. Field-pattern distortion

1-48. In your waveguide inspections, you should be alert for which of the following problems?

1. Corrosion
2. Damaged surface
3. Improperly sealed joints
4. Each of the above

1-49. What type of corrosion occurs when dissimilar metals are in contact?

1. Contact corrosion
2. Metallic corrosion
3. Electrical corrosion
4. Electrolytic corrosion

1-50. Internal arcing in a waveguide is usually a symptom of which of the following conditions?

1. Change in mode
2. Electrolysis at a joint
3. Moisture in the waveguide
4. Gradual change in frequency

1-51. What is the primary purpose of a directional coupler?

1. To sample the energy in a waveguide
2. To change the phase of the energy in the waveguide
3. To change the direction of energy travel in the waveguide
4. To allow energy in the waveguide to travel in one direction only

1-52. What is the electrical distance between the two holes in a simple directional coupler?

1. 1/8 wavelength
2. 1/4 wavelength
3. 1/2 wavelength
4. 3/4 wavelength

1-53. When the two portions of a reflected wave reach the pickup probe of an incident-wave directional coupler, what is their phase relationship?

1. 45º out of phase
2. 90º out of phase
3. 120º out of phase
4. 180º out of phase

1-54. The highest frequency at which a conventional circuit can oscillate is reached when which of the following values can be reduced no further?

1. Total resistance
2. Total inductance only
3. Total capacitance only
4. The total capacitance and inductance

1-55. For a device to be considered a resonant cavity, it must fulfill which of the following requirements?

1. Be enclosed by conducting walls
2. Possess resonant properties
3. Contain oscillating electromagnetic fields
4. All of the above

1-56. What property gives a resonant cavity a narrow bandpass and allows very accurate tuning?

1. Low Q
2. High Q
3. Inductive reactance
4. Capacitive reactance

1-57. What factor(s) determines the primary frequency of a resonant cavity?

1. Size only
2. Shape only
3. Size and shape
4. Q of the cavity

1-58. Tuning is the process of changing what property of a resonant cavity?

1. The Q
2. The power output
3. The cutoff frequency
4. The resonant frequency

1-59. An adjustable slug or screw placed in the area of maximum E lines in a resonant cavity provides what type of tuning?

1. Volume
2. Inductive
3. Resistive
4. Capacitive

1-60. What are the two basic types of waveguide T junctions?

1. H-type and T-type
2. H-type and E-type
3. H-type and magic T
4. E-type and magic T

1-61. A waveguide junction in which the arm area extends from the main waveguide in the same direction as the electric field is an example of what type junction?

1. E-type magic T
2. H-type magic T
3. H-type T junction
4. E-type T junction

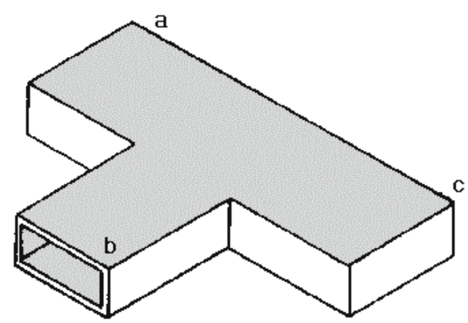

Figure 1C.—H-type T junction.

IN ANSWERING QUESTION 1-62, REFER TO FIGURE 1C.

1-62. When an input is fed into the "b" arm in the figure, which of the following output signal arrangements is/are available?

1. Out-of-phase signals from arms "a" and "c"
2. In-phase signals from arms "a" and "c"
3. An output from the "a" arm only
4. An output from the "c" arm only

1-63. E-type and H-type junctions are combined in which of the following devices?

1. Magic T
2. Rat race
3. Feed horn
4. Hybrid ring

1-64. Low power-handling capabilities and internal power losses are the primary disadvantages of which of the following devices?

1. Magic T
2. Rat race
3. Duplexer
4. Hybrid ring

1-65. The hybrid ring is usually used as what type of device in radar systems?

1. Mixer
2. Detector
3. Duplexer
4. Impedance matcher

1-66. Ferrite devices are useful in electronic and microwave applications because they possess magnetic properties and offer which of the following other properties?

1. Negative resistance to current flow
2. Low resistance to current flow
3. High resistance to current flow
4. High conductance for current flow

1-67. Electrons exhibit which of the following types of motion?

1. Spin
2. Orbital
3. Both 1 and 2 above
4. Linear

1-68. Electrons in a ferrite can be caused to wobble on their axes by which of the following actions?

1. Decreasing the internal resistance
2. Increasing the internal resistance
3. Applying a magnetic field
4. Applying an electric field

1-69. The energy in a ferrite attenuator that is attenuated is dissipated as which of the following energy forms?

1. Heat
2. Light
3. Magnetic
4. Electrical

1-70. The amount of rotation in a Faraday-rotation type ferrite phase shifter is dependent upon which of the following ferrite properties?

1. Length of the material
2. Diameter of the material
3. Strength of the material
4. Internal resistance of the material

ASSIGNMENT 2

Textbook assignment: Chapter 2, "Microwave Principles," pages 2-1 through 2-66. Chapter 3, "Microwave Antennas," pages 3-1 through 3-20.

2-1. As the frequency in a conventional vacuum tube is increased, what is the effect on the capacitive reactance of the tube?

1. It increases
2. It decreases
3. It remains the same

2-2. Undesirable degenerative feedback in conventional vacuum tubes can be caused by which of the following tube factors?

1. Grid bias
2. Transit time
3. Plate voltage
4. Lead inductance

2-3. A decrease in efficiency in a conventional vacuum tube caused by a phase shift between plate current and grid voltage can be the result of excessive

1. transit time
2. lead inductance
3. capacitive reactance
4. interelectrode capacitance

2-4. Moving tube electrodes further apart to decrease interelectrode capacitance causes which of the following tube characteristics to increase?

1. Transit time
2. Lead inductance
3. Inductive reactance
4. Capacitive reactance

2-5. Which of the following properties of an electron is directly proportional to its velocity?

1. Mass
2. Kinetic energy
3. Potential energy
4. All of the above

2-6. An electron that enters an electrostatic field and travels in the same direction as the lines of force will react in what way?

1. It will accelerate
2. It will decelerate
3. It will spin faster
4. It will spin slower

2-7. The alternate speeding up and slowing down of electrons in a beam that produces electron bunches is known as which of the following modulation terms?

1. Carrier modulation
2. Velocity modulation
3. Amplitude modulation
4. Frequency modulation

2-8. How is an electron affected, if at all, if it enters the buncher-grid gap when the potential across the grids is positive?

1. It is deflected
2. It is accelerated
3. It is decelerated

2-9. The point in a stream of electron bunches at which the catcher cavity will most efficiently remove power is determined by which of the following factors?

1. Electron spin velocity
2. The size of the cavity
3. The size of the bunches
4. Frequency of the buncher-grid signal

2-10. Which of the following electronic interactions is used in klystron operation?

1. Velocity-modulation
2. Voltage and current
3. Variable-capacitance
4. Crossed electromagnetic-field

2-11. In a klystron, an ac potential is superimposed on the dc voltage that is applied to the buncher grids by what component?

1. The cathode
2. The accelerator grid
3. The buncher-grid cavity resonator
4. The catcher-grid cavity resonator

2-12. A two-cavity klystron that has a feedback path from the catcher cavity to the buncher cavity will operate as what type of circuit?

1. Modulator
2. Amplifier
3. Oscillator
4. Discriminator

2-13. The input signal to a two-cavity klystron amplifier is applied to which of the following components?

1. The cathode
2. The catcher grids
3. The buncher grids
4. The accelerator grid

2-14. In a klystron, the placement of additional cavities between the buncher cavity and catcher cavity increases the power output by causing which of the following electronic actions?

1. Increased velocity modulation
2. Decreased velocity modulation
3. Increased electron-beam speed
4. Decreased electron-beam speed

2-15. What is the purpose of applying a large negative pulse to the cathode of a three-cavity klystron?

1. To focus the electron beam
2. To accelerate the electron beam
3. To decelerate the electron beam
4. To modulate the electron beam

2-16. In a three-cavity klystron, what cavity, if any, contributes most to the velocity modulation of the electron beam?

1. The middle cavity
2. The catcher cavity
3. The buncher cavity
4. None

2-17. The bandwidth of a multicavity klystron can be increased by using which of the following tuning methods?

1. Varactor tuning
2. Staggered tuning
3. Electronic tuning
4. Synchronous tuning

2-18. The repeller of a reflex klystron replaces what component in other types of klystrons?

1. The input cavity
2. The output cavity
3. The buncher cavity
4. The intermediate cavity

2-19. In a reflex klystron, what type(s) of electrical charge, if any, does the repeller have?

1. Positive only
2. Negative only
3. Alternately positive and negative
4. None

2-20. In a reflex klystron, the length of time a constant speed electron remains in the space separating the grid and repeller is determined by which of the following factor(s)?

1. Repeller voltage
2. Electron velocity
3. Both 1 and 2 above
4. The distance between grid and repeller

2-21. A reflex klystron in which the constant-speed electrons remain in the repeller field for 3/4 cycle is operating in what mode?

1. Mode 1
2. Mode 2
3. Mode 3
4. Mode 4

2-22. In a reflex klystron, the choice of operating mode is determined by which of the following circuit factors?

1. The voltage required
2. The power available
3. The frequency range available
4. Both 2 and 3 above

2-23. In the higher modes, power and amplitude limitations in a reflex klystron are caused by which of the following actions?

1. Electron debunching
2. Frequency fluctuation
3. Decreasing transit time
4. Increasing electron density

2-24. The term "bel" is a unit of measurement that expresses which of the following relationships?

1. Ratio of voltage and resistance
2. Logarithmic ratio between input and output
3. Geometric progression from input to output
4. Ratio of voltage to current

2-25. The term "dBm" is based on what standard reference level?

1. 1 watt
2. 1 volt
3. 1 milliwatt
4. 1 millivolt

2-26. Which of the following twt characteristics makes it ideal for use as an rf amplifier?

1. High-noise and narrow-bandwidth
2. Low-noise and wide-bandwidth
3. High-noise and wide-bandwidth
4. Low-noise and narrow-bandwidth

2-27. In a twt, what is the primary purpose of the helix?

1. To increase the forward velocity of the input
2. To decrease the forward velocity of the input
3. To decrease the reflected velocity of the output
4. To increase the reflected velocity of the output

2-28. Velocity modulation of the electron beam in a twt is achieved by what action?

1. By the action of resonant cavities
2. By interaction of the electron beam with the permanent magnet field
3. By interaction of the electron beam with the electric field in the helix
4. All of the above

2-29. In a twt, what is the purpose of the attenuators along the helix?

1. To focus the beam
2. To limit the input
3. To limit the output
4. To prevent reflections

2-30. A microwave tube that extracts energy from a wave that travels from the collector toward the cathode is referred to as the

1. klystron
2. traveling-wave tube
3. crossed-field amplifier
4. backward-wave oscillator

2-31. In a magnetron, the magnetic field between the plate and cathode serves what purpose?

1. Acts as a grid
2. Provides a plate load
3. Acts as a space-charge suppressor
4. Provides filament power

2-32. What property in a magnetron is controlled by the cavities in the plate?

1. Input power
2. Output power
3. Input voltage
4. Output frequency

2-33. In a magnetron, what causes the path of an electron to curve when it is moving from the cathode to the plate?

1. The cathode pulse
2. The electric field
3. The resonant cavities
4. The permanent magnetic field

2-34. The critical value of magnetic field strength in a magnetron causes which of the following electronic actions?

1. Plate cavities stop oscillating
2. Output power decreases to zero
3. Electrons strike the plate and return to the cathode
4. Electrons miss the plate and return to the cathode

2-35. Magnetron oscillators are divided into what total number of classes?

1. One
2. Two
3. Three
4. Four

2-36. THIS QUESTION HAS BEEN DELETED.

2-37. In a negative-resistance magnetron, which, if any, of the following values of magnetic field strengths is required to start oscillations?

1. Critical value
2. Slightly lower than critical value
3. Slightly higher than critical value
4. None of the above

2-38. In magnetrons, the effect of filament bombardment can be reduced by which of the following actions?

1. Increasing plate voltage
2. Reducing filament voltage
3. Reducing signal frequency
4. Increasing signal frequency

2-39. In electron-resonance magnetrons, which of the following anode blocks is/are used?

1. Vane anode
2. Rising-sun anode
3. Hole-and-slot anode
4. Each of the above

2-40. In the electron-resonance magnetron, the total electric field is produced by which of the following field combinations?

1. The dc field only
2. The ac and dc fields
3. The ac and magnetic fields
4. The dc and magnetic fields

2-41. Energy from working electrons is received by which of the following magnetron fields?

1. The ac field only
2. The dc field only
3. Both the ac and dc fields
4. The magnetic field

2-42. In a magnetron, the total action of many electrons returning to the cathode while others are moving toward the anode forms which of the following patterns?

1. Vertical wavefront
2. Space-charge wheel
3. Spherical wavefront
4. Horizontal space charge

2-43. The greatest power output is produced in what magnetron mode of operation?

1. Mode 1
2. Mode 2
3. The pi mode
4. The radian mode

2-44. Magnetic lines of force passing between cavities are intercepted in which, if any, of the following magnetron coupling methods?

1. Slot coupling method
2. Strap-fed loop method
3. Segment-fed loop method
4. None of the above

2-45. Inductive tuning in a magnetron is accomplished by which of the following actions?

1. Changing the cavity resistance
2. Altering the cavity surface-to-volume ratio
3. Decreasing the size of the slot gap
4. Decreasing the space charge

2-46. A magnetron should be "baked in" under which of the following conditions?

1. Before each use
2. After periods of idleness
3. After initial installation
4. Both 2 and 3 above

2-47. The crossed-field amplifier produces which of the following desirable circuit characteristics?

1. Wide bandwidth
2. High efficiency
3. Large power-handling capability
4. All of the above

2-48. The tunneling action of the tunnel diode produces which of the following useful properties?

1. Long transit time
2. Positive resistance
3. Negative resistance
4. Variable inductance

2-49. The tuned circuit in a tunnel-diode oscillator determines which of the following circuit values?

1. Frequency
2. Resistance
3. Power range
4. Capacitance

2-50. Tuning a tunnel-diode oscillator by changing the capacitance of the tuned circuit can be accomplished by which of the following tuning methods?

1. Bias tuning
2. Slot tuning
3. Current tuning
4. Varactor tuning

2-51. In the reflection-type, circulator-coupled tunnel-diode amplifier, what component prevents feedback to the tuned input circuit?

1. The circulator
2. The output loop
3. The tuned cavity
4. The tunnel diode

2-52. Stability is a problem in which, if any, of the following tunnel-diode frequency converters?

1. High-gain converter
2. Unity-gain converter
3. Conversion-loss converter
4. None of the above

2-53. The varactor is a type of pn junction that acts as which of the following types of electronic devices?

1. Fixed resistor
2. Fixed capacitor
3. Variable resistor
4. Variable capacitor

2-54. What is the most important feature of the parametric amplifier?

1. Low noise
2. High gain
3. Power output
4. Frequency range

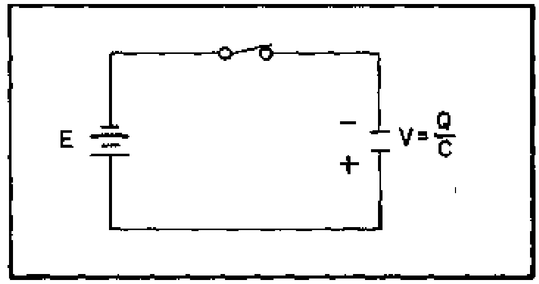

Figure 2A.—Voltage amplification circuit.

IN ANSWERING QUESTION 2-55, REFER TO FIGURE 2A.

2-55. How is amplification accomplished in the circuit?

1. By opening the switch
2. By varying the frequency
3. By varying the resistance
4. By varying the capacitance

2-56. In a nondegenerative parametric amplifier, how does the pump frequency compare to the input signal frequency?

1. The pump frequency is half the input signal frequency
2. The pump frequency is double the input signal frequency
3. The pump frequency is more than double the input signal
4. The pump frequency is equal to the input signal frequency

2-57. In a nondegenerative parametric amplifier with a pump frequency of 12 gigahertz and an idler frequency of 9 gigahertz, what is the input signal frequency?

1. 3 gigahertz
2. 18 gigahertz
3. 21 gigahertz
4. 108 gigahertz

2-58. Bulk-effect semiconductors have what primary advantage over normal pn-junction semiconductors?

1. Smaller size
2. Lower frequency
3. Simpler construction
4. Greater power output

2-59. Gallium-arsenide semiconductors begin to exhibit which of the following electrical characteristics at the threshold point?

1. Variable inductance
2. Positive resistance
3. Negative resistance
4. Variable capacitance

2-60. In an avalanche transit-time diode, what causes the dc bias energy previously absorbed by avalanche electrons to be given up to the microwave field?

1. The electron velocity
2. The negative-resistance property
3. The electron transit time
4. The amount of dc bias energy available

2-61. In a point-contact diode, passing a large current from the catwhisker to the silicon crystal produces what region?

1. A domain region
2. A small p region
3. A small n region
4. An avalanche region

2-62. A Schottky barrier diode has which of the following advantages over a point-contact diode?

1. Lower frequency range
2. Higher frequency range
3. Lower noise generation
4. Higher noise generation

2-63. The PIN diode begins acting as a variable resistance at what minimum frequency?

1. 100 megahertz
2. 200 megahertz
3. 300 megahertz
4. 400 megahertz

2-64. Power ratio is a term used to express what property of an antenna?

1. Efficiency
2. Reciprocity
3. Sensitivity
4. Power output

2-65. A standing-wave ratio (swr) describes which of the following quantities?

1. Transmission-to-reception efficiency value
2. The amount of output power
3. The amount of mismatch between a transmission line and its load
4. The amount of characteristic impedance

2-66. Directivity refers to which of the following properties of a radiated beam?

1. Power gain
2. Standing-wave ratio
3. Narrowness of the beam
4. Polarization of the beam

2-67. Surface angular measurements for antenna directivity in radar and communications systems are made in relationship to which of the following references?

1. Vertical plane only
2. Horizontal plane only
3. Horizontal plane and true north
4. Vertical plane and true north

2-68. Radar range is determined as a function of which of the following measures?

1. Pulse travel time
2. Elevation angle of the antenna
3. Distance to the horizon
4. Angular velocity of the energy

2-69. The parabolic reflector is often used because it produces a radiation pattern with which of the following antenna characteristics?

1. Omnidirectional
2. Highly directive
3. Many equal lobes
4. Spherical wavefronts

2-70. In a lens antenna, what is the purpose of the collimating lens?

1. It produces spherical wavefronts
2. It produces an omnidirectional pattern
3. It forces parallel segments of the wavefront into spherical paths
4. It forces radial segments of the wavefront into parallel paths

2-71. A lens antenna which accelerates some portion of the wavefronts so that all wavefronts exit the lens at the same time is referred to as the

1. metallic delay lens
2. waveguide-type lens
3. loaded microwave lens
4. dielectric delay lens

2-72. In a delay-type lens, the amount of delay in the phase of the wave passing through the lens is determined by which of the following characteristics?

1. The dielectric constant of the lens
2. The characteristic impedance of the lens
3. The physical size of the lens
4. All of the above

2-73. What is/are the basic type(s) of antenna array(s) in common use?

1. Driven only
2. Parasitic only
3. Parasitic and driven

2-74. In a frequency-sensitive antenna, the physical length of the serpentine section and its relationship to the wavelength of the applied energy determines which of the following characteristics?

1. Output power
2. Beam narrowness
3. Antenna efficiency
4. Direction of the beam

2-75. In a horizontal-slot antenna, the polarization of the energy is radiated in what direction?

1. Vertical
2. Spherical
3. Horizontal
4. Omnidirectional

PREFACE

About this course:

This is a self-study course. By studying this course, you can improve your professional/military knowledge, as well as prepare for the Navywide advancement-in-rate examination. It contains subject matter about day-to-day occupational knowledge and skill requirements and includes text, tables, and illustrations to help you understand the information. An additional important feature of this course is its reference to useful information in other publications. The well-prepared Sailor will take the time to look up the additional information.

Training series information:

This is Module 12 of a series.

History of the course:

Sep 1998: Original edition released.
May 2003: Administrative update released. Technical content was reviewed and minor changes *made.*

NAVSUP Logistics Tracking Number
0504-LP-026-8370

TABLE OF CONTENTS

CHAPTER 1

AMPLITUDE MODULATION

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions are based on the objectives. By successfully completing the OCC/ECC, you indicate that you have met the objectives and have learned the information. The learning objectives are listed below.

Upon completion of this chapter, you will be able to:

1. Discuss the generation of a sine wave by describing its three characteristics: amplitude, phase, and frequency.
2. Describe the process of heterodyning.
3. Discuss the development of continuous-wave (cw) modulation.
4. Describe the two primary methods of cw communications keying.
5. Discuss the radio frequency (rf) spectrum usage by cw transmissions.
6. Discuss the advantages and disadvantages of cw transmissions.
7. Explain the operation of typical cw transmitter circuitry.
8. Discuss the method of changing sound waves into electrical impulses.
9. Describe the rf usage of an AM signal.
10. Calculate the percent of modulation for an AM signal.
11. Discuss the difference between high- and low-level modulation.
12. Describe the circuit description, operation, advantages, and disadvantages of the following common AM tube/transistor modulating circuits: plate/collector, control grid/base, and cathode/emitter.
13. Discuss the advantages and disadvantages of AM communications.

INTRODUCTION TO MODULATION PRINCIPLES

People have always had the desire to communicate their ideas to others. Communications have not only been desired from a social point of view, but have been an essential element in the building of civilization. Through communications, people have been able to share ideas of mutual benefit to all mankind. Early attempts to maintain communications between distant points were limited by several factors. For example, the relatively short distance sound would carry and the difficulty of hand-carrying messages over great distances hampered effective communications.

As the potential for the uses of electricity were explored, scientists in the United States and England worked to develop the telegraph. The first practical system was established in London, England, in 1838. Just 20 years later, the final link to connect the major countries with electrical communications was completed when a transatlantic submarine cable was connected. Commercial telegraphy was practically worldwide by 1890. The telegraph key, wire lines, and Morse code made possible almost instantaneous communications between points at great distances. Submarine cables solved the problems of transoceanic communications, but communications with ships at sea and mobile forces were still poor.

In 1897 Marconi demonstrated the first practical wireless transmitter. He sent and received messages over a distance of 8 miles. By 1898 he had demonstrated the usefulness of wireless telegraph communications at sea. In 1899 he established a wireless telegraphic link across the English Channel. His company also established general usage of the wireless telegraph between coastal light ships (floating lighthouses) and land. The first successful transatlantic transmissions were achieved in 1902. From that time to the present, radio communication has grown at an extraordinary rate. Early systems transmitted a few words per minute with doubtful reliability. Today, communications systems reliably transmit information across millions of miles.

The desire to communicate directly by voice, at a higher rate of speed than possible through basic telegraphy, led to further research. That research led to the development of MODULATION. Modulation is the ability to impress intelligence upon a TRANSMISSION MEDIUM, such as radio waves. A transmission medium can be described as light, smoke, sound, wire lines, or radio-frequency waves. In this module, you will study the basic principles of modulation and DEMODULATION (removing intelligence from the medium).

In your studies, you will learn about modulation as it applies to radio-frequency communications. To modulate is to impress the characteristics (intelligence) of one waveform onto a second waveform by varying the amplitude, frequency, phase, or other characteristics of the second waveform. First, however, you will review the characteristics and generation of a sine wave. This review will help you to better understand the principles of modulation. Then, an important principle called HETERODYNING (mixing two frequencies across a nonlinear impedance) will be studied and applied to modulation. Nonlinear impedance will be discussed in the heterodyning section. You will also study several methods of modulating a radio-frequency carrier. You will come to a better understanding of the demodulation principle by studying the various circuits used to demodulate a modulated carrier.

Q-1. What is modulation?

Q-2. What is a transmission medium?

Q-3. What is heterodyning?

Q-4. What is demodulation?

SINE WAVE CHARACTERISTICS

The basic alternating waveform for all complex waveforms is the sine wave. Therefore, an understanding of sine wave characteristics and how they can be acted upon is essential for you to understand modulation. You may want to review sine waves in chapter 1 of *NEETS*, Module 2, *Introduction to Alternating Current and Transformers* at this point.

GENERATION OF SINE WAVES

Since numbers represent individual items in a group, arrows can be used to represent quantities that have magnitude and direction. This may be done by using an arrow and a number, as illustrated in figure 1-1, view (A). The number represents the magnitude of force and the arrow represents the direction of the force.

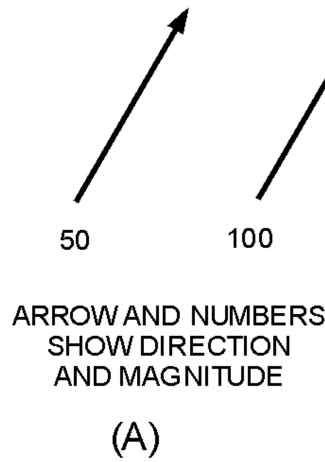

Figure 1-1A.—Vectors representing magnitude and direction.

View (B) illustrates a simpler method of representation. In this method, the length of the arrow is proportional to the magnitude of force, and the direction of force is indicated by the direction of the arrow. Thus, if an arrow 1-inch long represents 50 pounds of force, then an arrow 2-inches long would represent 100 pounds of force. This method of showing both magnitude and direction is called a VECTOR. To more clearly show the relationships between the amplitude, phase, and frequency of a sine wave, we will use vectors.

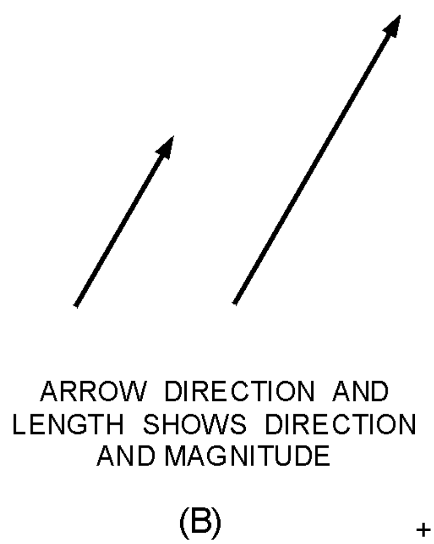

Figure 1-1B.—Vectors representing magnitude and direction.

Vector Applied to Sine-Wave Generation

As covered, in *NEETS*, Module 2, *Introduction to Alternating Current and Transformers*, an alternating current is generated by rotating a coil in the magnetic field between two magnets. As long as the magnetic field is uniform, the output from the coil will be a sine wave, as shown in figure 1-2. This wave shape is called a sine wave because the voltage of the coil depends on its angular position in the magnetic field.

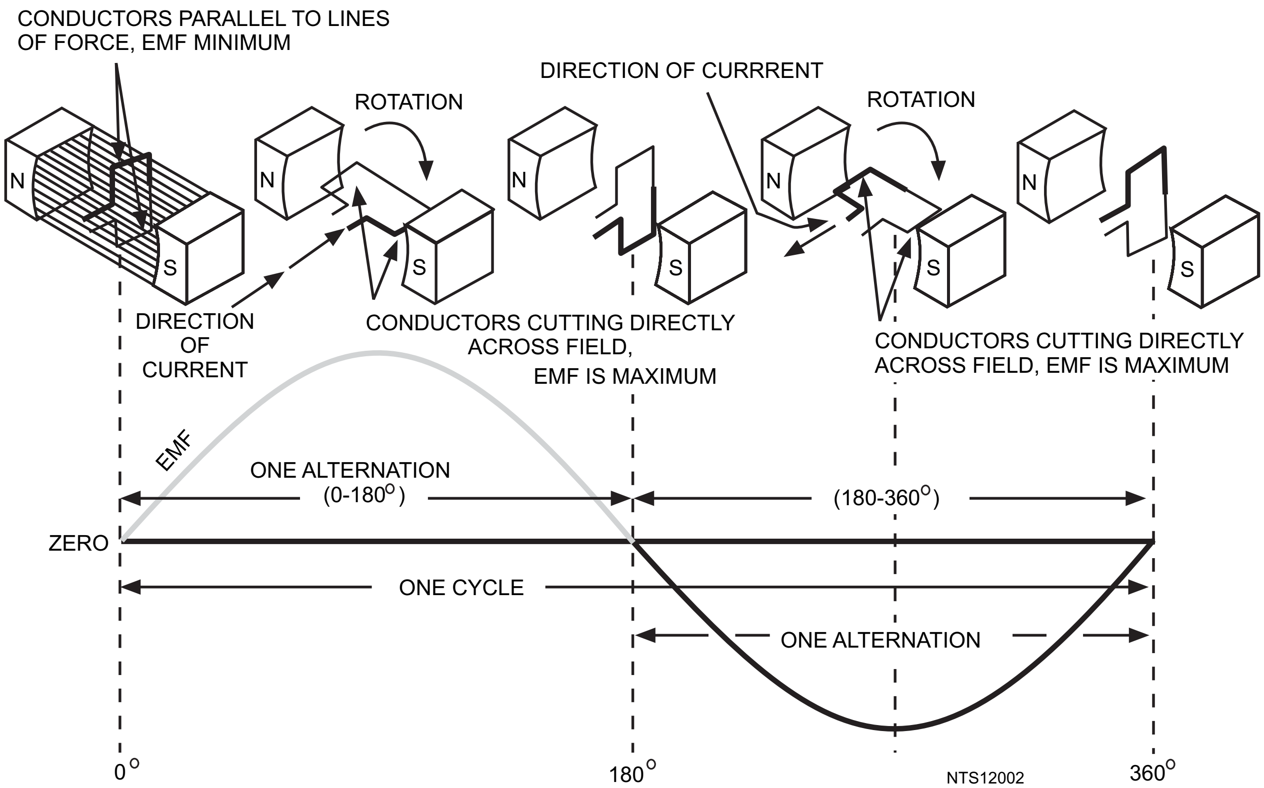

Figure 1-2.—Sine-wave generator.

This relationship can be expressed mathematically by the formula:

$$e = E_{max} \text{ sine} \theta$$

Where: e = instantaneous value of the voltage developed when the coil is at some angle (θ)

E_{max} = maximum value of the voltage

θ = angular position of the coil

You should recall that the trigonometric ratio (inset in figure 1-3) for the sine in a right triangle (a triangle in which one angle is 90 degrees) is:

$$\text{sine } \theta = \frac{\text{opposite side}}{\text{hypotenuse}}$$

Where:

θ = acute angle

opposite side = side of the triangle taht is opposite the angle θ

hypotenuse = the longest side of the triangle

When an alternating waveform is generated, the coil is represented by a vector which has a length that is equal to the maximum output voltage (E_{max}). The output voltage at any given angle can be found by applying the above trigonometric function. Because the output voltage is in direct relationship with the sine of the angle !, it is commonly called a sine wave.

You can see this relationship more clearly in figure 1-3 where the coil positions in relation to time are represented by the numbers 0 through 12. The corresponding angular displacements, shown as !, are shown along the horizontal time axis. The induced voltages (V_1 through V_{12}) are plotted along this axis. Connecting the induced voltage points, shown in the figure, forms a sine-wave pattern. This relationship can be proven by taking any coil position and applying the trigonometric function to an equivalent right triangle. When the vector is placed horizontally (position 0), the angle ! is 0 degrees. Since e = E_{max} sine !, and the sine of 0 degrees is 0, the output voltage is 0 volts, as shown below:

Where:

E_{max} = 100V

θ = 0 degrees

sine θ = 0

Solution:

$e = E_{max} \text{ sine } \theta$

$e = (100V)(0)$

$e = 0 V$

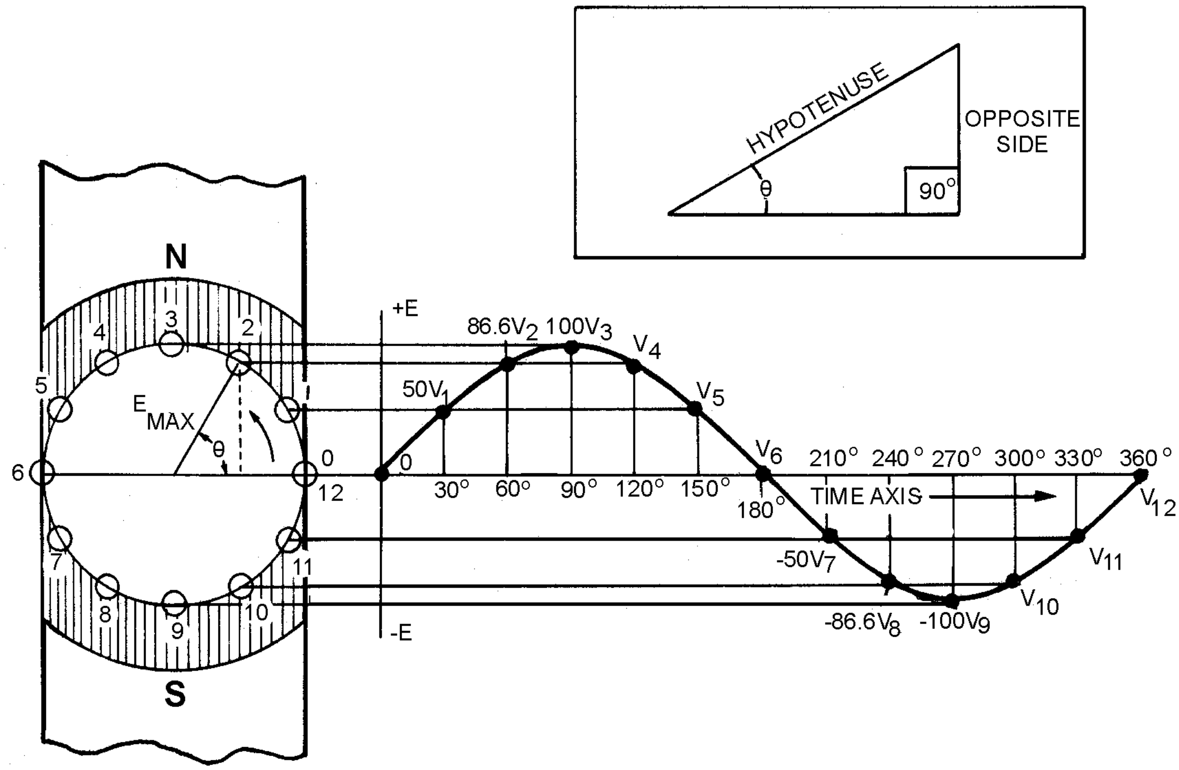

Figure 1-3.—Generation of sine-wave voltage.

At position 2, the sine of 60 degrees is 0.866 and an output of 86.6 volts is developed.

Where:

$E_{max} = 100V$

$\text{sine } \theta = 0.866$

Solution:

$e = (100V)(0.886)$

$e = 86.6V$

This relationship is plotted through 360 degrees of rotation. A continuous line is drawn through the successive points and is known as 1 CYCLE of a sine wave. If the time axis were extended for a second revolution of the vector plotted, you would see 2 cycles of the sine wave. The 0-degree point of the second cycle would be the same point as the 360-degree point of the first cycle.

Q-5. What waveform is the basis of all complex waveforms?

Q-6. What is the purpose of using vectors?

Q-7. What is the trigonometric ratio for the sine of an angle?

Q-8. What is the mathematical formula for computing the output voltage from a moving coil in a magnetic field?

AMPLITUDE

A sine wave is used to represent values of electrical current or voltage. The greater its height, the greater the value it represents. As you have studied, a sine wave alternately rises above and then falls below the reference line. That part above the line represents a positive value and is referred to as a POSITIVE ALTERNATION. That part of the cycle below the line has a negative value and is referred to as a NEGATIVE ALTERNATION. The maximum value, above or below the reference line, is called the PEAK AMPLITUDE. The value at any given point along the reference line is called the INSTANTANEOUS AMPLITUDE.

PHASE

PHASE or PHASE ANGLE indicates how much of a cycle has been completed at any given instant. This merely describes the angle that exists between the starting point of the vector and its position at that instant. The number of degrees of vector rotation and the number of degrees of the resultant sine wave that have been completed will be the same. For example, at time position 2 of figure 1-3, the vector has rotated to 60 degrees and 60 degrees of the resultant sine wave has been completed. Therefore, both are said to have an instantaneous phase angle of 60 degrees.

FREQUENCY

The rate at which the vector rotates determines the FREQUENCY of the sine wave that is generated; that is, the faster the vector rotates, the more cycles completed in a given time period. The basic time period used is 1 second. If a vector completes one revolution per 1 second, the resultant sine wave has a frequency 1 cycle per second (1 hertz). If the rate of rotation is increased to 1,000 revolutions per second, the frequency of the sine wave generated will be 1,000 cycles per second (1 kilohertz).

PERIOD

Another term that is important in the discussion of a sine wave is its duration, or PERIOD. The period of a cycle is the elapsed time from the beginning of a cycle to its completion. If the vector shown in figure 1-3 were to make 1 revolution per second, each cycle of the resultant sine wave would have a period of 1 second. If it were rotating at a speed of 1,000 revolutions per second, each revolution would require 1/1,000 of a second and the period of the resultant sine wave would be 1/1,000 of a second. This illustrates that the period is related to the frequency. As the number of cycles completed in 1 second increases, the period of each cycle will decrease proportionally. This relationship is shown in the following formulas:

Where:

t = period in seconds
f = frequency in hertz

$$f = \frac{1}{t}$$

or

$$t = \frac{1}{f}$$

WAVELENGTH

The WAVELENGTH of a sine wave is determined by its physical length. During the period a wave is being generated, its leading edge is moving away from the source at 300,000,000 meters per second. The physical length of the sine wave is determined by the amount of time it takes to complete one full cycle. This wavelength is an important factor in determining the size of equipments used to generate and transmit radio frequencies.

To help you understand the magnitude of the distance a wavefront (the initial part of a wave) travels during 1 cycle, we will compute the wavelengths (l;) of several frequencies. Consider a vector that rotates at 1 revolution per second. The resultant sine wave is transmitted into space by an antenna. As the vector moves from its 0-degree starting position, the wavefront begins to travel away from the antenna. When the vector reaches the 360-degree position, and the sine wave is completed, the sine wave is stretched out over 300,000,000 meters. The reason the sine wave is stretched over such a great distance is that the wavefront has been moving away from the antenna at 300,000,000 meters per second. This is shown in the following example:

$$\lambda = \text{rate of travel} \times \text{period}$$

$$\lambda = (300{,}000{,}000 \frac{\text{meters}}{\text{second}})(1 \text{ second})$$

$$\lambda = 300{,}000{,}000 \text{ meters}$$

If a vector were rotating at 1,000 revolutions per second, its period would be 0.001 second. By applying the formula for wavelength, you would find that the wavelength is 300,000 meters:

$$\lambda = \left(300{,}000{,}000 \frac{\text{meters}}{\text{second}}\right)(0.001 \quad \text{second})$$

$$\lambda = 300{,}000 \quad \text{meters}$$

Since we normally know the frequency of a sine wave instead of its period, the wavelength is easier to find using the frequency:

$$\lambda = \frac{\text{rate of travel}}{\text{frequency}}$$

Thus, for a sine wave with a frequency of 1,000,000 hertz (1 megahertz), the wavelength would be 300 meters, as shown below:

$$\lambda = \frac{\text{rate of travel}}{\text{frequency}}$$

$$\lambda = \frac{300{,}000{,}000 \ \frac{\text{meters}}{\text{second}}}{1{,}000{,}000 \text{ hertz}}$$

$$\lambda = 300 \text{ meters}$$

The *higher* the frequency, the *shorter* the wavelength of a sine wave. This important relationship between frequency and wavelength is illustrated in table 1-1.

Table 1-1.—Radio frequency versus wavelength

FREQUENCY	WAVELENGTH	
	METRIC	U.S.
300,000 MHz	.001 m	.04 in
EHF-		
30,000 MHz	.01 m	.39 in
SHF-		
3,000 MHz	.1 m	3.94 in
UHF--		
300 MHz	1 m	39.37 in
VHF---		
30 MHz	10 m	10.93 yd
HF----		
3 MHz	100 m	109.4 yd
MF----		
300 kHz	1 km	.62 mi
LF----		
30 kHz	10 km	6.2 mi
VLF-----		
3 kHz	100 km	62 mi

Q-9. What is the instantaneous amplitude of a sine wave?

Q-10. What term describes how much of a cycle has been completed?

Q-11. What determines the frequency of a sine wave?

Q-12. What is the period of a cycle?

Q-13. How do you calculate the wavelength of a sine wave?

HETERODYNING

Information waveforms are produced by many different sources and are generally quite low in frequency. A good example is the human voice. The frequencies involved in normal speech vary from one individual to another and cover a wide range. This range can be anywhere from a low of about 90 hertz for a deep bass to as high as 10 kilohertz for a high soprano.

The most important speech frequencies almost entirely fall below 3 kilohertz. Higher frequencies merely help to achieve more perfect sound production. The range of frequencies used to transmit voice intelligence over radio circuits depends on the degree of FIDELITY (the ability to faithfully reproduce the input in the output) that is desired. The minimum frequency range that can be used for the transmission of speech is 500 to 2,000 hertz. The average range used on radiotelephone circuits is 250 to 2,750 hertz.

Frequencies contained within the human voice can be transmitted over telephone lines without difficulty, but transmitting them via radio circuits is not practical. This is because of their extremely long wavelengths and the fact that antennas would have to be constructed with long physical dimensions to transmit or radiate these wavelengths. Generally, antennas have radiating elements that are 1/4, 1/2, 1, or more full wavelengths of the frequency to be radiated. The wavelengths of voice frequencies employed on radiotelephone circuits range from 1,200,000 meters at 250 hertz to 109,090 meters at 2,750 hertz. Even a quarter-wave antenna would require a large area, be expensive to construct, and consume enormous amounts of power.

As studied in *NEETS*, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas*, radio frequencies do not have the limitations just described for voice frequencies. Radio waves, given a suitable antenna, can often radiate millions of miles into space. Several methods of modulation can be used to impress voices frequencies onto radio waves for transmission through space.

In the modulation process, waves from the information source are impressed onto a radio-frequency sine wave called a CARRIER. This carrier is sufficiently high in frequency to have a wavelength short enough to be radiated from an antenna of practical dimensions. For example, a carrier frequency of 10 megahertz has a wavelength of 30 meters, as shown below:

$$\lambda = \frac{\text{rate of travel}}{\text{frequency}}$$

$$\lambda = \frac{300{,}000{,}000 \dfrac{\text{meters}}{\text{second}}}{10{,}000{,}000 \text{ hertz}}$$

$$\lambda = 30 \text{ meters } (98.4 \text{ feet})$$

Construction of an antenna related to that wavelength does not cause any problems.

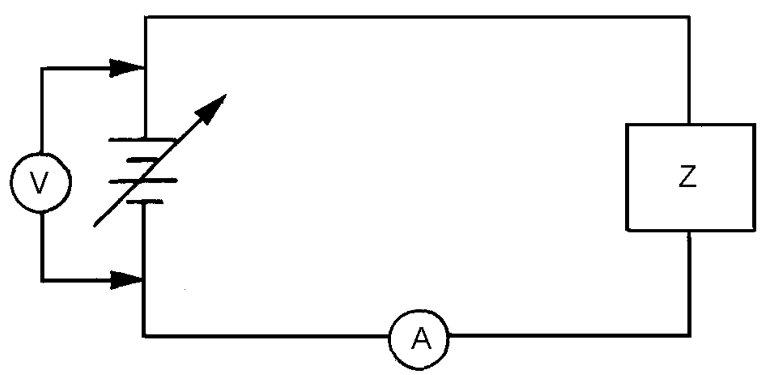
An information wave is normally referred to as a MODULATING WAVE. When a modulating wave is impressed on a carrier, the voltages of the modulating wave and the carrier are combined in such a manner as to produce a COMPLEX WAVE (a wave composed of two or more parts). This complex wave is referred to as the MODULATED WAVE and is the waveform that is transmitted through space. When the modulated wave is received and demodulated, the original component waves (carrier and modulating waves) are reproduced with their respective frequencies, phases, and amplitudes unchanged.

Modulation of a carrier can be achieved by any of several methods. Generally, the methods are named for the sine-wave characteristic that is altered by the modulation process. In this module, you will study AMPLITUDE MODULATION, which includes CONTINUOUS-WAVE MODULATION. You will also learn about two forms of ANGLE MODULATION (FREQUENCY MODULATION and PHASE MODULATION). A special type of modulation, known as PULSE MODULATION, will also be discussed. Before we present the methods involved in developing modulation, you need to study a process that is essential to the modulation of a carrier, known as heterodyning.

To help you understand the operation of heterodyning circuits, we will begin with a discussion of LINEAR and NONLINEAR devices. In linear devices, the output rises and falls directly with the input. In nonlinear devices, the output does *not* rise and fall directly with the input.

LINEAR IMPEDANCE

Whether the impedance of a device is linear or nonlinear can be determined by comparing the change in *current through* the device to the change in *voltage applied* to the device. The simple circuit shown in view (A) of figure 1-4 is used to explain this process.



(A)

Figure 1-4A.—Circuit with one linear impedance.

First, the current through the device must be measured as the voltage is varied. Then the current and voltage values can be plotted on a graph, such as the one shown in view (B), to determine the impedance of the device. For example, assume the voltage is varied from 0 to 200 volts in 50-volt steps, as shown in view (B). At the first 50-volt point, the ammeter reads 0.5 ampere. These ordinates are plotted as point **a** in view (B). With 100 volts applied, the ammeter reads 1 ampere; this value is plotted as point **b**. As these steps are continued, the values are plotted as points **c** and **d**. These points are connected with a straight line to show the linear relationship between current and voltage. For every change in voltage applied to the device, a proportional change occurs in the current through the device. When the change in current is proportional to the change in applied voltage, the impedance of the device is linear and a straight line is developed in the graph.

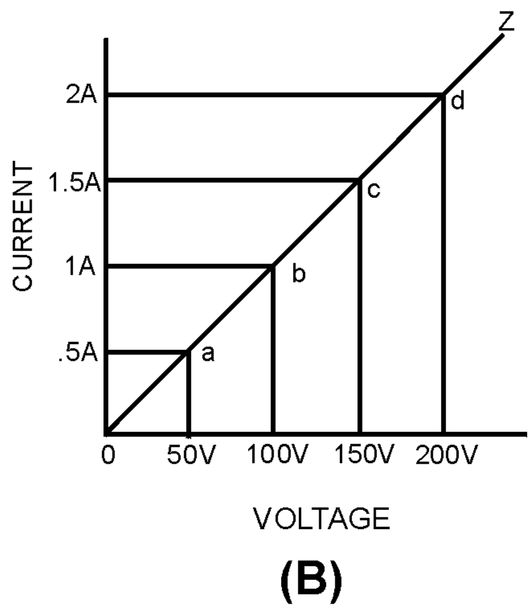


Figure 1-4B.—Circuit with one linear impedance.

The principle of linear impedance can be extended by connecting two impedance devices in series, as shown in figure 1-5, view (A). The characteristics of both individual impedances are determined as explained in the preceding section. For example, assume voltmeter V1 shows 50 volts and the ammeter shows 0.5 ampere. Point **a** in view (B) represents this ordinate. In the same manner, increasing the voltage in increments of 50 volts gives points **b**, **c**, and **d**. Lines Z1 and Z2 show the characteristics of the two impedances. The total voltage of the series combination can be determined by adding the voltages across Z1 and Z2. For example, at 0.5 ampere, point **a** (50 volts) plus point **e** (75 volts) produces point **i** (125 volts). Also, at 1 ampere, point **b** plus point **f** produces point **j**. Line Z1 + Z2 represents the combined voltage-current characteristics of the two devices.

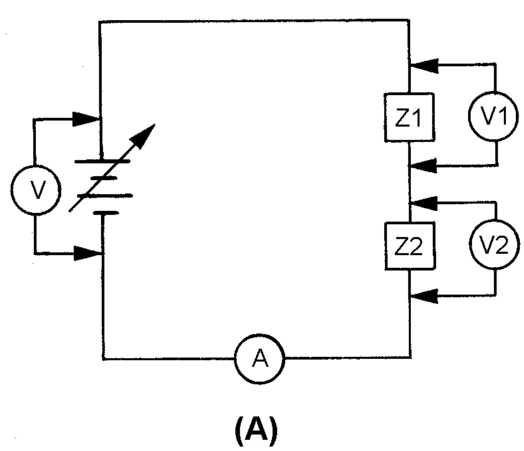

Figure 1-5A.—Circuit with two linear impedances.

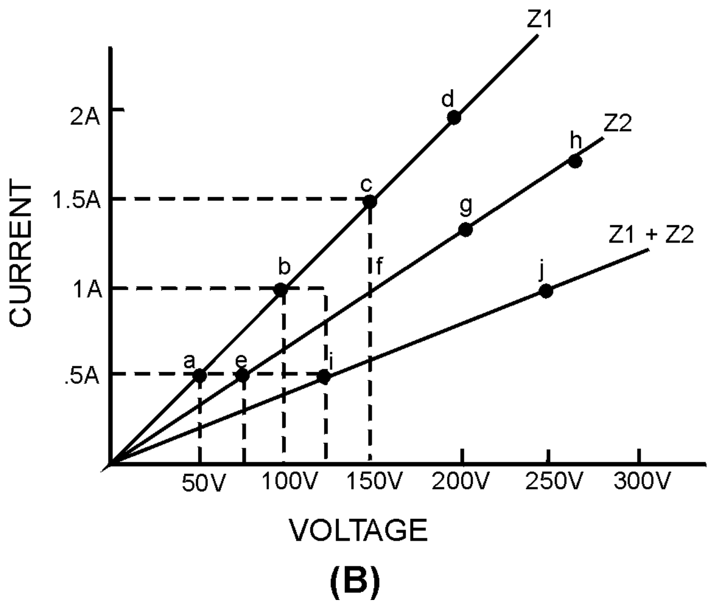

Figure 1-5B.—Circuit with two linear impedances.

View (A) of figure 1-6 shows two impedances in parallel. View (B) plots the impedances both individually (Z1 and Z2) and combined (Z1 x Z2)/(Z1 + Z2). Note that Z1 and Z2 are not equal. At 100 volts, Z1 has 1 ampere of current plotted at point **b** and Z2 has 0.5 ampere plotted at point **f**. The coordinates of the equivalent impedance of the parallel combination are found by adding the current through Z1 to the current through Z2. For example, at 100 volts, point **b** is added to point **f** to determine point **j** (1.5 amperes).

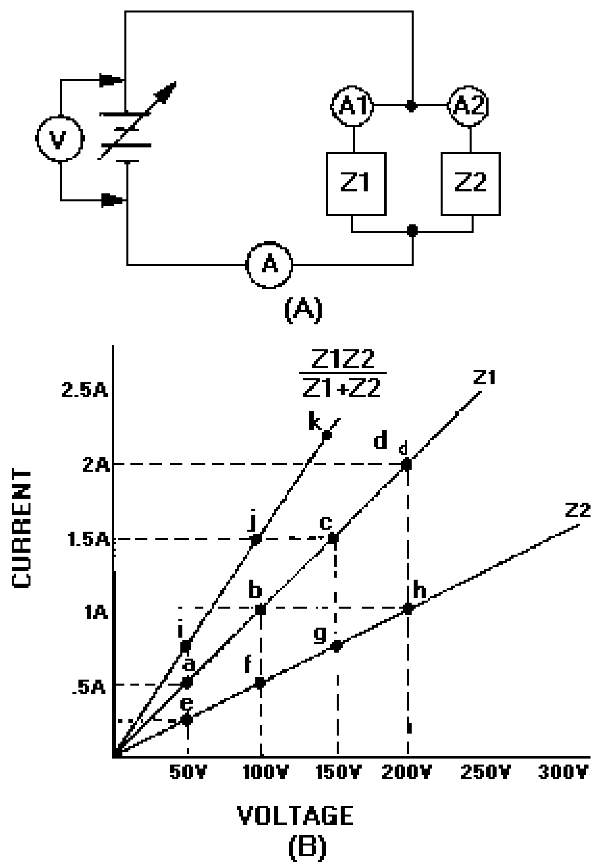

Figure 1-6.—Circuit with parallel linear impedances.

Positive or negative voltage values can be used to plot the voltage-current graph. Figure 1-7 shows an example of this situation. First, the voltage versus current is plotted with the battery polarity as shown in view (A). Then the battery polarity is reversed and the remaining voltage versus current points are plotted. As a result, the line shown in view (C) is obtained.

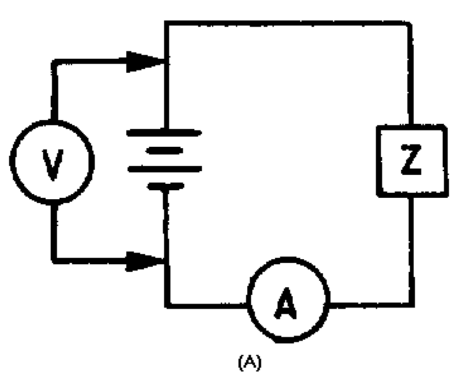

Figure 1-7A.—Linear impedance circuit.

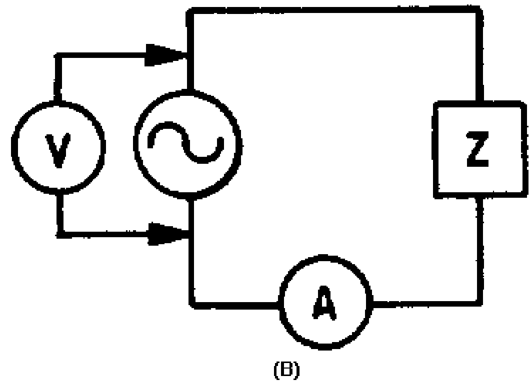

Figure 1-7B.—Linear impedance circuit.

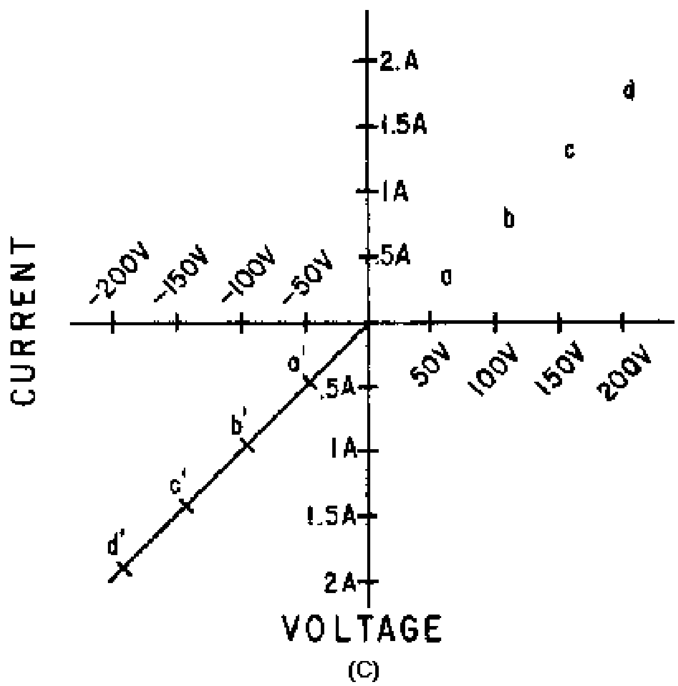

Figure 1-7C.—Linear impedance circuit

The battery in view (A) could be replaced with an ac generator, as shown in view (B), to plot the characteristic chart. The same linear voltage-current chart would result. Current flow in either direction is directly proportional to the change in voltage.

In conclusion, when dc or sine-wave voltages are applied to a linear impedance, the current through the impedance will vary directly with a change in the voltage. The device could be a resistor, an air-core inductor, a capacitor, or any other linear device. In other words, if a sine-wave generator output is applied to a combination of linear impedances, the resultant current will be a sine wave which is directly proportional to the change in voltage of the generator. The linear impedances do not alter the waveform of the sine wave. The amplitude of the voltage developed across each linear component may vary, or the phase of the wave may shift, but the shape of the wave will remain the same.

NONLINEAR IMPEDANCE

You have studied that a linear impedance is one in which the resulting current is directly proportional to a change in the applied voltage. A nonlinear impedance is one in which the resulting current is not directly proportional to the change in the applied voltage. View (A) of figure 1-8 illustrates a circuit which contains a nonlinear impedance (Z), and view (B) shows its voltage-current curve.

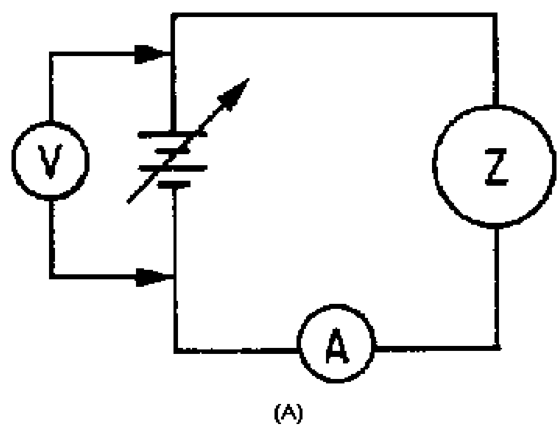

Figure 1-8A.—Nonlinear impedance circuit.

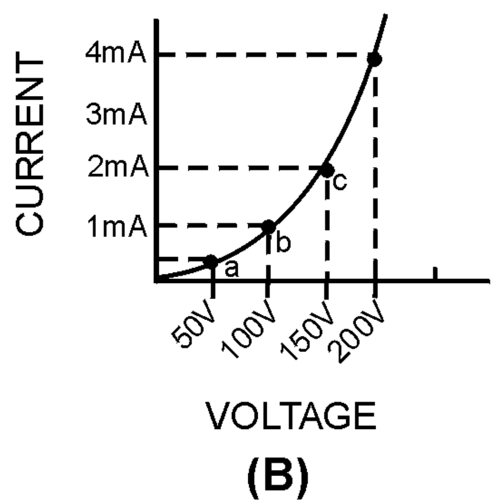

Figure 1-8B.—Nonlinear impedance circuit.

As the applied voltage is varied, ammeter readings which correspond with the various voltages can be recorded. For example, assume that 50 volts yields 0.4 milliampere (point **a**), 100 volts produces 1 milliampere (point **b**), and 150 volts causes 2.2 milliamperes (point **c**). Current through the nonlinear impedance does not vary proportionally with the voltage; the chart is not a straight line. Therefore, Z is a nonlinear impedance; that is, the current through the impedance does not faithfully follow the change in voltage. Various combinations of voltage and current for this particular nonlinear impedance may be obtained by use of this voltage-current curve.

COMBINED LINEAR AND NONLINEAR IMPEDANCES

The series combination of a linear and a nonlinear impedance is illustrated in view (A) of figure 1-9. The voltage-current charts of Z1 and Z2 are shown in view (B). A chart of the combined impedance can be plotted by adding the amount of voltage required to produce a particular current through linear impedance Z1 to the amount of voltage required to produce the same amount of current through nonlinear impedance Z2. The total will be the amount of voltage required to produce that particular current through the series combination. For example, point **a** (25 volts) is added to point **c** (50 volts) which yields point **e** (75 volts); and point **b** (50 volts) is added to point **d** (100 volts) which yields point **f** (150 volts). Intermediate points may be determined in the same manner and the resultant characteristic curve (Z1 + Z2) is obtained for the series combination.

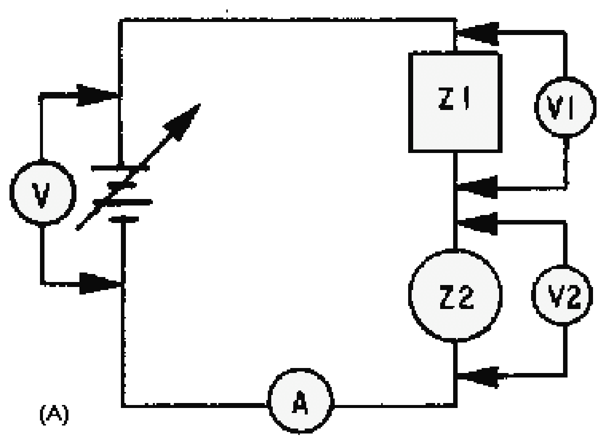

Figure 1-9A.—Combined linear and nonlinear impedances.

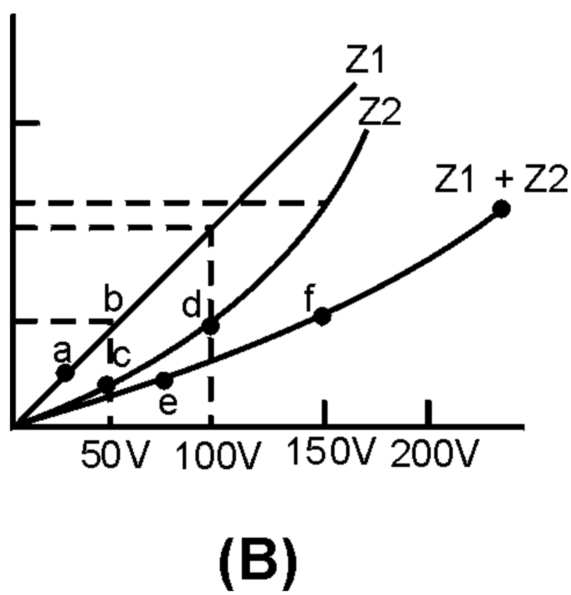

Figure 1-9B.—Combined linear and nonlinear impedances.

You should see from this graphic analysis that when a linear impedance is combined with a nonlinear impedance, the resulting characteristic curve is nonlinear. Some examples of nonlinear impedances are crystal diodes, transistors, iron-core transformers, and electron tubes.

AC APPLIED TO LINEAR AND NONLINEAR IMPEDANCES

Figure 1-10 illustrates an ac sine-wave generator applied to a circuit containing several linear impedances. A sine-wave voltage applied to linear impedances will cause a sine wave of current through them. The wave shape across each linear impedance will be identical to the applied waveform.

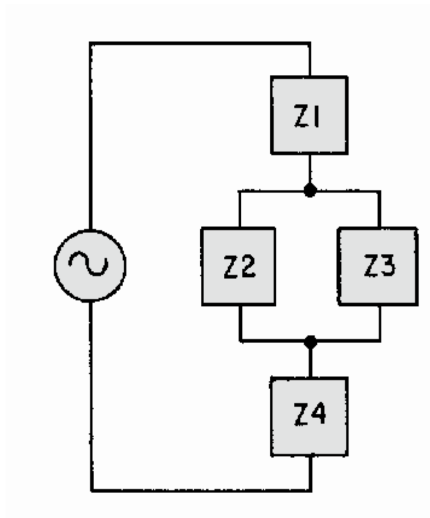

Figure 1-10.—Sine wave generator applied to several impedances.

The amplitude, on the other hand, may differ from the amplitude of the applied voltage. Furthermore, the phase of the voltage developed by any of the impedances may not be identical to the phase of the voltage across any of the other impedances or the phase of the applied voltage. If an impedance is a reactive component (coil or capacitor), voltage or current may lead or lag, but the wave shape will remain the same. In a linear circuit, the output of the generator is not distorted. The frequency remains the same throughout the entire circuit and no new frequencies are generated.

View (A) of figure 1-11 illustrates a circuit that contains a combination of linear and nonlinear impedances with a sine wave of voltage applied. Impedances Z2, Z3, and Z4 are linear; and Z1 is nonlinear. The result of a linear and nonlinear combination of impedances is a nonlinear waveform. The curve Z, shown in view (B), is the nonlinear curve for the circuit of view (A). Because of the nonlinear impedance, current can flow in the circuit only during the positive alternation of the sine-wave generator. If an oscilloscope is connected, as shown in view (A), the waveform across Z3 will not be a sine wave. Figure 1-12, view (A), illustrates the sine wave from the generator and view (B) shows the waveform across the linear impedance Z3. Notice that the nonlinear impedance Z1 has eliminated the negative half cycles.

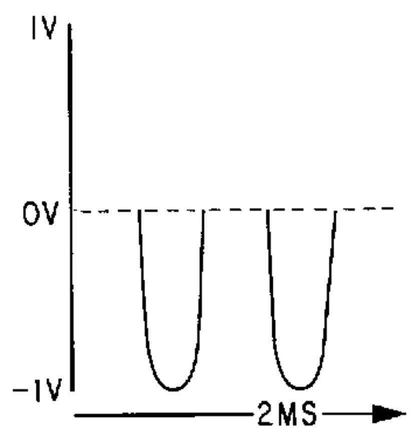
Figure 1-11B.—Circuit with nonlinear impedances.



(A)

Figure 1-12A.—Waveform in a circuit with nonlinear impedances.

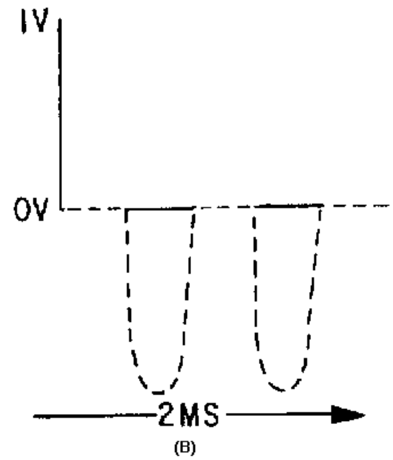


Figure 1-12B.—Waveform in a circuit with nonlinear impedances.

The waveform in view (B) is no longer identical to that of view (A) and the nonlinear impedance network has generated HARMONIC FREQUENCIES. The waveform now consists of the fundamental frequency and its harmonics. (Harmonics were discussed in *NEETS*, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*.)

TWO SINE WAVE GENERATORS IN LINEAR CIRCUITS

A circuit composed of two sine-wave generators, G1 and G2, and two linear impedances, Z1 and Z2, is shown in figure 1-13. The voltage applied to Z1 and Z2 will be the vector sum of the generator voltages. The sum of the individual instantaneous voltages across each impedance will equal the applied voltages.

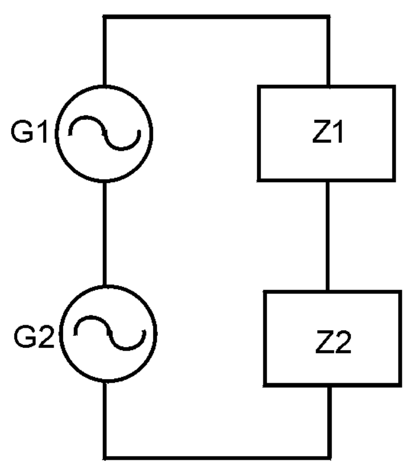

Figure 1-13.—Two sine-wave generators with linear impedances.

If the two generator outputs are of the same frequency, then the waveform across Z1 and Z2 will be a sine wave, as shown in figure 1-14, views (A) and (B). No new frequencies will be created. Relative amplitude and phase will be determined by the relative values and types of the impedances.

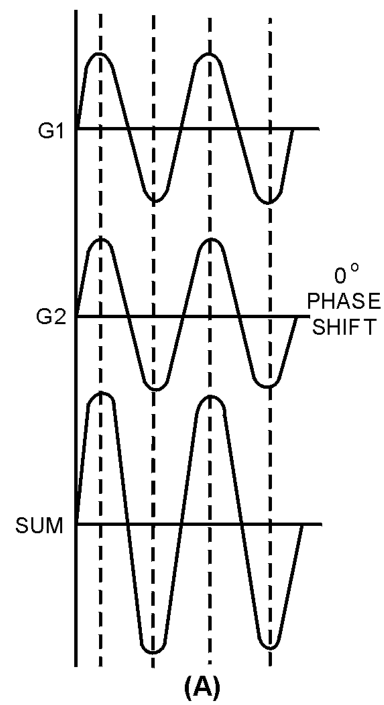

Figure 1-14A.—Waveforms across two nonlinear impedances.

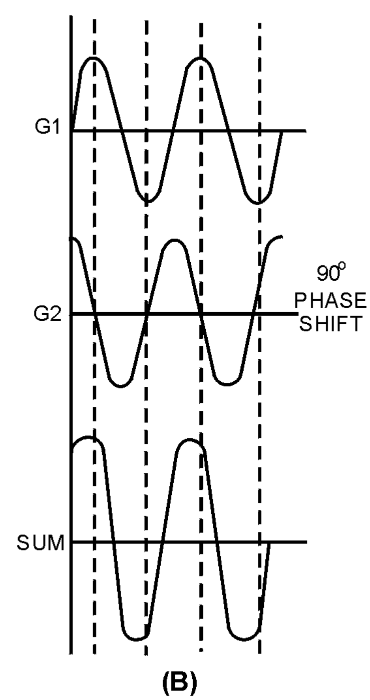

Figure 1-14B.—Waveforms across two nonlinear impedances.

If the two sine wave generators are of different frequencies, then the sum of the instantaneous values will appear as a complex wave across the impedances, as shown in figure 1-15, views (A) and (B). To determine the wave shape across each individual impedance, assume only one generator is connected at a time and compute the sine-wave voltage developed across each impedance for that generator input. Then, combine the instantaneous voltages (caused by each generator input) to obtain the complex waveform across each impedance. The nature of the impedance (resistive or reactive) will determine the shape of the complex waveform. Because the complex waveform is the sum of two individual sine waves, the composite waveform contains only the two original frequencies.

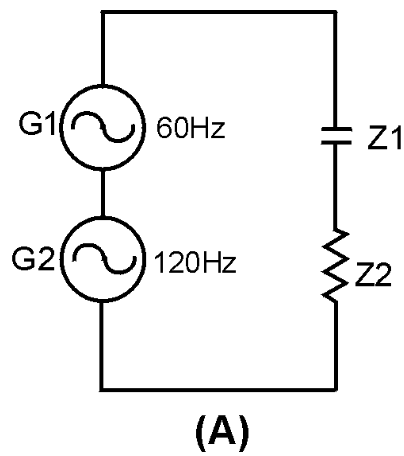

Figure 1-15A.—Sine-wave generators with different frequencies and linear impedances.

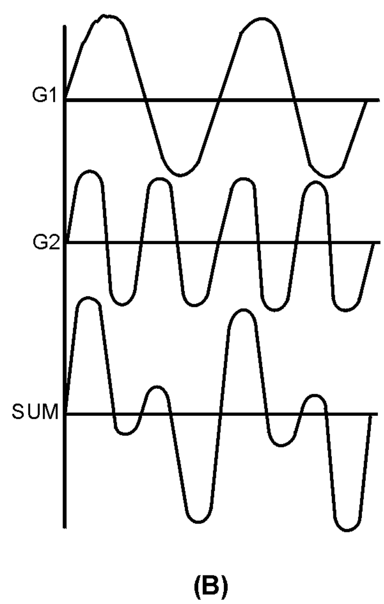

Figure 1-15B.—Sine-wave generators with different frequencies and linear impedances.

Linear impedances may alter complex waveforms, but they do not produce new frequencies. The output of one generator does not influence the output of the other generator.

TWO SINE WAVE GENERATORS AND A COMBINATION OF LINEAR AND NONLINEAR IMPEDANCES

Figure 1-16 illustrates a circuit that contains two sine-wave generators (G1 and G2), linear impedance Z1, and nonlinear impedance Z2, in series. When a single sine-wave voltage is applied to a combined linear and nonlinear impedance circuit, the voltages developed across the impedances are complex waveforms.

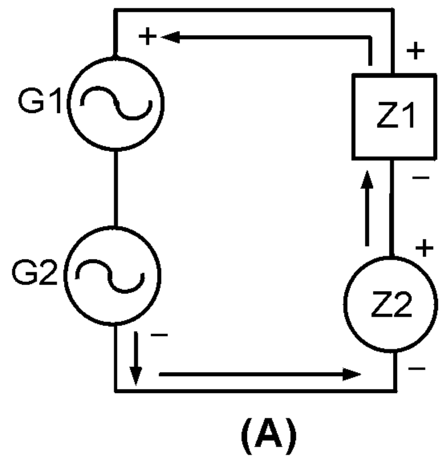

Figure 1-16.—Sine-wave generators with a combination of impedances.

When two sine wave voltages are applied to a circuit, as in figure 1-16, nonlinear impedance Z2 reshapes the two sine-wave inputs and their harmonics, resulting in a very complex waveform.

Assume that nonlinear impedance Z2 will allow current to flow only when the sum of the two sine-wave generators (G1 and G2) has the polarity indicated. The waveforms present across the linear impedance will appear as a varying waveform. This will be a complex waveform consisting of:

- a dc level
- the two fundamental sine wave frequencies
- the harmonics of the two fundamental frequencies
- the sum of the fundamental frequencies
- the difference between frequencies

The sum and difference frequencies occur because the phase angles of the two fundamentals are constantly changing. If generator G1 produces a 10-hertz voltage and generator G2 produces an 11-hertz voltage, the waveforms produced because of the nonlinear impedance will be as shown in the following list:

- a 10-hertz voltage
- an 11-hertz voltage
- harmonics of 10 hertz and 11 hertz (the higher the harmonic, the lower its strength)
- the sum of 10 hertz and 11 hertz (21 hertz)
- the difference between 10 hertz and 11 hertz (1 hertz)

Figure 1-17 illustrates the relationship between the two frequencies (10 and 11 hertz). Since the waveforms are not of the same frequency, the 10 hertz of view (B) and the 11 hertz of view (A) will be in phase at some points and out of phase at other points. You can see this by closely observing the two waveforms at different instants of time. The result of the differences in phase of the two sine waves is shown in view (C). View (D) shows the waveform that results from the nonlinearity in the circuit.

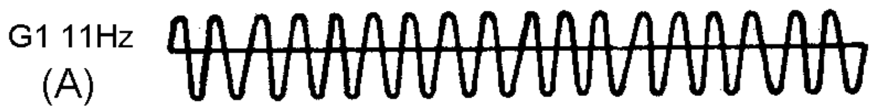

Figure 1-17A.—Frequency relationships.

Figure 1-17B.—Frequency relationships.

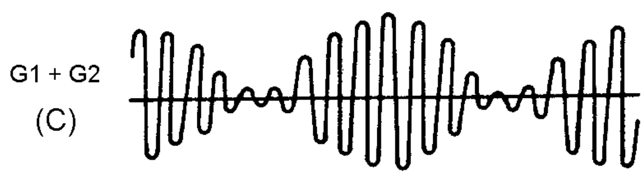

Figure 1-17C.—Frequency relationships.

Figure 1-17D.—Frequency relationships.

The most important point to remember is that when varying voltages are applied to a circuit which contains a nonlinear impedance, the resultant waveform contains frequencies which are not present at the input source.

The process of combining two or more frequencies in a nonlinear impedance results in the production of new frequencies. This process is referred to as heterodyning.

SPECTRUM ANALYSIS

The heterodyning process can be analyzed by using SPECTRUM ANALYSIS (the display of electromagnetic energy arranged according to wavelength or frequency). As shown in figure 1-18, spectrum analysis is an effective way of viewing the energy in electronic circuits. It clearly shows the relationships between the two fundamental frequencies (10 and 11 hertz) and their sum (21 hertz) and difference (1 hertz) frequencies. It also allows you to view the BANDWIDTH (the amount of the frequency spectrum that signals occupy) of the signal you are studying.

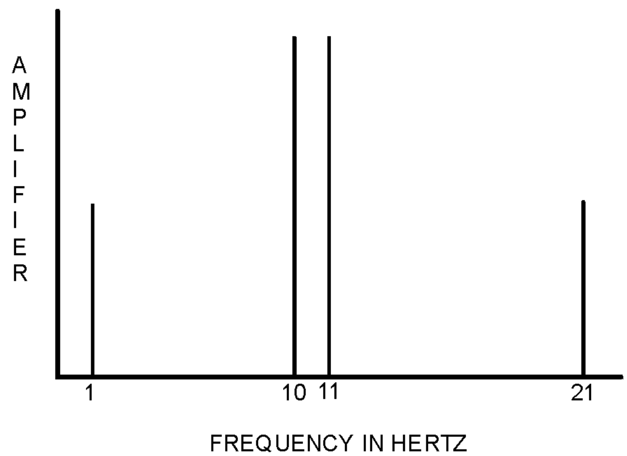

Figure 1-18.—Spectrum analysis of heterodyned signal.

TYPICAL HETERODYNING CIRCUIT

Two conditions must be met in a circuit for heterodyning to occur. First, at least two different frequencies must be applied to the circuit. Second, these signals must be applied to a nonlinear impedance. These two conditions will result in new frequencies (sum and difference) being produced. Any one of the frequencies can be selected by placing a frequency-selective device (such as a tuned tank circuit) in series with the nonlinear impedance in the circuit.

Figure 1-19 illustrates a basic heterodyning circuit. The diode D1 serves as the nonlinear impedance in the circuit. Generators G1 and G2 are signal sources of different frequencies. The primary of T1, with its associated capacitance, serves as the frequency-selective device.

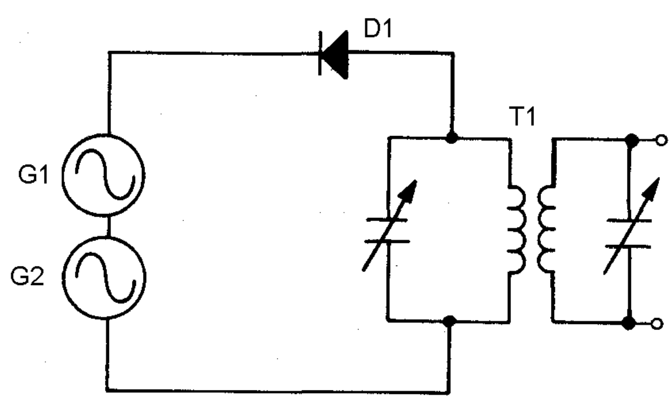

Figure 1-19.—Typical heterodyning circuit.

The principles of this circuit are similar to those of the block diagram circuit of figure 1-16. Notice in figure 1-19 that the two generators are connected in series. Therefore, the resultant waveform of their combined frequencies will determine when the cathode of D1 will be negative with respect to the anode, thereby controlling the conduction of the diode. The new frequencies that are generated by applying these signals to nonlinear impedance D1 are the sum and difference of the two original frequencies. The frequency-selective device T1 may be tuned to whichever frequency is desired for use in later circuit stages. Heterodyning action takes place, intentionally or not, whenever these conditions exist. Heterodyning (MIXING) circuits are found in most electronic transmitters and receivers. These transmitter and receiver circuits will be explained in detail later in this module.

Q-14. Define the heterodyne principle.

Q-15. What is a nonlinear impedance?

Q-16. What is spectrum analysis?

Q-17. What two conditions are necessary for heterodyning to take place?

AMPLITUDE-MODULATED SYSTEMS

Amplitude modulation refers to any method of varying the amplitude of an electromagnetic carrier frequency in accordance with the intelligence to be transmitted by the carrier. The CARRIER frequency is a radio-frequency wave suitable for modulation by the intelligence to be transmitted. One form of this method of modulation is simply to interrupt the carrier in accordance with a prearranged code.

CONTINUOUS WAVE (CW)

The "on-off" KEYING of a continuous wave (cw) carrier frequency was the principal method of modulating a carrier in the early days of electrical communications. The intervals of time when a carrier either was present or absent conveyed the desired intelligence. This is still used in modern communications. When applied to a continuously oscillating radio-frequency source, on-off keying is referred to as cw signaling. This type of communication is sometimes referred to as an interrupted continuous wave (icw).

Development

The use of a cw transmitter can be very simple. All that is required for the transmitter to work properly is a device to generate the oscillations, a method of keying the oscillations on and off, and an antenna to radiate the energy. Continuous wave was the first type of modulation used. It is still extensively used for long-range communications. When Marconi and others were attempting the transfer of intelligence between two points, without reliance on a conducting path, they employed the use of a practical coding system known as Morse code. You probably know that Morse code is a system of on-off keying developed for telegraph that is capable of passing intelligence over wire at an acceptable rate. Morse code consists only of periods of signal and no-signal.

Figure 1-20 is the International Morse code used with telegraphy and cw modulation. Each character in the code is made up of a series of elements referred to as DOTS or DASHES. These are short (dot) and long (dash) bursts of signal separated by intervals of no signal. The dot is the basic time element of the code. The dash has three times the duration of a dot interval. The waveforms for both are shown in figure 1-21. The elements within each character are separated by intervals of no signal with a time duration of one dot. The characters are separated by a no-signal interval equal in duration to one dash. Each interval during which signal is present is called the MARKING interval, and the period of no signal is called the SPACING interval. Figure 1-22 shows the relationships between the rf carrier view (A), the on-off keying waveform view (B), and the resultant carrier wave view (C).

Figure 1-22C.—Essential elements of ON-OFF keying.

Keying Methods

Keying a transmitter causes an rf signal to be radiated only when the key contacts are closed. When the key contacts are open, the transmitter does not radiate energy. Keying is accomplished in either the oscillator or amplifier stage of a transmitter. A number of different keying systems are used in Navy transmitters.

In most Navy transmitters, the hand telegraph key is at a low-voltage potential with respect to ground. A keying bar is usually grounded to protect the operator. Generally, a keying relay, with its contacts in the center-tap lead of the filament transformer, is used to key the equipment. Because one or more stages use the same filament transformer, these stages are also keyed. A class C final amplifier, when operated with fixed bias, is usually not keyed. This is because no output occurs when no excitation is applied in class C operation. Keying the final amplifier along with the other stages is not necessary in this case.

OSCILLATOR KEYING.—Two methods of OSCILLATOR KEYING are shown in figure 1-23. In view (A) the grid circuit is closed at all times. The key (K) opens and closes the negative side of the plate circuit. This system is called PLATE KEYING. When the key is open, no plate current can flow and the circuit does not oscillate. In view (B), the cathode circuit is open when the key is open and neither grid current nor plate current can flow. Both circuits are closed when the key is closed. This system is called CATHODE KEYING. Although the circuits of figure 1-23 may be used to key amplifiers, other keying methods are generally employed because of the high values of plate current and voltage encountered.

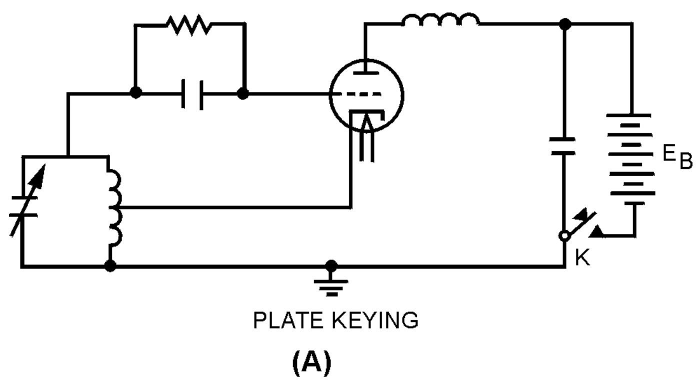

Figure 1-23A.—Oscillator keying.

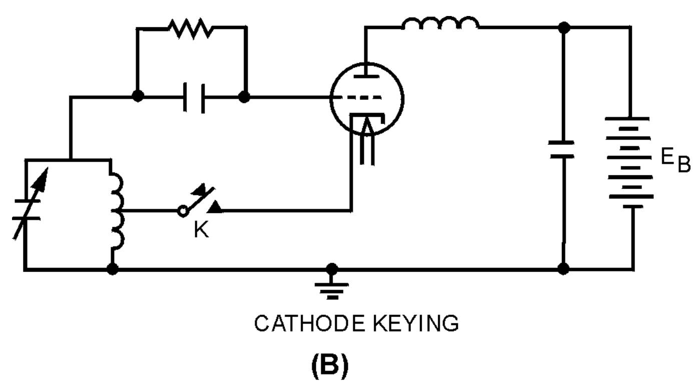

Figure 1-23B.—Oscillator keying.

BLOCKED-GRID KEYING.—Two methods of BLOCKED-GRID KEYING are shown in figure 1-24. The key in view (A) shorts cathode resistor R1 allowing normal plate current to flow. With the key open, reduced plate current flows up through resistor R1 making the end connected to grid resistor R_g negative. If R1 has a high enough value, the bias developed is sufficient to cause cutoff of plate current. Depressing the key short-circuits R1. This increases the bias above cutoff and allows the normal flow of plate current. Grid resistor R_g is the usual grid-leak resistor for normal biasing.

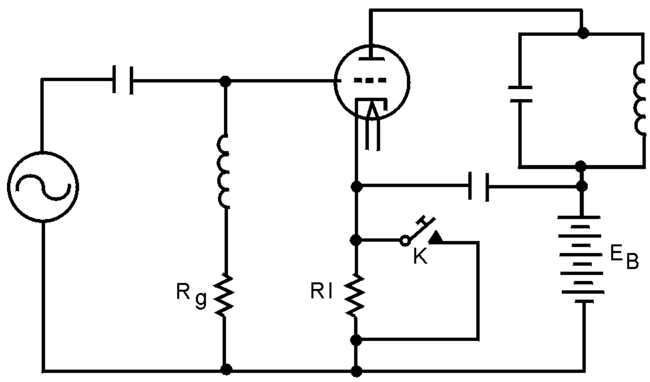

Figure 1-24A.—Blocked-grid keying.

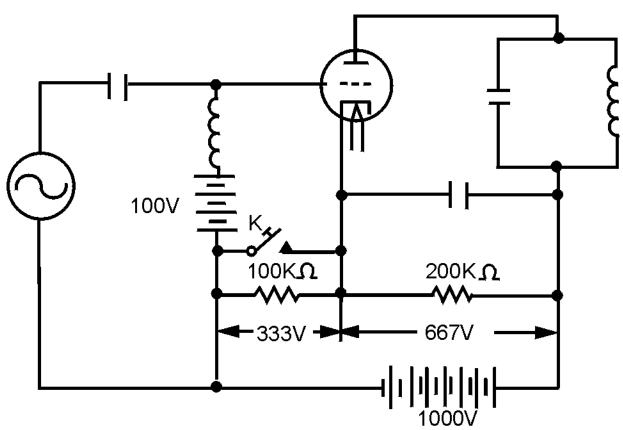

Figure 1-24B.—Blocked-grid keying.

The blocked-grid keying method in view (B) affords a complete cutoff of plate current. It is one of the best methods for keying amplifier stages in transmitters. In the voltage divider with the key open, two-thirds of 1,000 volts, or 667 volts, is developed across the 200-kilohm resistor; one-third of 1,000 volts, or 333 volts, is developed across the 100-kilohm resistor. The grid bias is the sum of 100 volts and 333 volts, or 433 volts. This sum is below cutoff and no plate current flows. The plate voltage is 667 volts. With the key closed, the 200-kilohm resistor drops 1,000 volts. The plate voltage becomes 1,000 volts at the same time the grid bias becomes 100 volts. Grid bias is reduced enough so that the triode amplifier will conduct only on the peaks of the drive signal.

When greater frequency stability is required, the oscillator should not be keyed, but should remain in continuous operation; other transmitter circuits may be keyed. This procedure keeps the oscillator tube at a normal operating temperature and offers less chance for frequency variations to occur each time the key is closed.

KEYING RELAYS.—In transmitters using a crystal-controlled oscillator, the keying is almost always in a circuit stage following the oscillator. In large transmitters (75 watts or higher), the ordinary hand key cannot accommodate the plate current without excessive arcing.

WARNING

BECAUSE OF THE HIGH PLATE POTENTIALS USED, OPERATING A HAND KEY IN THE PLATE CIRCUIT IS DANGEROUS. A SLIGHT SLIP OF THE HAND BELOW THE KEY KNOB COULD RESULT IN SEVERE SHOCK OR, IN THE CASE OF DEFECTIVE RF PLATE CHOKES, A SEVERE RF BURN.

In larger transmitters, some local low-voltage supply, such as a battery, is used with the hand key to open and close a circuit through the coils of a KEYING RELAY. The relay contacts open and close the keying circuit of the amplifier. A schematic diagram of a typical relay-operated keying system is shown in figure 1-25. The hand key closes the circuit from the low-voltage supply through the coil (L) of the keying relay. The relay armature closes the relay contacts as a result of the magnetic pull exerted on the armature. The armature moves against the tension of a spring. When the hand key is opened, the relay coil is deenergized and the spring opens the relay contacts.

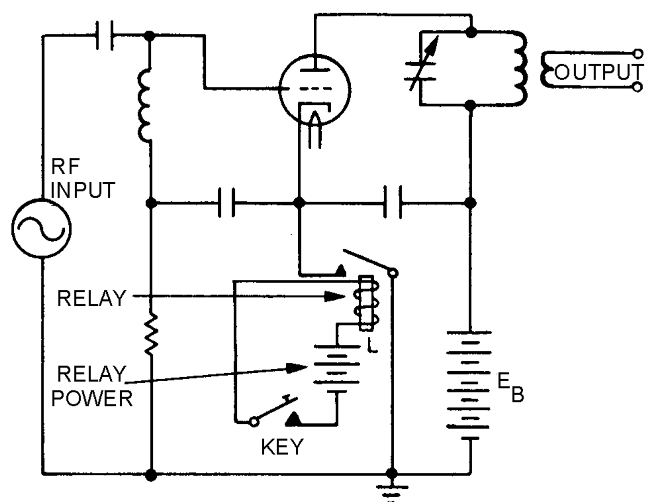

Figure 1-25.—Relay-operated keying system.

KEY CLICKS.—Ideally, cw keying a transmitter should instantly start and stop radiation of the carrier completely. However, the sudden application and removal of power causes rapid surges of current which may cause interference in nearby receivers. Even though such receivers are tuned to frequencies far removed from that of the transmitter, interference may be present in the form of "clicks" or "thumps." KEY-CLICK FILTERS are used in the keying systems of radio transmitters to prevent such interference. Two types of key-click filters are shown in figure 1-26.

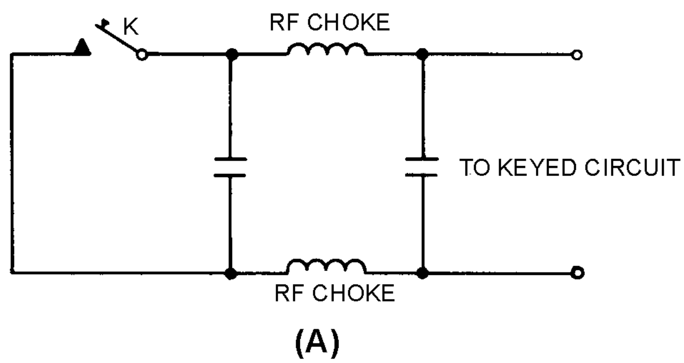

Figure 1-26A.—Key-click filters.

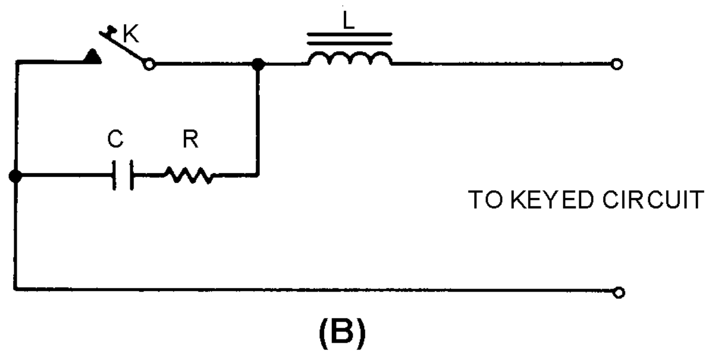

Figure 1-26B.—Key-click filters.

The capacitors and rf chokes in figure 1-26, views (A) and (B), prevent surges of current. In view (B), the choke coil causes a lag in the current when the key is closed, and the current builds up gradually instead of instantly. The capacitor charges as the key is opened and slowly releases the energy stored in the magnetic field of the inductor. The resistor controls the rate of charge of the capacitor and also prevents sparking at the key contacts by the sudden discharge of the capacitor when the key is closed.

MACHINE KEYING.—The speed with which information can be transmitted using a hand key depends on the keying ability of the operator. Early communicators turned to mechanized methods of keying the transmitters to speed transmissions. More information could be passed in a given time by replacing the hand-operated key with a keying device capable of reading information from punched tape. Using this method, several operators could prepare tapes at their normal operating speed. The tapes could then be read through the keying device at a higher rate of speed and more information could be transmitted in a given amount of time.

Spectrum Analysis

Continuous-wave transmission has the disadvantage of being a relatively slow transmission method. Still, it has several advantages. Some of the advantages of cw transmission are a high degree of clarity under severe noise conditions, long-range operation, and narrow bandwidth. A highly skilled operator can pick out and read a cw signal even though it has a high degree of background noise or interference. Since only a single-carrier frequency is being transmitted, all of the transmitter power can be concentrated in the intelligence. This concentration of power gives the transmission a greater range. The use of spectrum analysis (figure 1-27) illustrates the transmitted frequency characteristics of a cw signal. Because the cw signal is a pure sine wave, it occupies only a single frequency in the rf spectrum and the system is relatively simple.

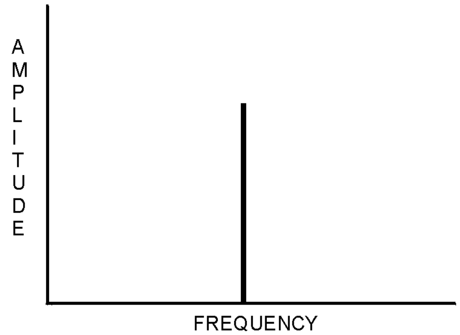

Figure 1-27.—Carrier-wave signal spectrum analysis.

Q-18. What is amplitude modulation?

Q-19. What are the three requirements for cw transmission?

Q-20. Name two methods of oscillator keying.

Q-21. State the method used to increase the speed of keying in a cw transmitter.

Q-22. Name three advantages of cw transmission.

Single-Stage Transmitters

A simple, single-tube cw transmitter can be made by coupling the output of an oscillator directly to an antenna (figure 1-28). The primary purpose of the oscillator is to develop an rf voltage which has a constant frequency and is immune to outside factors which may cause its frequency to shift. The output of this simple transmitter is controlled by placing a telegraph key at point **K** in series with the voltage supply. Since the plate supply is interrupted when the key is open, the circuit oscillates only as long as the key is closed. Although the transmitter shown uses a Colpitts oscillator, any of the oscillators previously described in *NEETS*, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits* can be used.

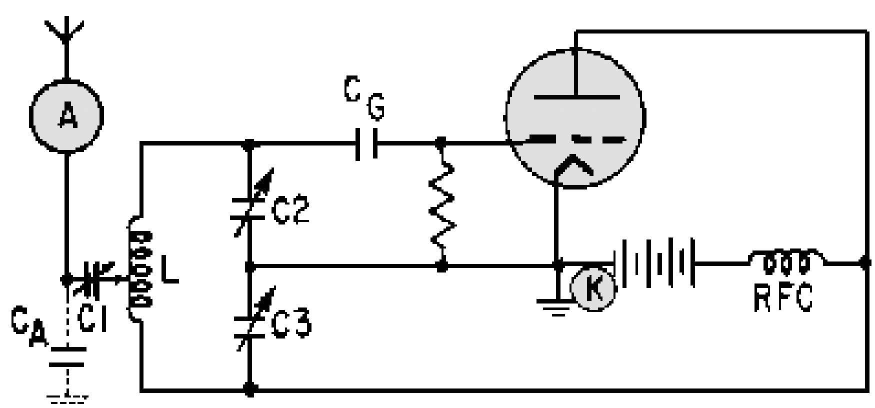

Figure 1-28.—Simple electron-tube transmitter.

Capacitors C2 and C3 can be GANGED (mechanically linked together) to simplify tuning. Capacitor C1 is used to tune (resonate) the antenna to the transmitter frequency. C_A is the effective capacitance existing between the antenna and ground. This antenna-to-ground capacitance is in parallel with the tuning capacitors, C2 and C3. Since the antenna has capacitance, any change in its length or position, such as that caused by swaying of the antenna, changes the value of C_A and causes the oscillator to change frequency. Because these frequency changes are undesirable for reliable communications, the multistage transmitter was developed to increase reliability.

Multistage Transmitters

The simple, single-tube transmitter, shown in figure 1-28, is rarely used in practical equipment. Most of the transmitters you will see use a number of tubes or stages. The number used depends on the frequency, power, and application of the equipment. For your study, the following three categories of cw transmitters are discussed: (1) master oscillator power amplifier (mopa) transmitters, (2) multistage, high-power transmitters, (3) high- and very-high frequency transmitters.

The mopa is both an oscillator and a power amplifier. Power-amplifying stages and frequency-multiplying stages must be used to increase power and raise the frequency from those achievable in a mopa. The main difference between many low- and high-power transmitters is in the number of power-amplifying stages that are used. Similarly, the main difference between many high- and very-high frequency transmitters is in the number of frequency-multiplying stages used.

MASTER OSCILLATOR POWER AMPLIFIER.—For a transmitter to be stable, its oscillator must not be LOADED DOWN. This means that its antenna (which can present a varying impedance) must not be connected directly to the oscillator circuit. The rf oscillations must be sent through another circuit before they are fed to the antenna for good frequency stability to be obtained. That additional circuit is an rf power amplifier. Its purpose is to raise the amplitude of rf oscillations to the required output power level and isolate the oscillator from the antenna. Any transmitter consisting of an oscillator and a single-amplifier stage is called a master oscillator power amplifier transmitter (mopa), as shown in figure 1-29.

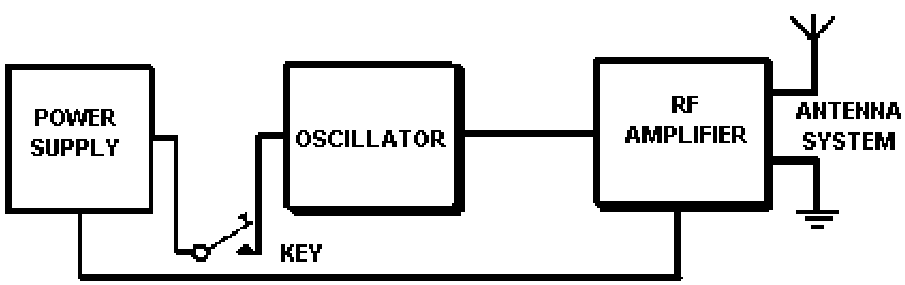

Figure 1-29.—Block diagram of a master oscillator power amplifier transmitter (mopa).

Most mopa transmitters have only one tube amplifier in the power-amplifier stage. However, the oscillator may not produce sufficient power to drive a power-amplifier tube to the power output level required for the antenna. In such cases, the power-amplifier stages are designed to use two or more amplifiers which can be driven by the oscillator. Two or more amplifiers can be connected in parallel (with similar elements of each tube connected) or in a push-pull arrangement. In a push-pull amplifier, the grids are fed equal rf voltages that are 180 degrees out of phase.

The main advantage of a mopa transmitter is that the power-amplifier stage isolates the oscillator from the antenna. This prevents changes in antenna-to-ground capacitance from affecting the oscillator frequency. A second advantage is that the rf power amplifier is operated so that a small change in the voltage applied to its grid circuit will produce a large change in the power developed in its plate circuit.

Rf power amplifiers require that a specific amount of power be fed into the grid circuit. Only in this way can the tube deliver an amplified power output. However, the stable oscillator can produce only limited amounts of power. Therefore, the mopa transmitter is limited in the amount of power it can develop. This is one of the disadvantages of the mopa transmitter. Another disadvantage is that it often is impractical for use at very- and ultra-high frequencies. The reason is that the stability of self-excited oscillators decreases rapidly as the operating frequency increases. Circuit tuning capacitances are small at high frequencies and stray capacitances adversely affect frequency stability.

MULTISTAGE HIGH-POWER TRANSMITTERS.—The power amplifier of a high-power transmitter may require far more driving power than can be supplied by an oscillator. Therefore, one or more low-power intermediate amplifiers may be inserted between the oscillator and the final power amplifier to boost power to the antenna. In some types of equipment, a VOLTAGE AMPLIFIER, called a BUFFER is used between the oscillator and the first intermediate amplifier. The ideal buffer is operated class A and is biased negatively to prevent grid current flow during the excitation cycle. Therefore, it does not require driving power from, nor does it load down, the oscillator. The purpose of the buffer is to isolate the oscillator from the following stages and to minimize changes in oscillator frequency that occur with changes in loading. A buffer is required when keying takes place in an intermediate or final amplifier operating at comparatively high power. Look at the block diagrams of several medium-frequency transmitters in figure 1-30. The input and output powers are given for each stage. You should be able to see that the power output rating of a transmitter can be increased by adding amplifier tubes capable of delivering the power required.

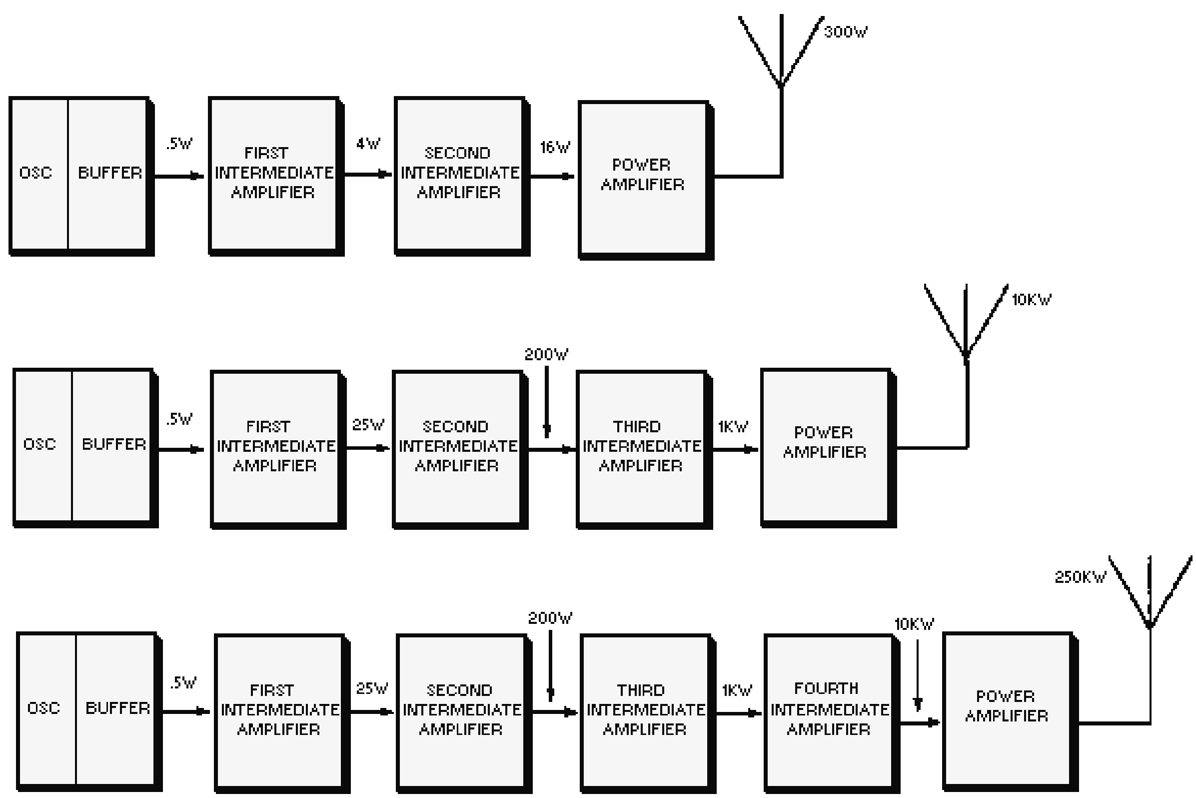

Figure 1-30.—Block diagram of several medium-frequency transmitters.

HF AND VHF TRANSMITTERS.—Oscillators are too unstable for direct frequency control in very- and ultra-high frequency transmitters. Therefore, these transmitters have oscillators operating at comparatively low frequencies, sometimes as low as 1/100 of the output frequency. The oscillator frequency is raised to the required output frequency by passing it through one or more FREQUENCY MULTIPLIERS. Frequency multipliers are special rf power amplifiers which multiply the input frequency. In practice, the MULTIPLICATION FACTOR (number of times the input frequency is multiplied) is seldom larger than five in any one stage. The block diagram of a typical VHF transmitter, designed for continuous tuning between 256 and 288 megahertz, is shown in figure 1-31.

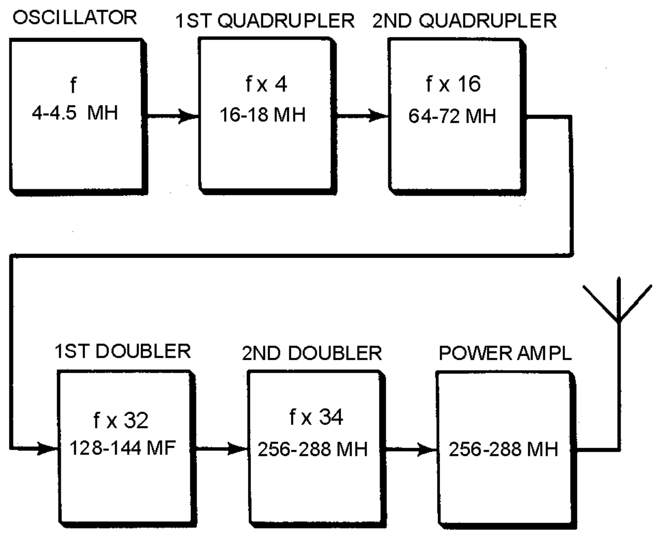

Figure 1-31.—Block diagram of a vhf transmitter.

The stages which multiply the frequency by two are DOUBLERS; those which multiply by four are QUADRUPLERS. The oscillator is tunable from 4 to 4.5 megahertz. The multiplier stages increase the frequency by multiplying successively by 4, 4, 2, and 2, for a total factor of 64. In high-power, high-frequency transmitters, one or more intermediate amplifiers may be used between the last frequency multiplier and the power amplifier.

Q-23. Name a disadvantage of a single-stage cw transmitter.

Q-24. What is the purpose of the power-amplifier stage in a master oscillator power amplifier cw transmitter?

Q-25. What is the purpose of frequency-multiplier stages in a VHF transmitter?

AMPLITUDE MODULATION

The telegraph and radiotelegraph improved man's ability to communicate by allowing speedy passage of information between two distant points. However, it failed to satisfy one of man's other communications needs; that is, the ability to hear and be heard, by voice, at a great distance. In an effort to improve on the telegraph, Alexander Graham Bell developed the principles on which modern communications are built. He developed the modulation of an electric current by complex waveforms, the demodulation of the resulting wave, and recovery of the original waveform. This section will examine the process of varying an electric current in amplitude at an audio frequency.

Microphones

If an rf carrier is to convey intelligence, some feature of the carrier must be varied in accordance with the information to be transmitted. In the case of speech intelligence, sound waves must be converted to electrical energy.

A MICROPHONE is an energy converter that changes sound energy into electrical energy. A diaphragm in the microphone moves in and out in accordance with the compression and rarefaction of the atmosphere caused by sound waves. The diaphragm is connected to a device that causes current flow in proportion to the instantaneous pressure delivered to it. Many devices can perform this function. The particular device used in a given application depends on the characteristics desired, such as sensitivity, frequency response, impedance matching, power requirements, and ruggedness.

The SENSITIVITY or EFFICIENCY of a microphone is usually expressed in terms of the electrical power level which the microphone delivers to a matched-impedance load compared to the sound level being converted. The sensitivity is rated in dB and must be as high as possible. A high microphone output requires less gain in the amplifiers used with the microphone. This keeps the effects of thermal noise, amplifier hum, and noise pickup at a minimum.

For good quality sound reproduction, the electrical signal from the microphone must correspond in frequency content to the original sound waves. The microphone response should be uniform, or flat, within its frequency range and free from the electrical or mechanical generation of new frequencies.

The impedance of a microphone is important in that it must be matched to the microphone cable and to the amplifier input as well as to the amplifier input load. Exact impedance matching is not always possible, especially in the case where the impedance of the microphone increases with an increase in frequency. A long microphone cable tends to seriously attenuate the high frequencies if the microphone impedance is high. This attenuation is caused by the increased capacitive action of the line at higher frequencies. If the microphone has a low impedance, a lower voltage is developed in the microphone, and more voltage is available at the load. Because many microphone lines used aboard ship are long, low-impedance microphones must be used to preserve a sufficiently high voltage level- over the required frequency range.

The symbol used to represent a microphone in a schematic diagram is shown in figure 1-32. The schematic symbol identifies neither the type of microphone used nor its characteristics.

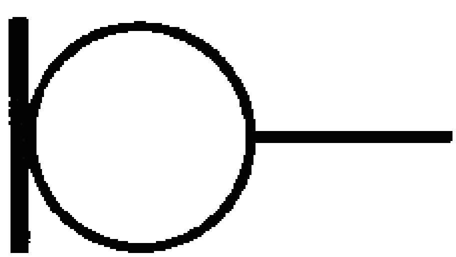

Figure 1-32.—Microphone schematic symbol.

CARBON MICROPHONE.—Operation of the SINGLE-BUTTON CARBON MICROPHONE figure 1-33, view (A) is based on varying the resistance of a pile of carbon granules located within the microphone. An insulated cup, referred to as the button, holds the loosely piled granules. It is so mounted that it is in constant contact with the thin metal diaphragm. Sound waves striking the diaphragm vary the pressure on the button which varies the pressure on the pile of carbon granules. The dc resistance of the carbon granule pile is varied by this pressure. This varying resistance is in series with a battery and the primary of a transformer. The changing resistance of the carbon pile produces a corresponding change in the current of the circuit. The varying current in the transformer primary produces an alternating voltage in the secondary. The transformer steps up the voltage and matches the low impedance of the microphone to the high impedance of the first amplifier. The voltage across the secondary may be as high as 25 volts peak. The impedance of this type of microphone varies from 50 to 200 ohms. This effect is caused by the pressure of compression and rarefaction of sound waves, discussed in chapter 1 of *NEETS*, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas.*

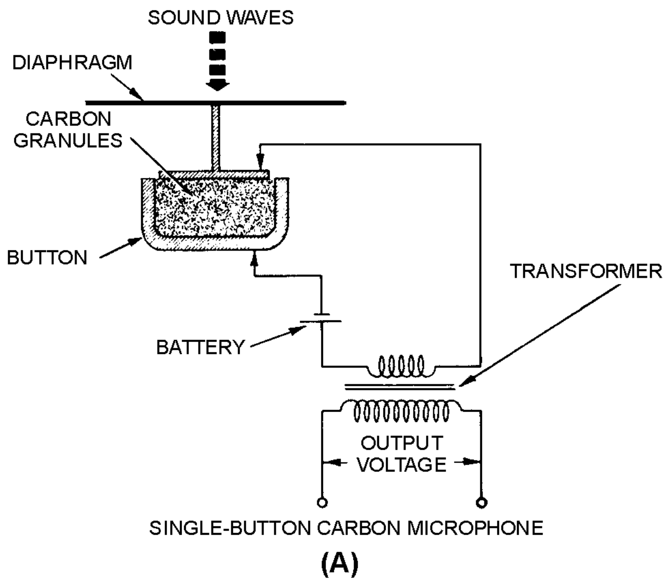

Figure 1-33A.—Carbon microphones. SINGLE-BUTTON CARBON MICROPHONE.

The DOUBLE-BUTTON CARBON MICROPHONE is shown in figure 1-33, view (B). Here, one button is positioned on each side of the diaphragm so that an increase in resistance on one side is accompanied by a simultaneous decrease in resistance on the other. Each button is in series with the battery and one-half of the transformer primary. The decreasing current in one-half of the primary and the increasing current in the other half produces an output voltage in the secondary winding. The output voltage is proportional to the sum of the primary winding signal components. This action is similar to that of push-pull amplifiers.

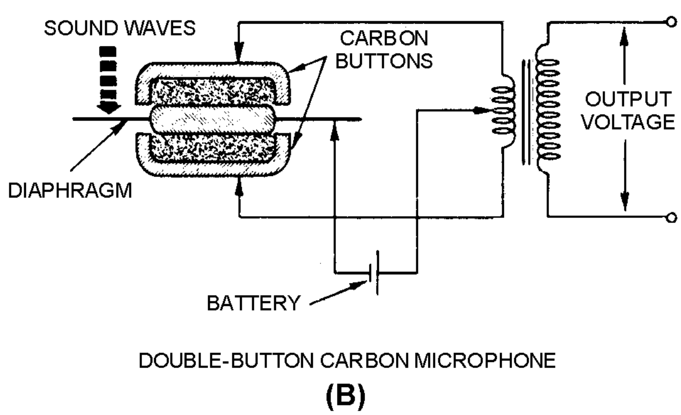

Figure 1-33B.—Carbon microphones. DOUBLE-BUTTON CARBON MICROPHONE.

One disadvantage of carbon microphones is that of a constant BACKGROUND HISS (hissing noise) which results from random changes in the resistance between individual carbon granules. Other disadvantages are reduced sensitivity and distortion that may result from the granules packing or sticking together. The carbon microphone also has a limited frequency response. Still another disadvantage is a requirement for an external voltage source.

The disadvantages, however, are offset by advantages that make its use in military applications widespread. It is lightweight, rugged, and can produce an extremely high output.

CRYSTAL MICROPHONE.—The CRYSTAL MICROPHONE uses the PIEZOELECTRIC EFFECT of Rochelle salt, quartz, or other crystalline materials. This means that when mechanical stress is placed upon the material, a voltage electromagnetic force (EMF) is generated. Since Rochelle salt has the largest voltage output for a given mechanical stress, it is the most commonly used crystal in microphones. View (A) of figure 1-34 is a crystal microphone in which the crystal is mounted so that the sound waves strike it directly. View (B) has a diaphragm that is mechanically linked to the crystal so that the sound waves are indirectly coupled to the crystal.

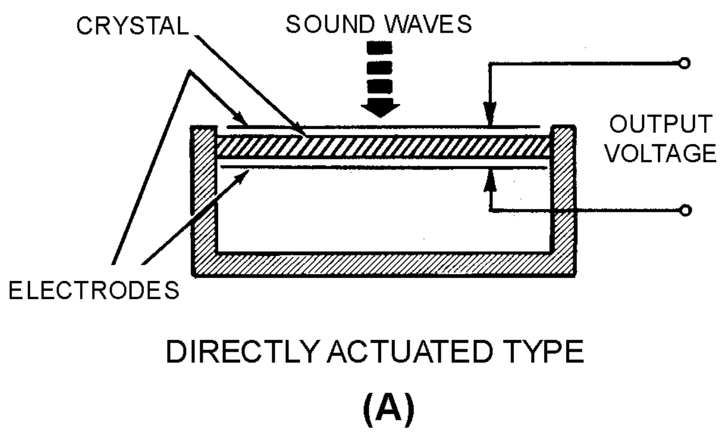

Figure 1-34A.—Crystal microphones.

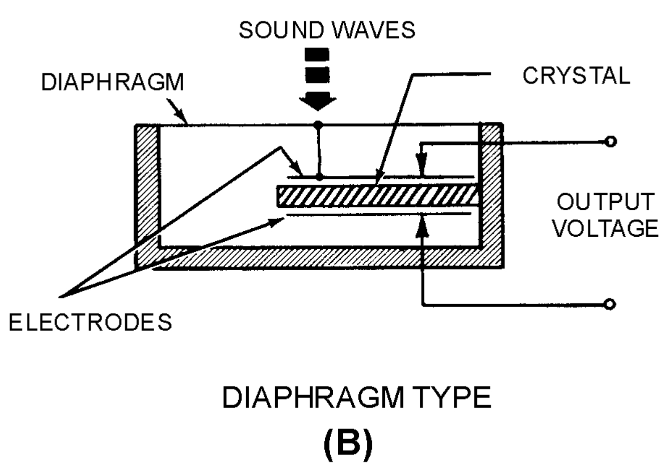

Figure 1-34B.—Crystal microphones.

A crystal microphone has a high impedance and does not require an external voltage source. It can be connected directly into the input circuit of a high-gain amplifier. However, because its output is low, several stages of high-gain amplification are required. Crystal microphones are delicate and must be handled with care. Exposure to temperatures above 52 degrees Celsius (125 degrees Fahrenheit) may permanently damage the crystal unit. Crystals are also soluble in water and other liquids and must be protected from moisture and excessive humidity.

DYNAMIC MICROPHONE.—A cross section of the DYNAMIC or MOVING-COIL MICROPHONE is shown in figure 1-35. A coil of fine wire is mounted on the back of the diaphragm and located in the magnetic field of a permanent magnet. When sound waves strike the diaphragm, the coil moves back and forth cutting the magnetic lines of force. This induces a voltage into the coil that is an electrical reproduction of the sound waves.

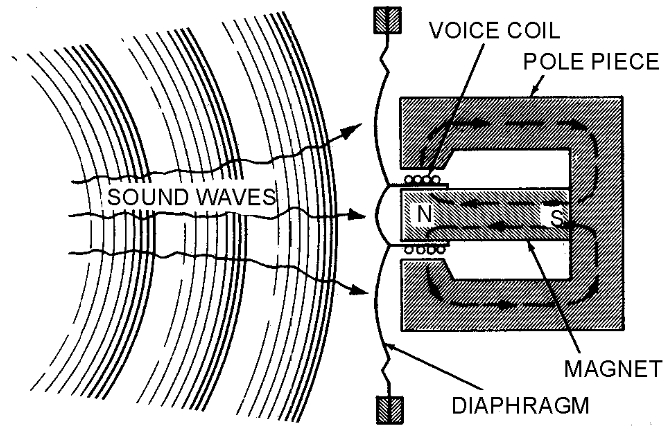

Figure 1-35.—Dynamic microphone.

The sensitivity of the dynamic microphone is almost as high as that of the carbon type. It is lightweight and requires no external voltage. The dynamic microphone is rugged and can withstand the effects of vibration, temperature, and moisture. This microphone has a uniform response over a frequency range that extends from 40 to 15,000 hertz. The impedance is very low (generally 50 ohms or less). A transformer is required to match its impedance to that of the input of an af amplifier.

MAGNETIC MICROPHONE.—The MAGNETIC or MOVING-ARMATURE MICROPHONE (figure 1-36) consists of a coil wound on an armature that is mechanically connected to the diaphragm with a driver rod. The coil is located between the pole pieces of the permanent magnet. Any vibration of the diaphragm vibrates the armature at the same rate. This varies the magnetic flux in the armature and through the coil.

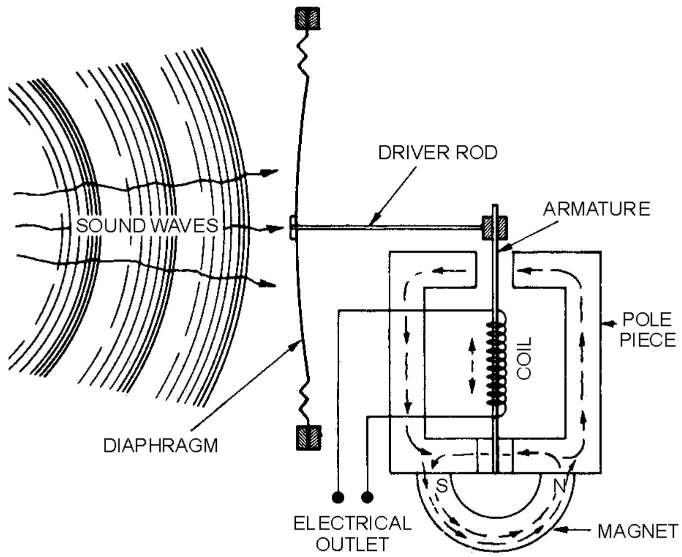

Figure 1-36.—Magnetic microphone action.

When the armature is in its resting position (midway between the two poles), the magnetic flux is established across the air gap. However, no resultant flux is established in the armature. When a compression wave strikes the diaphragm, the armature is deflected to the right. Most of the flux continues to move in the direction of the arrows. However, some flux now flows from the north pole of the magnet across the reduced gap at the upper right, down through the armature, and around to the south pole of the magnet.

When a rarefaction wave occurs at the diaphragm, the armature is deflected to the left. Some flux is now directed from the north pole of the magnet, up through the armature, through the reduced gap at the upper left, and back to the south pole.

The vibrations of the diaphragm cause an alternating flux in the armature which induces an alternating voltage in the coil. This voltage has the same waveform as that of the sound waves striking the diaphragm.

The magnetic microphone is very similar to the dynamic microphone in terms of impedance, sensitivity, and frequency response. However, it is more resistant to vibration, shock, and rough handling than other types of microphones.

Changing sound waves into electrical impulses is the first step in voice communications. It is common to all the transmission media you will study in the remainder of this chapter. We will discuss the various types of modulation that arc used to transfer this information to a transmission medium in the following sections.

Q-26. What is a microphone?

Q-27. What special electromechanical effect is the basis for carbon microphone operation?

Q-28. What is a major disadvantage of a carbon microphone?

Q-29. What property of a crystalline material is used in a crystal microphone?

Q-30. What is the difference between a dynamic microphone and a magnetic microphone?

AM TRANSMITTER PRINCIPLES

In this section we will describe the methods used to apply voice signals (intelligence) to a carrier wave by the process of amplitude modulation (AM).

An AM transmitter can be divided into two major sections according to the frequencies at which they operate, radio-frequency (rf) and audio-frequency (af) units. The rf unit is the section of the transmitter used to generate the rf carrier wave. As illustrated in figure 1-37, the carrier originates in the master oscillator stage where it is generated as a constant-amplitude, constant-frequency sine wave. The carrier is not of sufficient amplitude and must be amplified in one or more stages before it attains the high power required by the antenna. With the exception of the last stage, the amplifiers between the oscillator and the antenna are called INTERMEDIATE POWER AMPLIFIERS (ipa). The final stage, which connects to the antenna, is called the FINAL POWER AMPLIFIER (fpa).

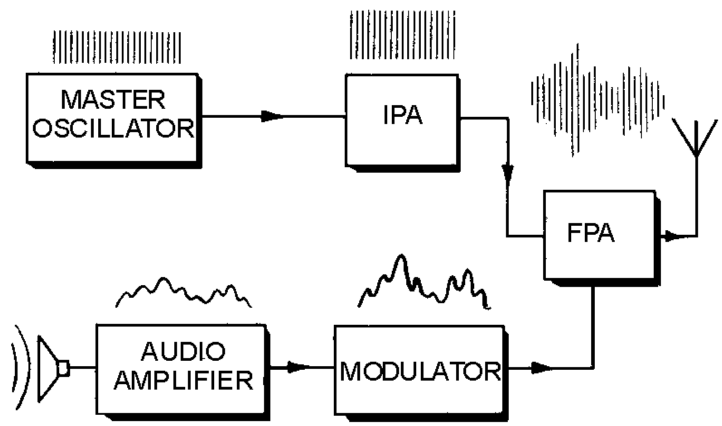

Figure 1-37.—Block diagram of an AM transmitter.

The second section of the transmitter contains the audio circuitry. This section of the transmitter takes the small signal from the microphone and increases its amplitude to the amount necessary to fully modulate the carrier. The last audio stage is the MODULATOR. It applies its signal to the carrier in the final power amplifier. In this way, intelligence is included in the radiated rf waveform.

The Modulated Wave

The frequencies present in a signal can be conveniently represented by a graph of the frequency spectrum, shown in figure 1-38. In this graph, each individual frequency is portrayed as a vertical line. The position of the line along the horizontal axis indicates the frequency of the signal. The height of the frequency line is proportional to the amplitude of the signal. The rf spectrum in figure 1-38 shows the frequencies present when heterodyning occurs between frequencies of 5 and 100 kilohertz.

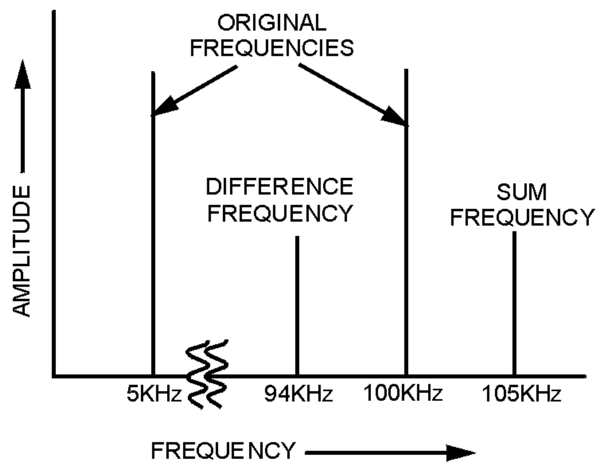

Figure 1-38.—Radio-frequency spectrum.

Radiating energy at audio frequencies (discussed earlier in this chapter) is not practical. The heterodyning principle, however, makes possible the conversion of an af signal (intelligence) to an rf signal (with af intelligence) which can be radiated or transmitted through space.

Look again at figure 1-38. The sum and difference frequencies are located very near the rf signal (100 kilohertz), while the audio signal (5 kilohertz) is spaced a considerable distance away. Because of this frequency separation, the audio frequency can be easily removed by filter circuits, leaving just three radio frequencies of 95, 100, and 105 kilohertz. These three radio frequencies are radiated through space to the receiving station. At the receiver, the process is reversed. The frequency of 95 kilohertz, for example, is heterodyned with the frequency of 100 kilohertz and the sum and difference frequencies are again produced. (A similar process occurs between the frequencies of 100 and 105 kilohertz.) Of the resultant frequencies (95, 100, 105, and 5 kilohertz), all are filtered out except the 5 kilohertz difference frequency. This frequency, which is identical to the original 5 kilohertz audio applied at the transmitter, is retained and amplified. Thus, the 5 kilohertz audio tone *appears* to have been radiated through space from the transmitter to the receiver.

In the process just described, the 100 kilohertz frequency is referred to as the CARRIER FREQUENCY, and the sum and difference frequencies are referred to as SIDE FREQUENCIES. Since the sum frequency appears above the carrier frequency, it is referred to as the UPPER SIDE FREQUENCY. The difference frequency appears below the carrier and is referred to as the LOWER SIDE FREQUENCY.

When a carrier is modulated by voice or music signals, a large number of sum and difference frequencies are produced. All of the sum frequencies above the carrier are spoken of collectively as the UPPER SIDEBAND. All the difference frequencies below the carrier, also considered as a group, are called the LOWER SIDEBAND.

If the carrier and the modulating signal are constant in amplitude, the sum and difference frequencies will also be constant in amplitude. However, when the carrier and sidebands are combined in a single impedance and viewed simultaneously with an oscilloscope, the resultant waveform appears as shown in figure 1-39. This resultant wave is called the MODULATION ENVELOPE. The modulation envelope has the same frequency as the carrier. However, it rises and falls in amplitude with the continual phase shift between the carrier and sidebands. This causes these signals to first aid and then oppose one another. These cyclic variations in the amplitude of the envelope have the same frequency as the audio-modulating voltage. The audio intelligence is actually contained in the spacing or difference between the carrier and sideband frequencies.

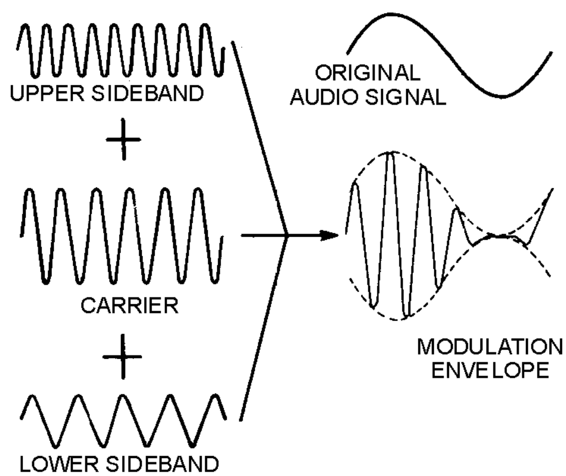

Figure 1-39.—Formation of the modulation envelope.

BANDWIDTH OF AN AM WAVE.—An ideal carrier wave contains a single frequency and occupies very little of the frequency spectrum. When the carrier is amplitude modulated, sideband frequencies are created both above and below the carrier frequency. This causes the signal to use up a greater portion of the frequency spectrum. The amount of space in the frequency spectrum required by the signal is called the BANDWIDTH of the signal.

The bandwidth of a modulated wave is a function of the frequencies contained in the modulating signal. For example, when a 100-kilohertz carrier is modulated by a 5-kilohertz audio tone, sideband frequencies are created at 95 and 105 kilohertz. This signal requires 10 kilohertz of space in the spectrum.

If the same 100-kilohertz carrier is modulated by a 10-kilohertz audio tone, sideband frequencies will appear at 90 and 110 kilohertz and the signal will have a bandwidth of 20 kilohertz. Notice that as the modulating signal becomes higher in frequency, the bandwidth required also becomes greater. As illustrated by the above examples, the bandwidth of an amplitude-modulated wave at any instant is two times the highest modulating frequency applied at that time. Thus, if a 400-kilohertz carrier is modulated with 3, 5, and 8 kilohertz simultaneously, sideband frequencies will appear at 392, 395, 397, 403, 405, and 408 kilohertz. This signal extends from 392 to 408 kilohertz and has a bandwidth of 16 kilohertz, twice the highest modulating frequency of 8 kilohertz.

Musical instruments produce complex sound waves containing a great number of frequencies. The frequencies produced by a piano, for example, range from approximately 27 to 4,200 hertz with harmonic frequencies extending beyond 10 kilohertz. Modulating frequencies of up to 15 kilohertz must be included in the signal to transmit a musical passage with a high degree of fidelity. This requires a bandwidth of at least 30 kilohertz to prevent attenuation of higher-order harmonic frequencies.

If the signal to be transmitted contains voice frequencies only, and fidelity is of minor importance, the bandwidth requirement is much smaller. A baritone voice includes frequencies of approximately 100 to 350 hertz, or 250 hertz. Intelligible voice communications can be carried out as long as the communications system retains audio frequencies up to several thousand hertz. Comparing the conditions for transmitting voice signals with those for transmitting music reveals that much less spectrum space is required for voice communications.

Radio stations in the standard broadcast band are assigned carrier frequencies by the Federal Communications Commission (FCC). When two stations are located near each other, their carriers must be spaced some minimum distance apart in the radio spectrum. Otherwise, the sideband frequencies of one station will interfere with sideband frequencies of the other station. The standard AM broadcast band starts at 535 kilohertz and ends at 1,605 kilohertz. Carrier assignments start at 540 kilohertz and continue in a succession of 10-kilohertz increments until the upper limit of the broadcast band is reached. This adds up to a total of 107 carrier assignments, or CHANNELS, over the entire broadcast band. If stations were assigned to all 107 channels (in a given geographical area), each station would be allotted a channel width of 10 kilohertz. This leaves 5 kilohertz on each side of each carrier for sidebands. Since interference between such closely spaced stations would be nearly impossible to prevent, the FCC avoids assigning adjacent channels to stations in the same area. As a consequence of this policy, one or more vacant channels normally exist between stations in the broadcast band. In the interest of better fidelity, the stations are permitted to use modulating frequencies higher than 5 kilohertz as long as no interference with other stations is produced.

Q-31. What are the two major sections of a typical AM transmitter?

Q-32. When 100 kilohertz and 5 kilohertz are heterodyned, what frequencies are present?

Q-33. What is the upper sideband of an AM transmission?

Q-34. Where is the intelligence in an AM transmission located?

Q-35. What determines the bandwidth of an AM transmission?

ANALYSIS OF AN AM WAVE.—A significant amount of information concerning the basic principles of amplitude modulation can be obtained from a study of the properties of the modulation envelope.

A carrier wave which has been modulated by voice or music signals is accompanied by two sidebands; each sideband contains individual frequencies that vary continuously. Since a wave of this nature is nearly impossible to analyze, you can assume in the following sections that the modulating signal, unless otherwise qualified, is a single-frequency, constant-amplitude sine wave.

PERCENT OF MODULATION IN AN AM WAVE.—The degree of modulation is defined in terms of the maximum permissible amount of modulation. Thus, a fully modulated wave is said to be 100-PERCENT MODULATED. The modulation envelope in figure 1-40, view (A), shows the conditions for 100-percent sine-wave modulation. For this degree of modulation, the peak audio voltage must be equal to the dc supply voltage to the final power amplifier. Under these conditions, the rf output voltage will reach 0 on the negative peak of the modulating signal; on the positive peak, it will rise to twice the amplitude of the unmodulated carrier.

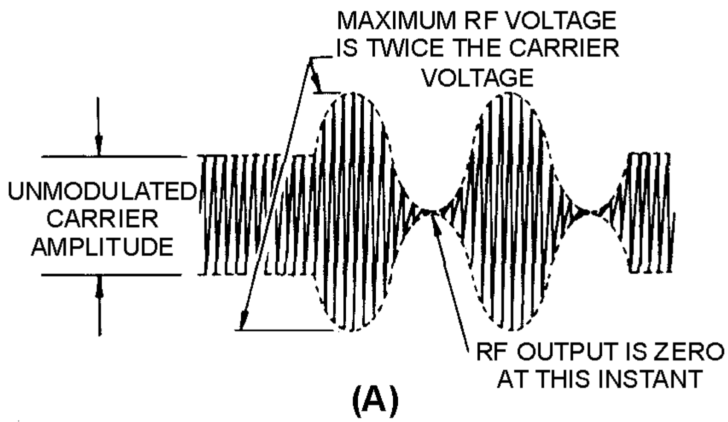

Figure 1-40A.—Conditions for 100-percent modulation.

When analyzed, the modulation envelope consists of the unmodulated rf carrier voltage plus the combined voltage of the two sidebands. The combined sideband voltages are approximately equal to the rf carrier voltage since each sideband frequency contains one-half the carrier voltage, as shown in view (B). This condition is known as 100-percent modulation and the maximum modulated rf voltage is twice the carrier voltage. The audio-modulating voltage can be increased beyond the amount required to produce 100-percent modulation. When this happens, the negative peak of the modulating signal becomes larger in amplitude than the dc plate-supply voltage to the final power amplifier. This causes the final plate voltage to be negative for a short period of time near the negative peak of the modulating signal. For the duration of the negative plate voltage, no rf energy is developed across the plate tank circuit and the rf output voltage remains at 0, as shown in figure 1-41, view (A).

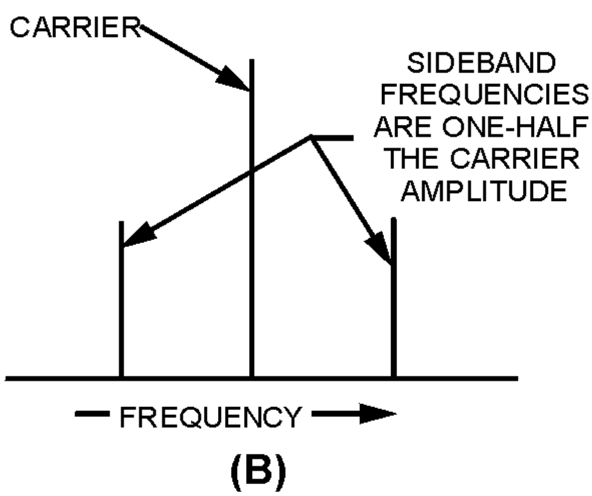

Figure 1-40B.—Conditions for 100-percent modulation.

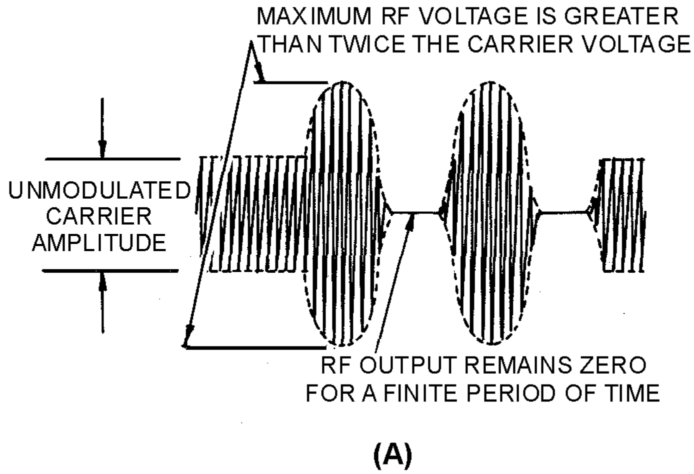

Figure 1-41A.—Overmodulation conditions.

Look carefully at the modulation envelope in view (A). It shows that the negative peak of the modulating signal has effectively been limited. If the signal were demodulated (detected in the receiver), it would have an appearance somewhat similar to a square wave. This condition, known as OVERMODULATION, causes the signal to sound severely distorted (although this will depend on the degree of overmodulation).

Overmodulation will generate unwanted (SPURIOUS) sideband frequencies. This effect can easily be detected by tuning a receiver near, but somewhat outside the desired frequency. You would likely be able to tune to one or more of these undesired sideband frequencies, but the reception would be severely distorted, possibly unintelligible. (Without overmodulation, no such unwanted sideband frequencies would exist and you would be able to tune only to the desired frequency.) These unwanted frequencies will appear for a considerable range both above and below the desired channel. This effect is sometimes called SPLATTER. These spurious frequencies, shown in view (B), cause interference with other stations operating on adjacent channels. You should clearly understand that overmodulation, and its attendant distortion and interference is to be avoided.

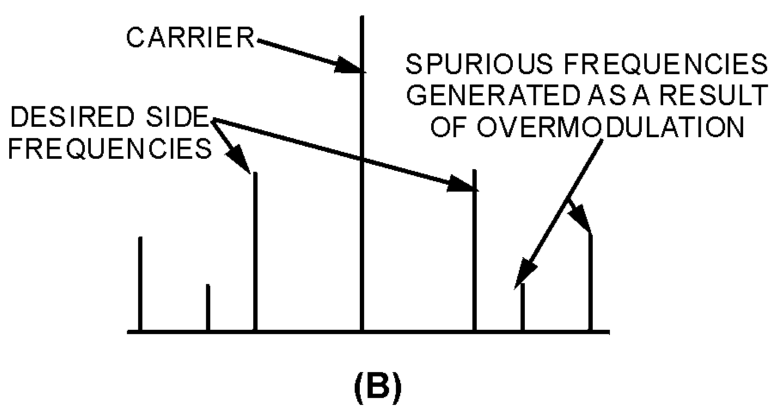

Figure 1-41B.—Overmodulation conditions.

In addition to the above problems, overmodulation also causes abnormally large voltages and currents to exist at various points within the transmitter. Therefore, sufficient overload protection by circuit breakers and fuses should be provided. When this protection is not provided, the excessive voltages can cause arcing between transformer windings and between the plates of capacitors, which will permanently destroy the dielectric material. Excessive currents can also cause overheating of tubes and other components.

Ideally, you will want to operate a transmitter at 100-percent modulation so that you can provide the maximum amount of energy in the sideband. However, because of the large and rapid fluctuations in amplitude that these signals normally contain, this ideal condition is seldom possible. When the modulator is properly adjusted, the loudest parts of the transmission will produce 100-percent modulation. The quieter parts of the signal then produce lesser degrees of modulation.

To measure degrees of modulation less than 100 percent, you can use a MODULATION FACTOR (M) to indicate the relative magnitudes of the rf carrier and the audio-modulating signal. Numerically, the modulation factor is:

$$M = \frac{E_m}{E_c}$$

Where:

M = the modulation factor

E_m = the peak, peak-to-peak, or rms value of the modulating voltage

E_c = the peak, peak-to-peak,

To illustrate this use of the equation, assume that a carrier wave with a peak amplitude of 400 volts is modulated by a 3-kilohertz sine wave with a peak amplitude of 200 volts. The modulation factor is figured as follows:

$$M = \frac{E_m}{E_c}$$

$$M = \frac{200}{400}$$

$$M = 0.5$$

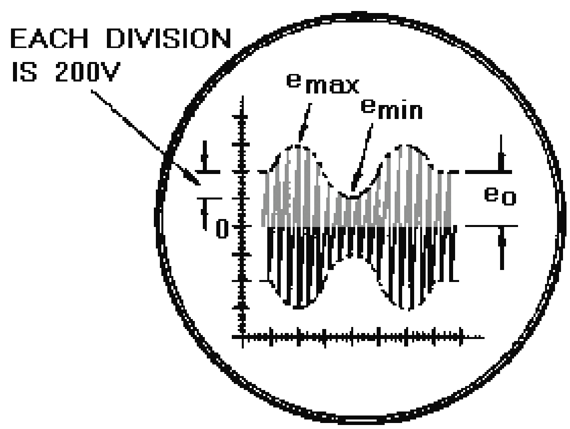
If the modulation factor were multiplied by 100, the resultant quantity would be the PERCENT OF MODULATION (%M):

$$\%M = \frac{E_m}{E_c} \times 100$$

$$\%M = \frac{200}{400} \times 100$$

$$\%M = 50 \text{ percent}$$

By using the correct equation, you can determine the percent of modulation from the modulation envelope pattern. This method is useful when the percent of modulation is to be determined using the pattern on the screen of an oscilloscope. For example, assume that your oscilloscope is connected to the output of a modulator circuit and produces the screen pattern shown in figure 1-42. According to the setting of the calibration control, each large division on the vertical scale is equal to 200 volts. By using this scale, you can see that the peak carrier amplitude (unmodulated portion) is 400 volts. The peak amplitude of the carrier is designated as e_o in figure 1-42.



$$\%M = \frac{e_{max} - e_{min}}{2e_o} \times 100$$

-OR-

$$\%M = \frac{e_{max} - e_{min}}{e_{max} + e_{min}} \times 100$$

Figure 1-42.—Computing percent of modulation from the modulation envelope.

The amplitude of the audio-modulating voltage can also be determined from amplitude variations in the envelope pattern. Notice that the peak-to-peak variations in envelope amplitude ($e_{max} - e_{min}$) is equal to 400 volts on the scale. Note then that the peak amplitude of the audio voltage is 200 volts. If these rf and audio voltage values are inserted into the equation, the pattern in figure 1-42 is found to represent 50-percent modulation.

If E_m and E_c in the equation are assumed to represent peak-to-peak values, the following formula results:

$$\%M = \frac{E_m}{E_c} \times 100$$

Since the peak-to-peak value of E_m in figure 1-42 is $e_{max} - e_{min}$, we can substitute as follows:

$$\%M = \frac{e_{max} - e_{min}}{E_c} \times 100$$

Also, since the peak-to-peak value of the carrier E_c is 2 times e_o, we can subsititute $2e_o$ for E_c as follows:

$$\%M = \frac{e_{max} - e_{min}}{2e_o} \times 100$$

Linear vertical distance represents voltage on the screen of a cathode-ray tube. Vertical distance units can be used in place of voltage in equations. Thus, if only the percent of modulation is required, the oscilloscope need not be calibrated and the actual circuit voltages are not required. In figure 1-42, e_{max} represents 600 volts (3 large divisions); e_{min} is 200 volts (1 division); and e_o is 400 volts (2 divisions). Using the equation and the dimensions of the screen pattern, you can figure the percent of modulation as follows:

$$\%M = \frac{e_{max} - e_{min}}{2e_o} \times 100$$

$$\%M = \frac{3 - 1}{2 \times 2} \times 100$$

$$\%M = \frac{2}{4} \times 100$$

$$\%M = 50 \text{ percent}$$

When e_o of the equation is difficult to measure, an alternative solution can be obtained with the equation below:

$$\%M = \frac{e_{max} - e_{min}}{e_{max} + e_{min}} \times 100$$

VECTOR ANALYSIS OF AN AM WAVE.—You studied earlier in this chapter that the modulation envelope results when the instantaneous sums of the carrier and sideband voltages are plotted with respect to time. An attempt to add these three voltages, point-by-point, would prove to be a huge task. The same end result can be obtained by using a rotating vector to represent each of the three frequencies in the composite envelope. In the following analysis, vectors will be scaled to indicate the peak voltage value of the frequencies they represent.

The analysis has been simplified further by using a frequency of 8 hertz to represent the carrier frequency. Each cycle of the carrier then requires 1/8 of a second to complete 360 degrees. The carrier will be 100-percent modulated by a sine wave having a frequency of 1 hertz, thereby producing sideband frequencies of 7 and 9 hertz.

Envelope Development from Vectors.—The modulating signal, upper sideband, carrier, and lower sideband waveforms are illustrated in views (A) through (D), respectively, in figure 1-43. Notice that the vertical lines passing through the figure divide each waveform into segments of 1/8 of a second each. These lines also coincide with the starting and ending points of each cycle of the carrier wave.

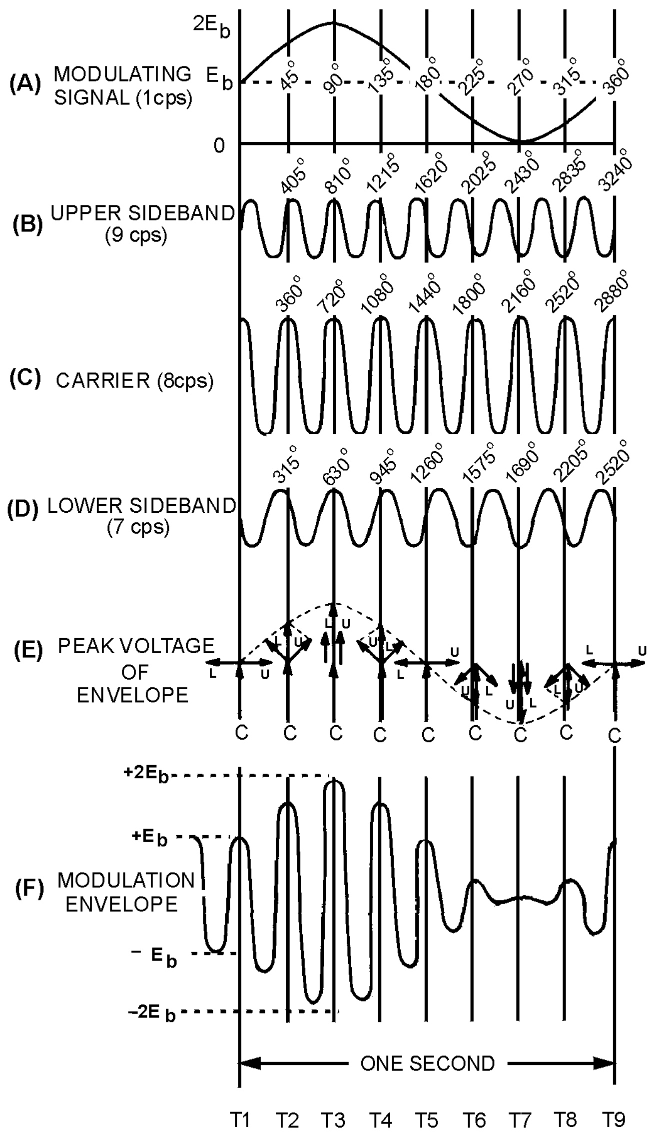


Figure 1-43.—Formation of the modulation envelope by the addition of vectors representing the carrier and sidebands.

During the first 1/8 of a second (T1 to T2), the carrier wave completes exactly 1 cycle, or 360 degrees, as shown in view (C). The upper sideband, which has a frequency of 9 hertz, will complete each cycle in less than 1/8 of a second. Therefore, during the time required for the carrier to complete 1 cycle of 360 degrees, the upper sideband [view (B)] is able to complete 1 cycle of 360 degrees plus an additional 45 degrees of the next cycle, for a total of 405 degrees.

The lower sideband [view (D)] has a frequency of 7 hertz and cannot complete an entire cycle in 1/8 of a second. During the time interval required for the carrier wave to progress through 360 degrees, the lower sideband frequency of 7 hertz can complete only 315 degrees, 45 degrees short of a full cycle.

Keeping these factors in mind, you should be able to see that the phase angles between the two sideband frequencies, and between each sideband frequency and the carrier frequency, will continually shift. At an instant in time (T3), the carrier and sidebands will be in phase [view (E)], causing the envelope amplitude [view (F)] to be twice the amplitude of the carrier. At another instant in time (T7), the sidebands are out of phase with the carrier [view (E)], causing complete cancellation of the rf voltage. The envelope amplitude will become 0 at this point. You should see that, although the carrier and sideband frequencies have constant amplitudes, the ever-changing phase differences between them causes the modulation envelope to vary continuously in amplitude.

The vector analysis of the modulation envelope will be developed with the aid of figure 1-44. In figure 1-44, view (A), a vertical vector (C) has been drawn to represent the carrier wave in figure 1-43. At T1 in figure 1-43, the upper and lower sideband frequencies are of opposite phase with respect to each other, and 90 degrees out of phase with respect to the carrier. This condition is illustrated in figure 1-44, view (A), by sideband vectors U and L drawn in opposite directions along the horizontal axis. Since the upper sideband U is equal in amplitude but opposite in phase to lower sideband L, the two sideband voltages cancel one another; the amplitude of the envelope at T1 is equal to the amplitude of the carrier. The same vector diagram is shown on a smaller scale in figure 1-43, view (E).

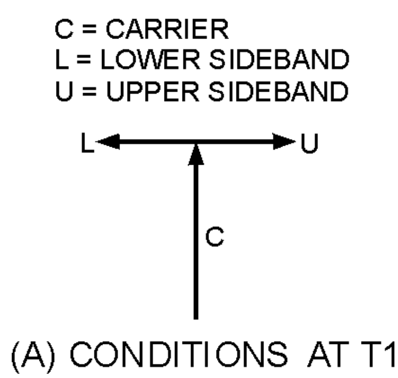

Figure 1-44A.—Vector diagrams for T1 and T2.

During the 1/8 of a second time interval between T1 and T2, all three vectors rotate in a counterclockwise direction at a velocity determined by their respective frequencies. The vector representing the carrier, for example, has made one complete rotation of 360 degrees and is back in its original position, as shown in figure 1-44, view (B). The upper sideband frequency, however, will complete 405 degrees in this same 1/8 of a second. Notice in view (B) that vector U has made one complete counterclockwise rotation of 360 degrees, plus an additional 45 degrees for a total rotation of

405 degrees. Vector L, representing the lower sideband, rotates at a velocity less than that of either the carrier or the upper sideband. In 1/8 of a second, vector L completes only 315 degrees, which is 45 degrees short of one complete rotation. At the end of 1/8 of a second, the three vectors have advanced to the positions shown in view (B).

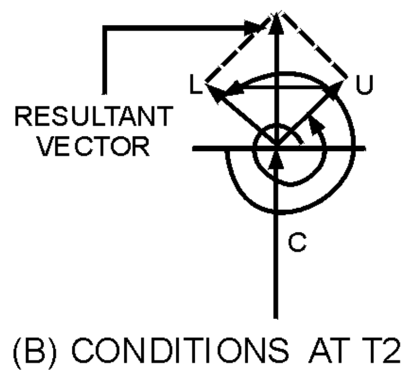

Figure 1-44B.—Vector diagrams for T1 and T2.

The resultant vector in view (B) is obtained by adding vector U to vector L. Since each sideband has one-half the amplitude of the carrier, and the two sidebands differ in phase by 90 degrees, the amplitude of the resultant vector can be computed. This computation (not shown) would show the resultant vector to have an amplitude that is approximately 70 percent that of the carrier. Thus, at T2 the amplitude of the modulation envelope is about 1.7 times the amplitude of the carrier. This condition is shown in figure 1-43, view (F).

By a similar procedure, vector diagrams can be constructed for time intervals T3 through T9. This has been done in figure 1-43, view (E). From these nine individual vector diagrams, the complete modulation envelope in figure 1-43, view (F), can be constructed.

Notice in particular the vector diagrams for T3 and T7. At T3, all three waves, and therefore all three vectors, are in phase. The modulation envelope at this instant must, therefore, be equal to twice the amplitude of the carrier since each sideband frequency has one-half the amplitude of the carrier.

At T7, the two sideband frequencies are in phase with each other but 180 degrees out of phase with the carrier. This causes the combined sideband voltage to cancel the carrier voltage, and the modulation envelope becomes 0 at that instant. Note that for the transmitter output to be 0 at T7, both the carrier and sideband frequencies must be present. If any one of these three frequencies were missing, complete cancellation would not occur and rf energy would be present in the output.

Although this vector analysis was made for frequencies of 7, 8, and 9 hertz, the same description could be applied to the frequencies actually present at the output of a transmitter.

Modulation Level of an AM Wave

As stated earlier, the modulating signal can be introduced into any active element of a tube. In addition to the various arrangements possible within a single stage, the modulating signal can also be applied to any of the rf stages in the transmitter. For example, the modulating signal could be applied to the control grid or plate of one of the intermediate power amplifiers.

A modulator circuit is usually placed into one of two categories, high- or low-level modulation. Circuits are categorized according to the level of the carrier wave at the point in the system where the modulation is applied. The FCC defines HIGH-LEVEL MODULATION in the Code of Federal Regulations as "modulation produced in the plate circuit of the last radio stage of the system." This same document defines LOW-LEVEL MODULATION as "modulation produced in an earlier stage than the final."

Q-36. What is percent of modulation?

Q-37. With a single modulating tone, what is the amplitude of the sideband frequencies at 100-percent modulation?

Q-38. What is the formula for percent of modulation?

Q-39. What is high-level modulation?

MODULATION SYSTEMS

To complete your understanding of AM modulation, we are now going to analyze the operation of a typical plate modulator. Detailed circuit descriptions will be used to give you an understanding of a basic AM plate modulator. In addition, we will cover basic circuit descriptions for cathode and grid electron-tube modulators and for base, emitter, and collector transistor modulators in this chapter.

Plate Modulator

Figure 1-45 is a basic plate-modulator circuit. Plate modulation permits the transmitter to operate with high efficiency. It is the simplest of the modulators available and is also the easiest to adjust for proper operation. The modulator is coupled to the plate circuit of the final rf amplifier through the modulation transformer. For 100-percent modulation, the modulator must supply enough power to cause the plate voltage of the final rf amplifier to vary between 0 and twice the dc operating plate voltage. The modulator tube (V2) is a power amplifier biased so that it operates class A. The final rf power amplifier (V1) is biased in the nonlinear portion of its operating range (class C). This provides for efficient operation of V1 and produces the necessary heterodyning action between the rf carrier and the af modulating frequencies.

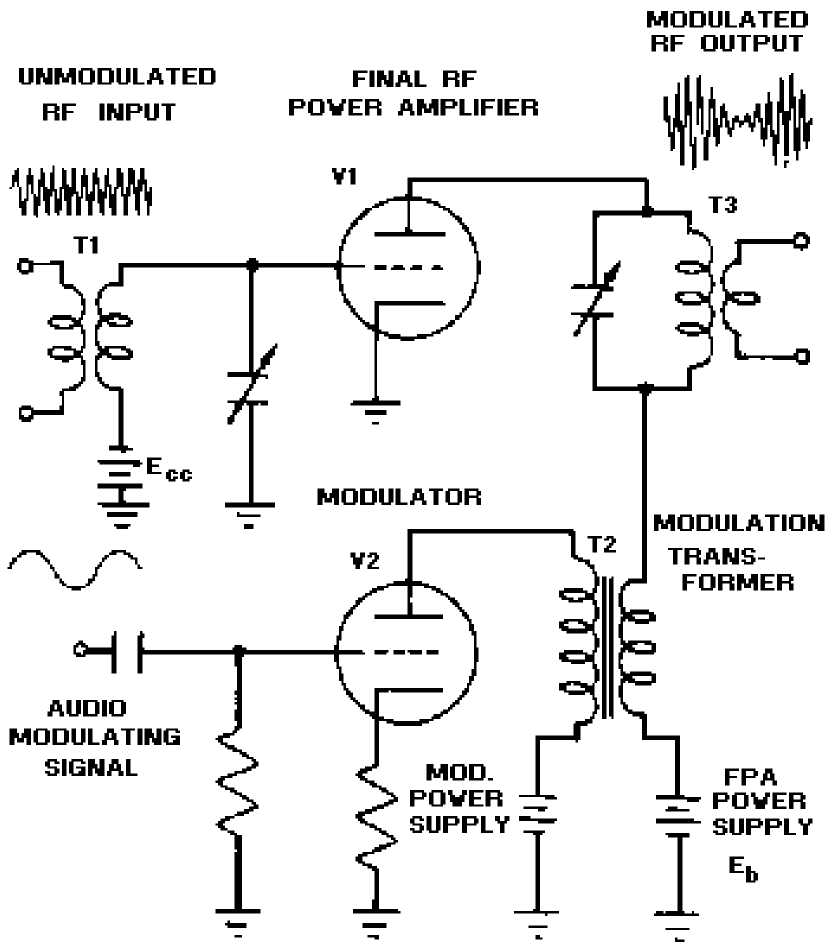

Figure 1-45.—Plate-modulation circuit.

PLATE MODULATOR CIRCUIT OPERATION.—Figure 1-46, views (A) through (E), shows the waveforms associated with the plate-modulator circuit shown in figure 1-45. Refer to these two figures throughout the following discussion.

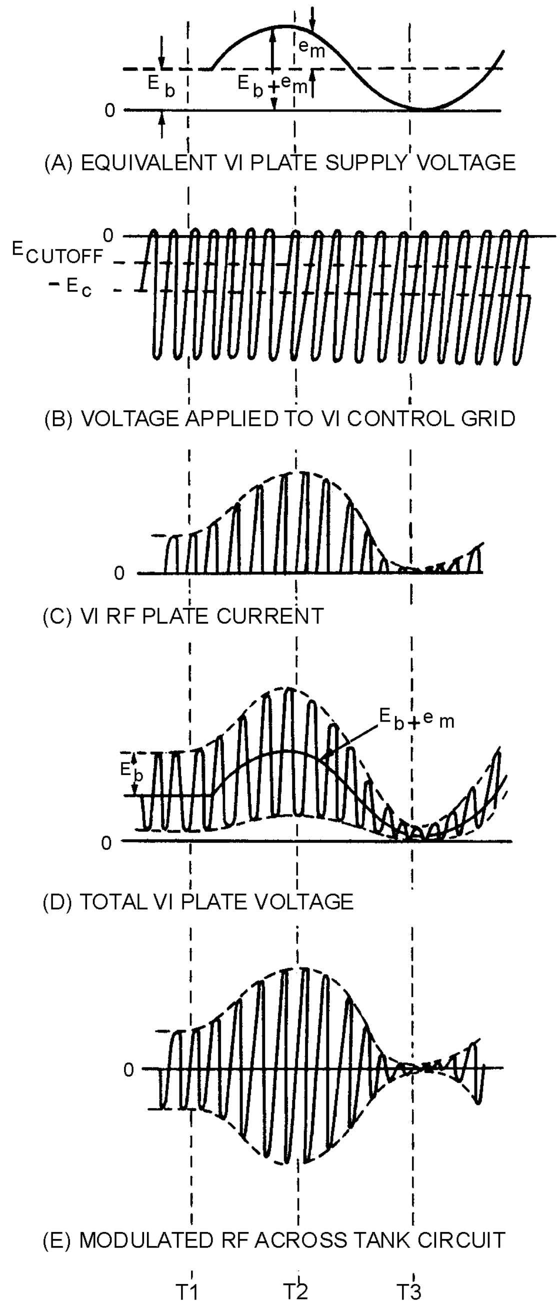

Figure 1-46.—Plate-modulator waveforms.

The rf power amplifier (V1) acts as a class C amplifier when no modulation is present in the plate circuit. V2 is the modulator which transfers the modulating voltage to the plate circuit of V1. Let's see how this circuit produces a modulated rf output.

View (A) of figure 1-46 shows the plate supply voltage for V1 as a constant dc value (E_b) at time 1 with no modulating signal applied. V1 is biased at cutoff at this time. The incoming rf carrier [view (A)] is applied to the grid of V1 by transformer T1 and causes the plate circuit current to PULSE (SURGE) each time the grid is driven positive. These rf pulses are referred to as current pulses and are shown in view (C). The plate tank output circuit (T3) is shocked into oscillation by these current pulses and the rf output waveform shown in view (E) is developed. The rf plate voltage waveform is shown in view (D).

An audio-modulating voltage applied to the grid of V2 is amplified by the modulator and coupled to the plate of V1 by modulation transformer T2. The secondary of T2 is in series with the plate-supply voltage (E) of V1. The modulating voltage will either add to or subtract from the plate voltage of V1. This is shown in view (A) at time 2 and time 3. At time 2 in view (A), the plate supply voltage for V1 increases to twice its normal value and the rf plate current pulses double, as shown in view (C). At time 3 in view (A), the supply voltage is reduced to 0 and the rf plate current decreases to 0, as shown in view (C). These changes in rf plate current cause rf tank T3 voltage to double at time 2 and to decrease to 0 at time 3, as shown in view (E). This action results in the modulation envelope shown in view (E) that represents 100-percent modulation. This is transformer-coupled out of tank circuit T3 to an antenna. Because of the oscillating action of tank circuit T3, V1 has to be rated to handle at least four times its normal plate supply voltage (E_b), as shown by the plate voltage waveform in view (D).

Heterodyning the audio frequency intelligence from the modulator (V2) with the carrier in the plate circuit of the final power amplifier (V1) requires a large amount of audio power. All of the power or voltage that contains the intelligence must come from the modulator stage. This is why plate modulation is called high-level modulation.

The heterodyning action in the plate modulator effectively changes an audio frequency to a different part of the frequency spectrum. This action allows antennas and equipment of practical sizes to be used to transmit the intelligence. Now, let's look at several other typical modulators.

Collector-Injection Modulator

The COLLECTOR-INJECTION MODULATOR is the transistor equivalent of the electron-tube AM plate modulator. This transistor modulator can be used for low-level or relatively high-level modulation. It is referred to as relatively high-level modulation because, at the present time, transistors are limited in their power-handling capability. As illustrated in figure 1-47, the circuit design for a transistor collector-injection modulator is very similar to that of a plate modulator. The collector-injection modulator is capable of 100-percent modulation with medium power-handling capabilities.

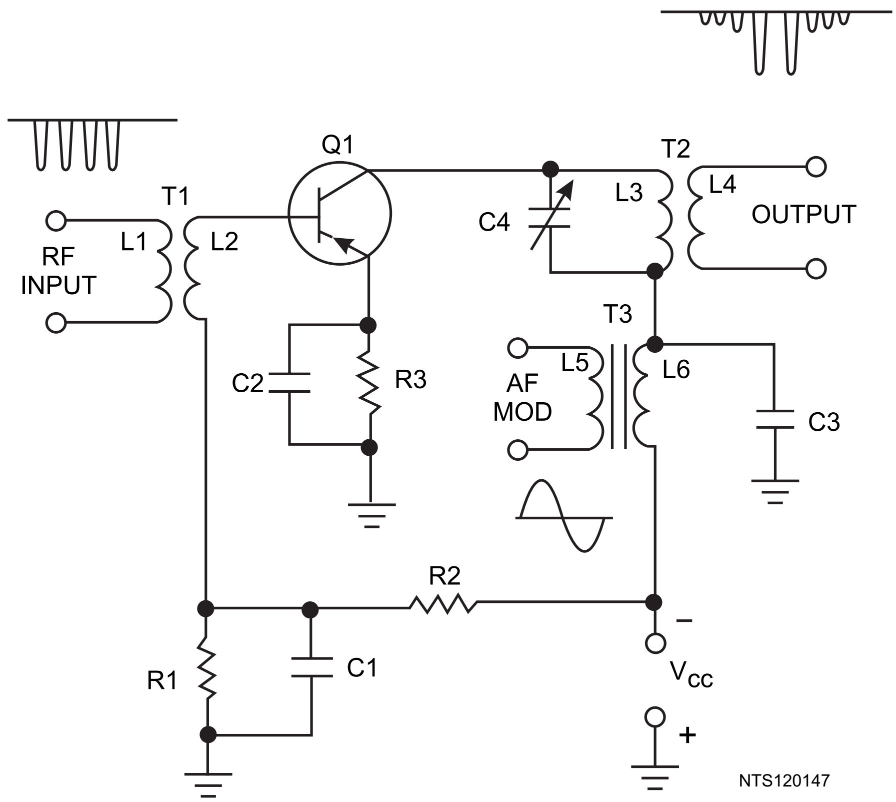

Figure 1-47.—Collector-injection modulator.

In figure 1-47, the rf carrier is applied to the base of modulator Q1. The modulating signal is applied to the collector in series with the collector supply voltage through T3. The output is then taken from the secondary of T2. With no modulating signal, Q1 acts as an rf amplifier for the carrier frequency. When the modulation signal is applied, it adds to or subtracts from the collector supply voltage. This causes the rf current pulses of the collector to vary in amplitude with the collector supply voltage. These collector current pulses cause oscillations in the tank circuit (C4 and the primary of T2). The tank circuit is tuned to the carrier frequency. During periods when the collector current is high, the tank circuit oscillates strongly. At times when the collector current is small, or entirely absent, little or no energy is supplied to the tank and oscillations become weak or die out. Thus, the modulation envelope is developed as it was in a plate modulator.

As transistor technology continues to develop, higher power applications of transistor collector-injection modulation will be employed. Plate and collector-injection modulation are the most commonly used types of modulation because the modulating signal can be applied in the final stages of rf amplification. This allows the majority of the rf amplifier stages to be operated class C for maximum efficiency. The plate and collector-injection modulators also require large amounts of af modulating power since the modulator stage must supply the power contained in the sidebands.

Q-40. For what class of operation is the final rf power amplifier of a plate-modulator circuit biased?

Q-41. The modulator is required to be what kind of a circuit stage in a plate modulator?

Q-42. How much must the fpa plate current vary to produce 100-percent modulation in a plate modulator?

Q-43. The collector-injection modulator is similar to what type of tube modulator?

Control-Grid Modulator

In cases when the use of a minimum of af modulator power is desired, a form of low-level modulation is necessary. The CONTROL-GRID MODULATOR is used widely in portable and mobile equipment to reduce size and power requirements. It is also used in extremely high-power, wideband equipment such as television transmitters where high-level or plate modulation is difficult and costly to achieve. Figure 1-48 is a basic schematic for a typical control-grid modulator.

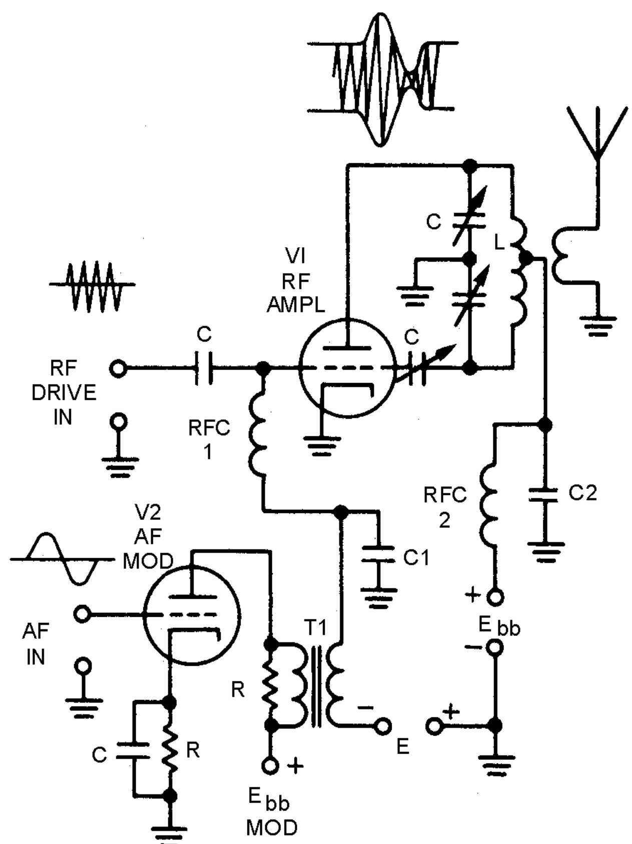

Figure 1-48.—Control-grid modulator.

The control-grid modulator uses a variation of grid bias (at the frequency of the modulating signal) to vary the instantaneous plate voltage and current. These variations cause modulation of the carrier frequency. The carrier frequency is introduced through coupling capacitor $_{Cc}$. The modulating frequency is introduced in series with the grid bias through T1. As the modulating signal increases and decreases (positive and negative), it will add to or subtract from the bias on rf amplifier V1. This change in bias causes a corresponding change in plate voltage and current. These changes in plate voltage and current add vectorially to the carrier frequency and provide a modulation envelope in the same fashion as does the plate modulator. Since changes in the plate circuit of the rf amplifier are controlled by changes in the grid bias, the gain of the tube requires only a low-level modulating signal. Even when the input signals are at these low levels, occasional modulation voltage peaks will occur that will cause V1 to saturate. This creates distortion in the output. Care must be taken to bias the rf amplifier tube for maximum power out while maintaining minimum distortion. The power to develop the modulation envelope comes from the rf amplifier. Because the rf amplifier has to be capable of supplying this additional power, it is biased for (and driven by the carrier frequency at) a much lower output level than its rating. This reduced efficiency is necessary during nonmodulated periods to provide the tube with the power to develop the sidebands.

Compared to plate modulation, grid modulation is less efficient, produces more distortion, and requires the rf power amplifier to supply all the power in the output signal. Grid modulation has the advantage of not requiring much power from the modulator.

Base-Injection Modulator

The BASE-INJECTION MODULATOR is similar to the control-grid modulator in electron-tube circuits. It is used to produce low-level modulation in equipment operating at very low power levels.

In figure 1-49, the bias on Q1 is established by the voltage divider R1 and R2. With the rf carrier input at T1, and no modulating signal, the circuit acts as a standard rf amplifier. When a modulating signal is injected through C1, it develops a voltage across R1 that adds to or subtracts from the bias on Q1. This change in bias changes the gain of Q1, causing more or less energy to be supplied to the collector tank circuit. The tank circuit develops the modulation envelope as the rf frequency and af modulating frequency are mixed in the collector circuit. Again, this action is identical to that in the plate modulator.

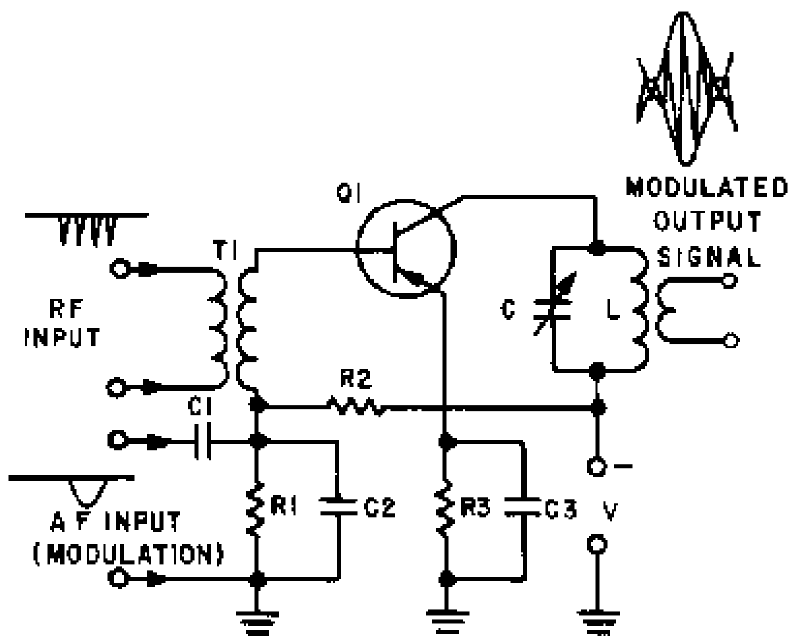

Figure 1-49.—Base-injection modulator.

Because of the extremely low-level signals required to produce modulation, the base-injection modulator is well suited for use in small, portable equipment, such as "walkie-talkies," and test equipment.

Cathode Modulator

Another low-level modulator, the CATHODE MODULATOR, is generally employed where the audio power is limited and distortion of the grid-modulated circuit cannot be allowed. The cathode modulator varies the voltage of the cathode to produce the modulation envelope. Since the cathode is in series with the grid and plate circuits, you should be able see that changing the cathode voltage will effectively change the voltage of the other tube elements. By properly controlling the voltages on the tube, you can cause the cathode modulator to operate in a form of plate modulation with high efficiency. Usually, the cathode modulator is designed to perform about midway between plate and grid modulator levels, using the advantages of each type. When operated between the two levels, the modulator provides a more linear output with moderate efficiency and a modest audio power requirement.

In figure 1-50, the rf carrier is applied to the grid of V1 and the modulating signal is applied in series with the cathode through T1. Since the modulating signal is effectively in series with the grid and plate voltage, the level of modulating voltage required will be determined by the relationships of the three voltages. The modulation takes place in the plate circuit with the plate tank developing the modulation envelope, just as it did in the plate modulator.

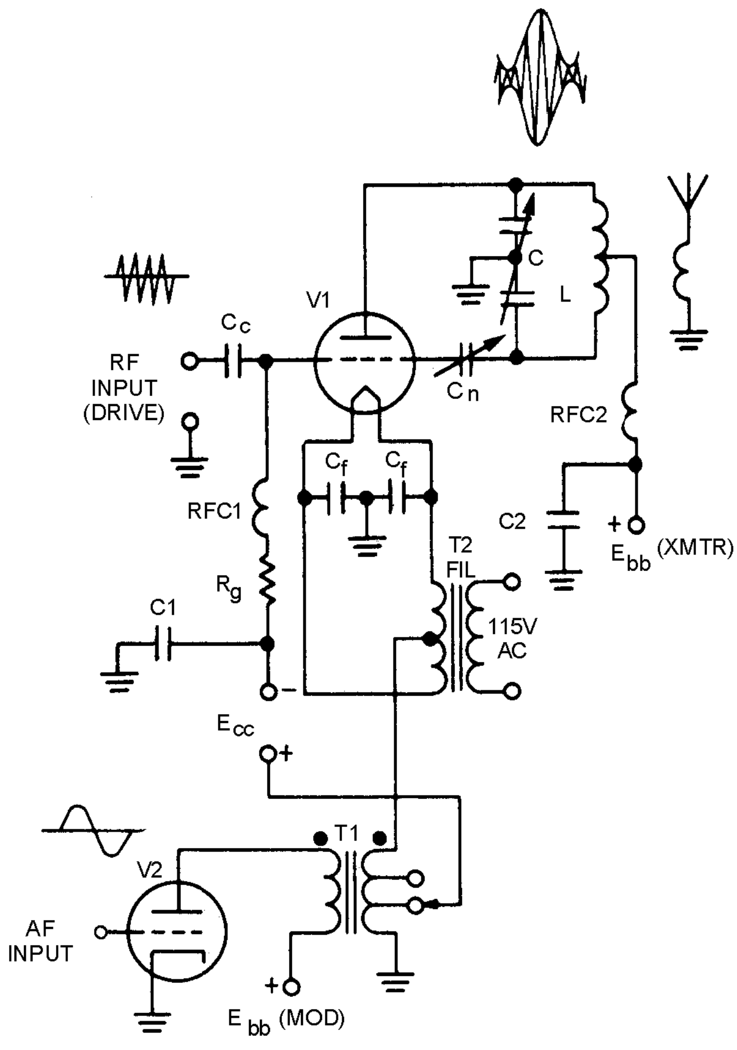

Figure 1-50.—Cathode modulator.

Emitter-Injection Modulator

This is the transistor equivalent of the cathode modulator. The EMITTER-INJECTION MODULATOR has the same characteristics as the base-injection modulator discussed earlier. It is an extremely low-level modulator that is useful in portable equipment. In emitter-injection modulation, the gain of the rf amplifier is varied by the changing voltage on the emitter. The changing voltage is caused by the injection of the modulating signal into the emitter circuitry of Q1, as shown in figure 1-51. Here the modulating voltage adds to or subtracts from transistor biasing. The change in bias causes a change in collector current and results in a heterodyning action. The modulation envelope is developed across the collector-tank circuit.

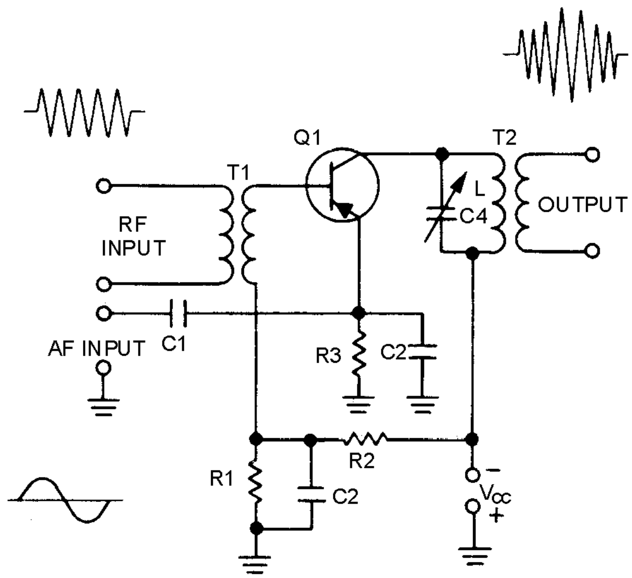

Figure 1-51.—Emitter-injection modulator.

Q-44. When is a control-grid modulator used?

Q-45. What type of modulator is the cathode modulator (low- or high-level)?

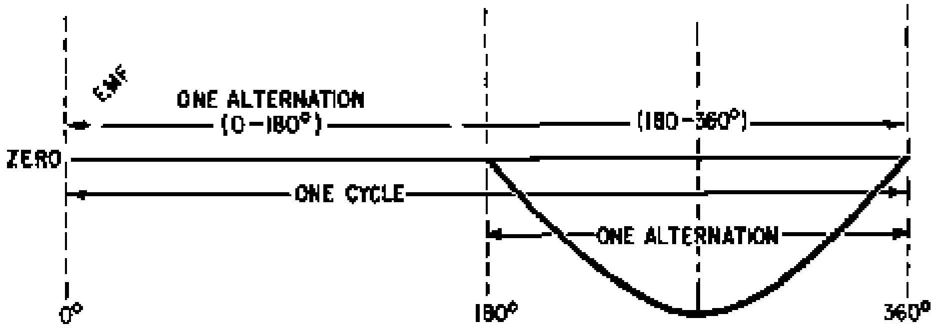
Q-46. What causes the change in collector current in an emitter-injection modulator?

You have studied six methods of amplitude modulation. These are not the only methods available, but they are the most common. All methods of AM modulation use the same theory of heterodyning across a nonlinear device. AM modulation is one of the easiest and least expensive types of modulation to achieve. The primary disadvantages of AM modulation are susceptibility to noise interference and the inefficiency of the transmitter. Power is wasted in the transmission of the carrier frequency because it contains no AM intelligence. In the next chapter, you will study other forms of modulation that have been developed to overcome these disadvantages.

SUMMARY

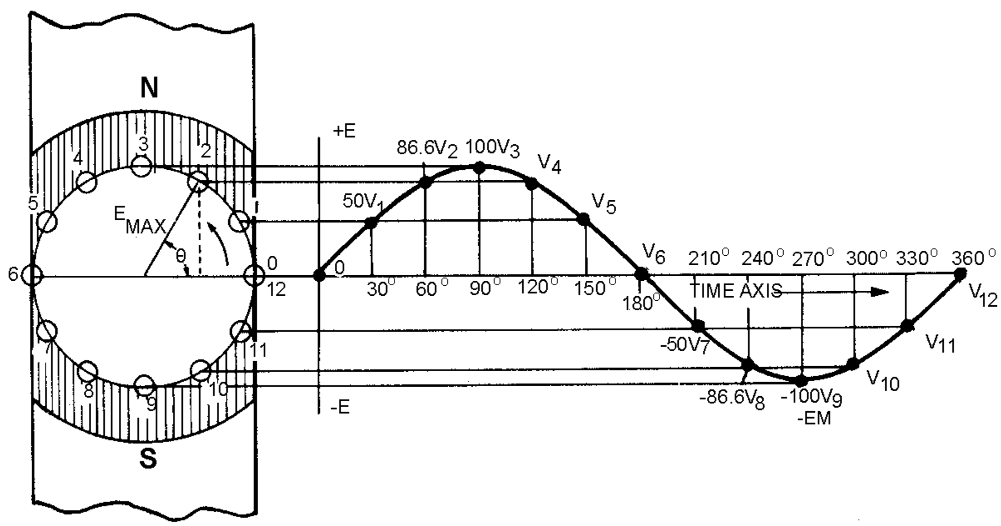
Now that you have completed this chapter, a short review of what you have learned is in order. The following summary will refresh your memory of amplitude modulation, its basic principles, and typical circuitry used to generate this modulation.

The **SINE WAVE** is the basis for all complex waveforms and is generated by moving a coil through a magnetic field.



AMPLITUDE (instantaneous voltage) of a coil is found by the formula:

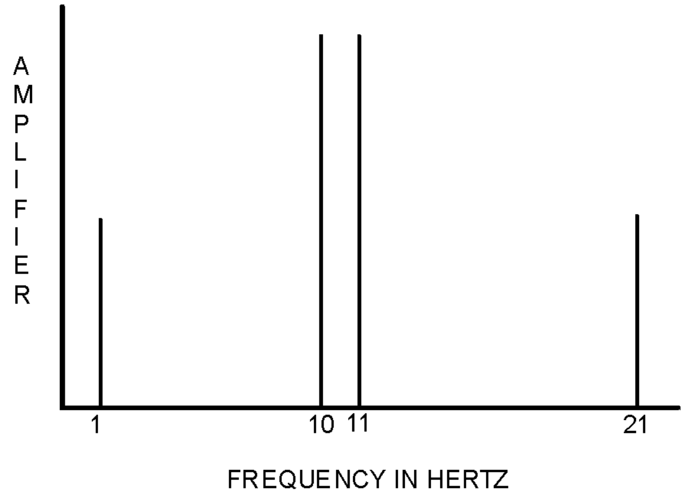
$$e = E_{max} \sin e\,\theta$$



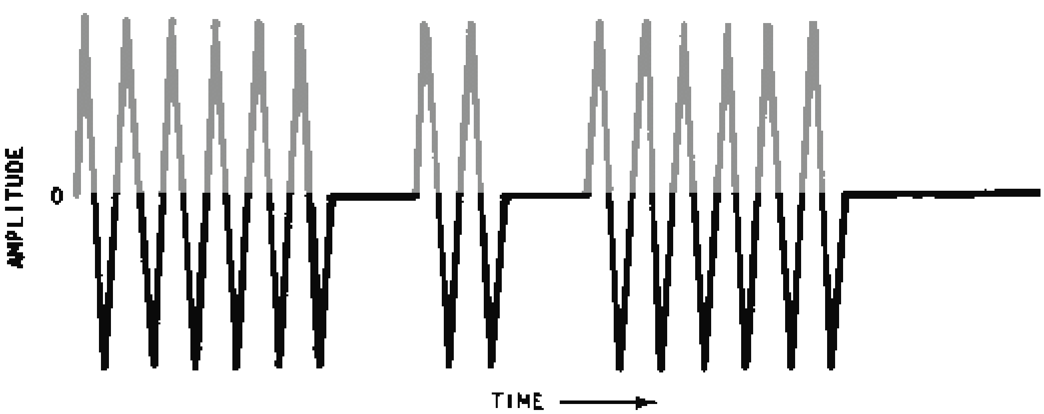
PHASE or **PHASE ANGLE** is the angle that exists between the starting position of a vector generating the sine wave and its position at a given instant.

FREQUENCY is the rate at which the vector rotates.

HETERODYNING is the process of mixing two different frequencies across a nonlinear impedance to give the ORIGINAL frequencies, a SUM frequency, and a DIFFERENCE frequency.



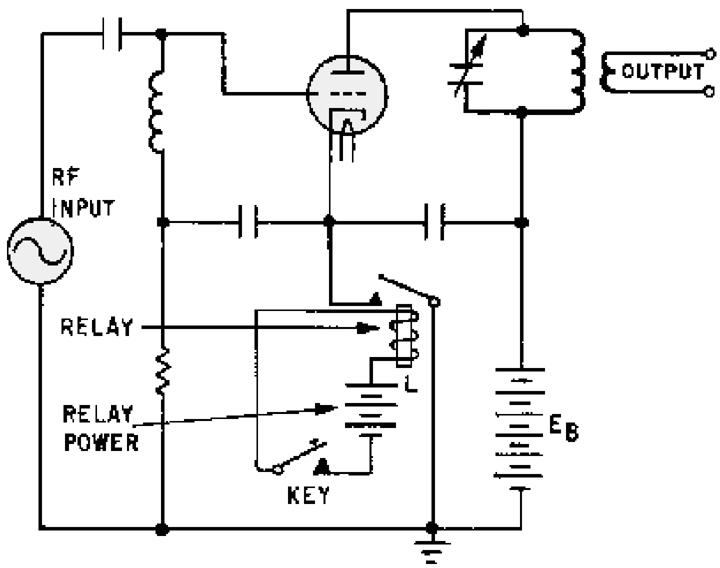
CONTINUOUS-WAVE MODULATION is the basic form of rf communications. It is essentially on-off keying of an rf carrier.



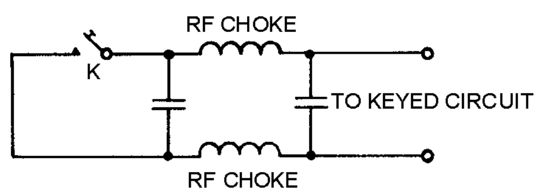
(C) RESULTANT CARRIER WAVE TRANSMITTED ALONG CONNECTING PATH.

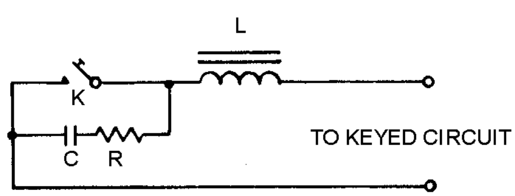
HAND-OPERATED and MACHINE KEYING are two types of cw keying. PLATE, CATHODE, and BLOCKED-GRID KEYING are circuits commonly used in hand-operated and machine keying.

KEYING RELAYS are used for safety and to handle the current requirements in high-power transmitters.



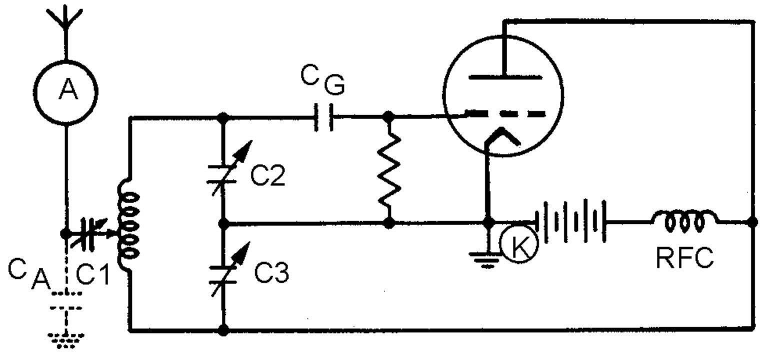
KEY-CLICK FILTERS are used to prevent interference in cw transmitters.



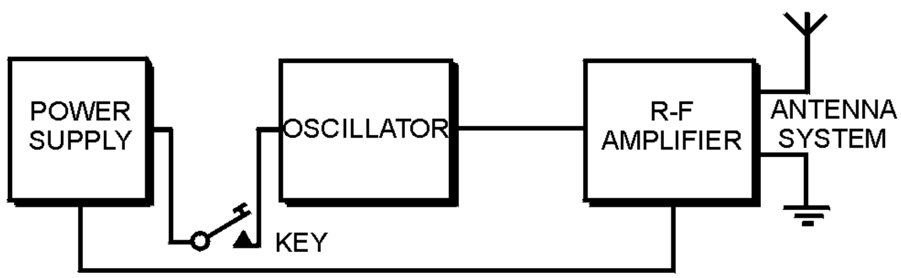


Although it is a relatively slow transmission method, CW COMMUNICATIONS is highly reliable under severe noise conditions for long-range operation.

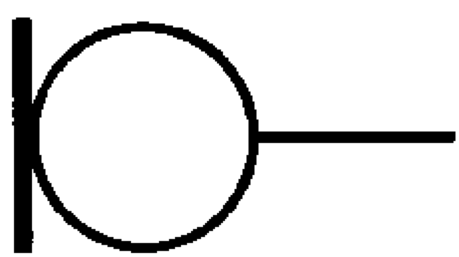
SINGLE-STAGE CW TRANSMITTERS can be made by coupling the output of an oscillator to an antenna.



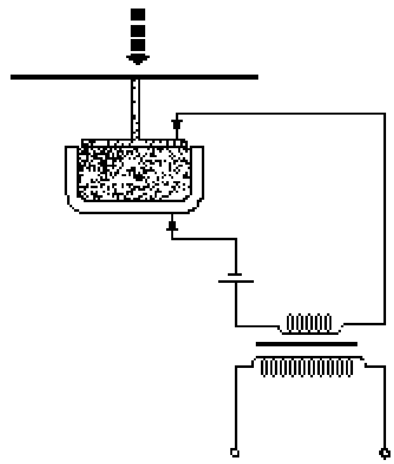
MULTISTAGE CW TRANSMITTERS are used to improve frequency stability and increase output power.



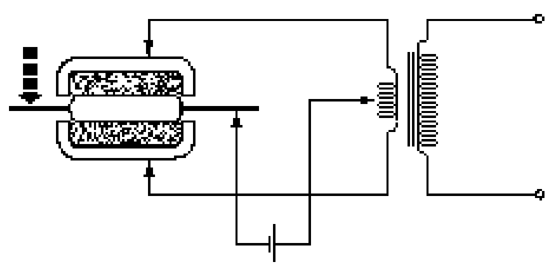
A **MICROPHONE** is an energy converter that changes sound energy into electrical energy.



A **CARBON MICROPHONE** uses carbon granules and an external battery supply to generate af voltages from sound waves.

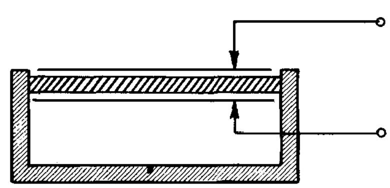


SINGLE-BUTTON CARBON MICROPHONE

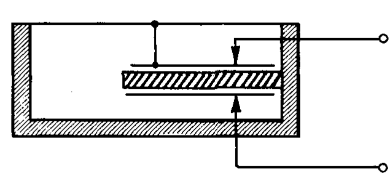


DOUBLE-BUTTON CARBON MICROPHONE

A **CRYSTAL MICROPHONE** uses the piezoelectric effect to generate an output voltage.

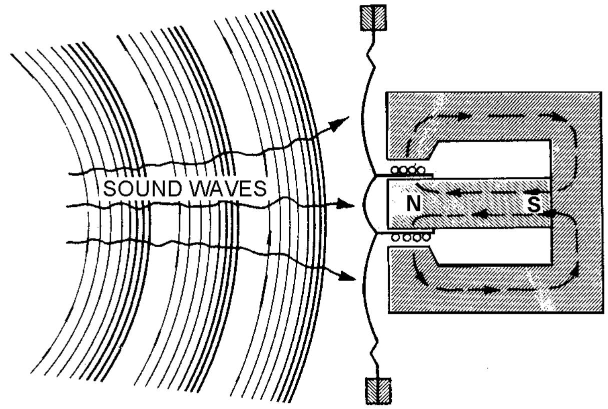


DIRECTLY ACTUATED TYPE

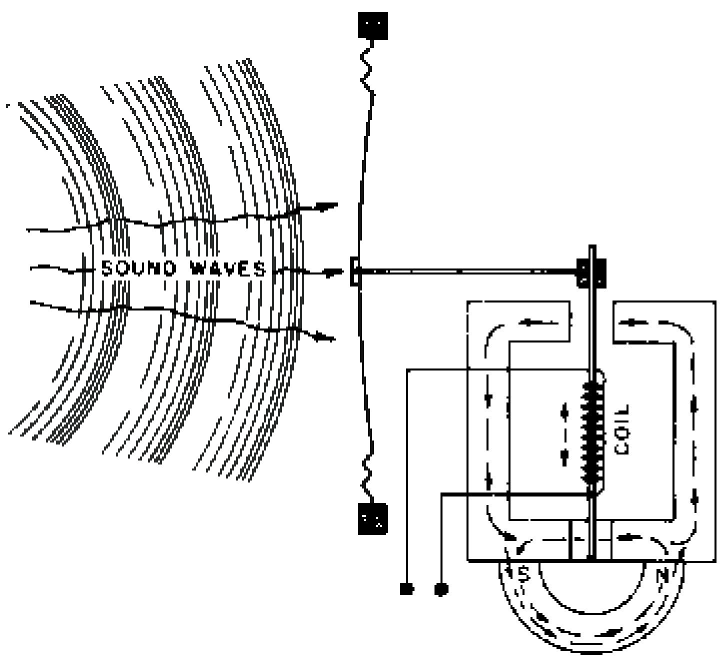


DIAPHRAGM TYPE

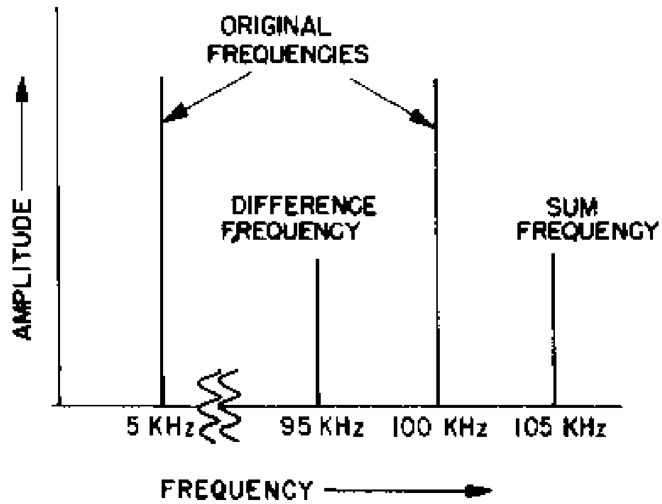
A **DYNAMIC MICROPHONE** uses a coil of fine wire mounted on the back of a diaphragm located in the magnetic field of a permanent magnet.



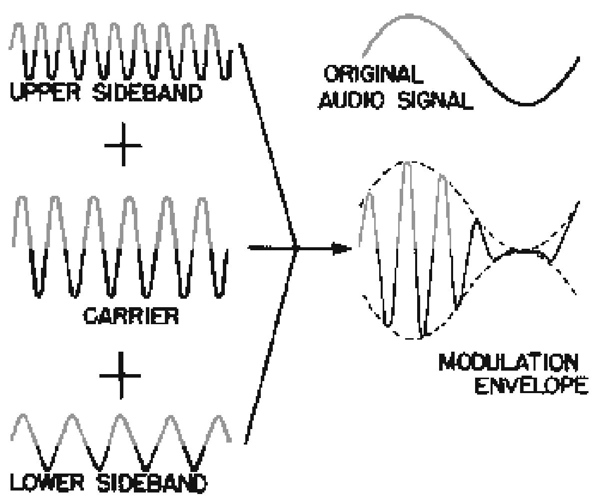
A **MAGNETIC MICROPHONE** uses a moving armature in a magnetic field to generate an output.



The **FREQUENCY SPECTRUM** of a modulated wave can be conveniently illustrated in graph form as frequency versus amplitude.

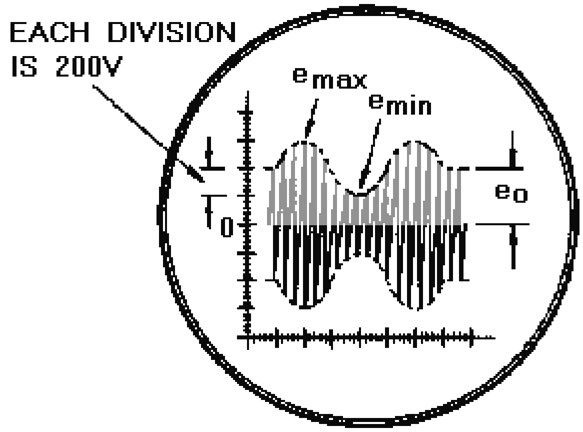


The **MODULATION ENVELOPE** is the waveform observed when the CARRIER, UPPER SIDEBAND, and LOWER SIDEBAND are combined in a single impedance and observed as time versus amplitude.



The **BANDWIDTH** of an rf signal is the amount of space in the frequency spectrum used by the signal.

PERCENT OF MODULATION is a measure of the relative magnitudes of the rf carrier and the af modulating signal.



$$\%M = \frac{e_{max} - e_{min}}{2e_o} \times 100$$

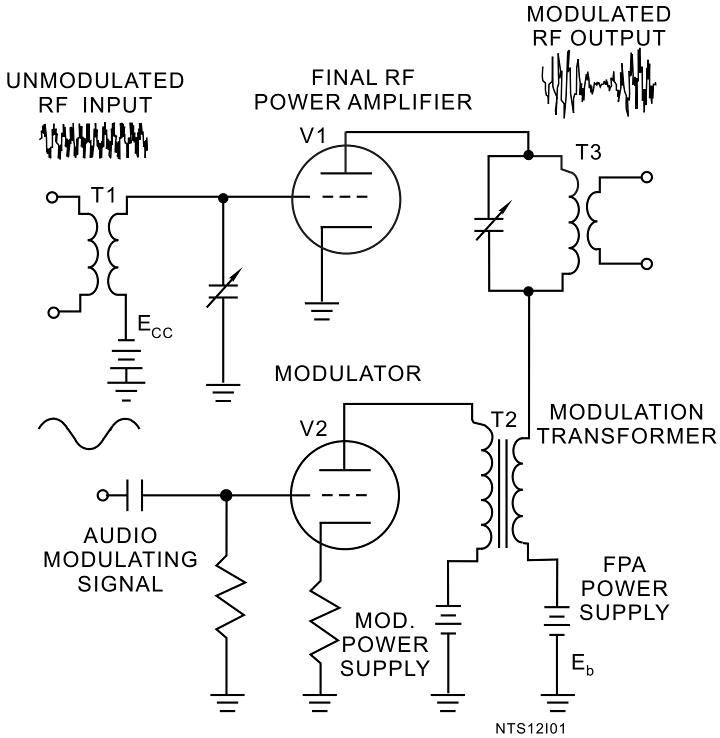
-OR-

$$\%M = \frac{e_{max} - e_{min}}{e_{max} + e_{min}} \times 100$$

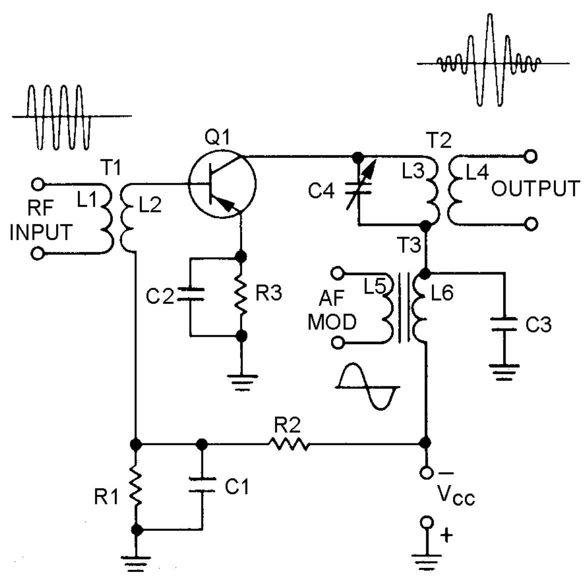
HIGH-LEVEL MODULATION is modulation produced in the plate circuit of the last radio stage of the system.

LOW-LEVEL MODULATION is modulation produced in an earlier stage than the final power amplifier.

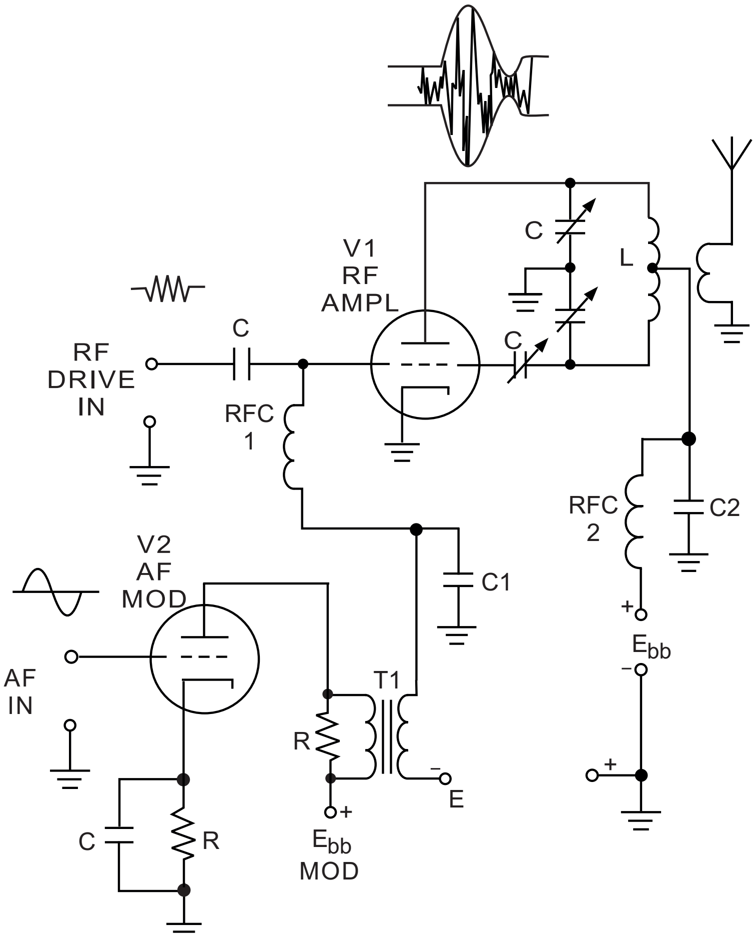
The **PLATE MODULATOR** is a high-level modulator. The modulator tube must be capable of varying the plate-supply voltage of the final power amplifier. It must vary the plate voltage so that the plate current pulses will vary between 0 and nearly twice their unmodulated value to achieve 100-percent modulation.



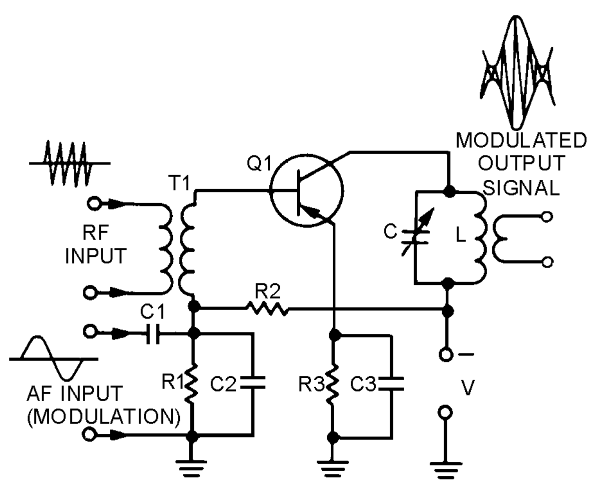
A **COLLECTOR-INJECTION MODULATOR** is a transistorized version of the plate modulator. It is classified as a high-level modulator, although present state-of-the-art transistors limit them to medium-power applications.



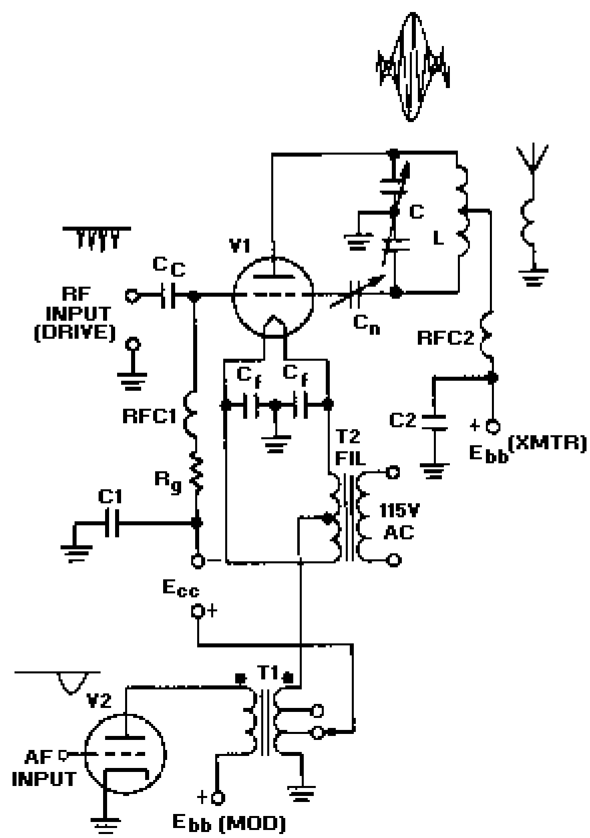
A **CONTROL-GRID MODULATOR** is a low-level modulator that is used where a minimum of af modulator power is desired. It is less efficient than a plate modulator and produces more distortion.



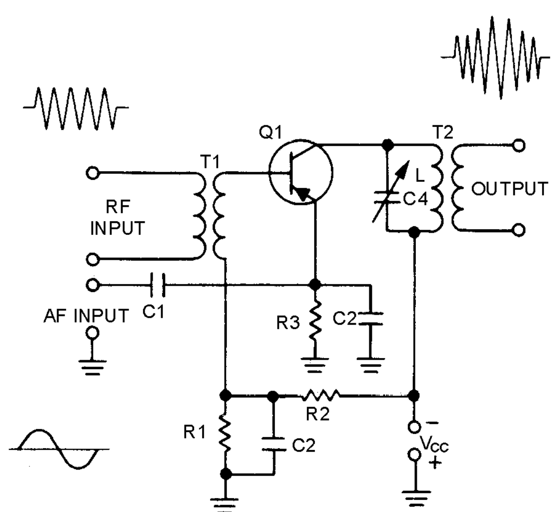
A **BASE-INJECTION MODULATOR** is used to produce low-level modulation in equipment operating at very low power levels. It is often used in small portable equipment and test equipment.



The **CATHODE MODULATOR** is a low-level modulator employed where the audio power is limited and the inherent distortion of the grid modulator cannot be tolerated.



The **EMITTER-INJECTION MODULATOR** is an extremely low-level modulator that is useful in portable equipment.



The primary disadvantages of AM modulation are susceptibility to NOISE INTERFERENCE and the INEFFICIENCY of the transmitter.

ANSWERS TO QUESTIONS Q1. THROUGH Q46.

A-1. Modulation is the impressing of intelligence on a transmission medium.

A-2. May be anything that transmits information, such as light, smoke, sound, wire lines, or radio-frequency waves.

A-3. Mixing two frequencies across a nonlinear impedance.

A-4. The process of recovering intelligence from a modulated carrier.

A-5. The sine wave.

A-6. To represent quantities that have both magnitude and direction.

A-7. Sine ! = opposite side ÷ hypotenuse.

A-8. $e = E_{max}$ *sine ! .*

A-9. The value at any given point on the sine wave.

A-10. Phase or phase angle.

A-11. The rate at which the vector which is generating the sine wave is rotating.

A-12. The elapsed time from the beginning of cycle to its completion.

A-13. Wavelength = rate of travel × period.

A-14. Process of combining two signal frequencies in a nonlinear device.

A-15. An impedance in which the resulting current is not proportional to the applied voltage.

A-16. The display of electromagnetic energy that is arranged according to wavelength or frequency.

A-17. At least two different frequencies applied to a nonlinear impedance.

A-18. Any method of modulating an electromagnetic carrier frequency by varying its amplitude in accordance with the intelligence.

A-19. A method of generating oscillations, a method of turning the oscillations on and off (keying), and an antenna to radiate the energy.

A-20. Plate keying and cathode keying.

A-21. Machine keying.

A-22. A high degree of clarity even under severe noise conditions, long-range operation, and narrow bandwidth.

A-23. Antenna-to-ground capacitance can cause the oscillator frequency to vary.

A-24. To isolate the oscillator from the antenna and increase the amplitude of the rf oscillations to the required output level.

A-25. To raise the low frequency of a stable oscillator to the vhf range.

A-26. An energy converter that changes sound energy into electrical energy.

A-27. The changing resistance of carbon granules as pressure is applied to them.

A-28. Background hiss resulting from random changes in the resistance between individual carbon granules.

A-29. The piezoelectric effect.

A-30. A dynamic microphone has a moving coil and the magnetic microphone has a moving armature.

A-31. Rf and af units.

A-32. 100 kilohertz, 5 kilohertz, 95 kilohertz, and 105 kilohertz.

A-33. All of the sum frequencies above the carrier.

A-34. The intelligence is contained in the spacing between the carrier and sideband frequencies.

A-35. The highest modulating frequency.

A-36. The depth or degree of modulation.

A-37. One-half the amplitude of the carrier.

A-38.

$$\%M = \frac{E_m}{E_c} \times 100$$

A-39. Modulation produced in the plate circuit of the last radio stage of the system.

A-40. Class C.

A-41. Power amplifier.

A-42. Between 0 and nearly two times its unmodulated value.

A-43. Plate modulator.

A-44. In cases when the use of a minimum of af modulator power is desired.

A-45. Low-level.

A-46. Gain is varied by changing the voltage on the emitter.

CHAPTER 2

ANGLE AND PULSE MODULATION

LEARNING OBJECTIVES

Upon completion of this chapter you will be able to:

1. Describe frequency-shift keying (fsk) and methods of providing this type of modulation.
2. Describe the development of frequency modulation (fm) and methods of frequency modulating a carrier.
3. Discuss the development of phase modulation (pm) and methods of phase modulating a carrier.
4. Describe phase-shift keying (psk), its generation, and application.
5. Discuss the development and characteristics of pulse modulation.
6. Describe the operation of the spark gap and thyratron modulators.
7. Discuss the characteristics of a pulse train that may be varied to provide communications capability.
8. Describe pulse-amplitude modulation (pam) and generation.
9. Describe pulse-duration modulation (pdm) and generation.
10. Describe pulse-position modulation (ppm) and generation.
11. Describe pulse-frequency modulation (pfm) and generation.
12. Describe pulse-code modulation (pcm) and generation.

INTRODUCTION

In chapter 1 you learned that modulation of a carrier frequency was necessary to allow fast communications between two points. As the volume of transmissions increased, a need for more reliable methods of communication was realized. In this chapter you will study angle modulation and pulse modulation. These two types of modulation have been developed to overcome one of the main disadvantages of amplitude modulation - susceptibility to noise interference. In addition, a special application of pulse type modulation for ranging and detection equipment will be discussed.

ANGLE MODULATION

ANGLE MODULATION is modulation in which the angle of a sine-wave carrier is varied by a modulating wave. FREQUENCY MODULATION (fm) and PHASE MODULATION (pm) are two types of angle modulation. In frequency modulation the modulating signal causes the carrier frequency to vary. These variations are controlled by both the frequency and the amplitude of the modulating wave. In phase modulation the phase of the carrier is controlled by the modulating waveform. Let's study these modulation methods for an understanding of their similarities and differences.

FREQUENCY-MODULATION SYSTEMS

In frequency modulation an audio signal is used to shift the frequency of an oscillator at an audio rate. The simplest form of this is seen in FREQUENCY-SHIFT KEYING (fsk). Frequency-shift keying is somewhat similar to continuous-wave keying (cw) in AM transmissions.

Frequency-Shift Keying

Consider figure 2-1, views (A) through (D). View (A) is a radio frequency (rf) carrier which is actually several thousand or million hertz. View (B) represents the intelligence to be transmitted as MARKS and SPACES. Recall that in cw transmission, this intelligence was applied to the rf carrier by interrupting the signal, as shown in view (C). The amplitude of the rf alternated between maximum and 0 volts. By comparing views (B) and (C), you can see the mark/space intelligence of the Morse code character on the rf. The spacing of the waveform in view (D) is an example of the same intelligence as it is applied to the frequency instead of the amplitude of the rf. This is simple frequency-shift keying of the same Morse code character.

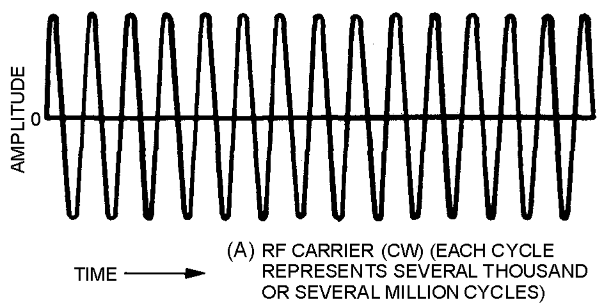


Figure 2-1A.—Comparison of ON-OFF and frequency-shift keying. RF CARRIER (CW) (EACH CYCLE REPRESENTS SEVERAL THOUSAND OR SEVERAL MILLION CYCLES).

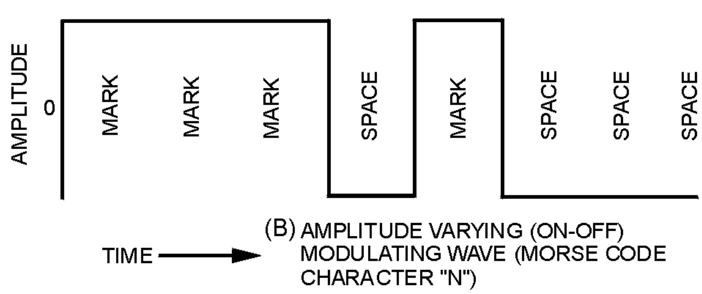

Figure 2-1B.—Comparison of ON-OFF and frequency-shift keying. AMPLITUDE VARYING (ON-OFF) MODULATING WAVE (MORSE CODE CHARACTER "N").

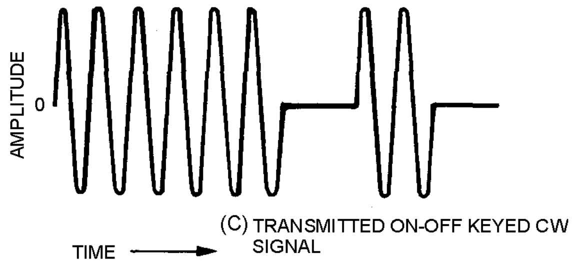

Figure 2-1C.—Comparison of ON-OFF and frequency-shift keying. TRANSMITTED ON-OFF KEYED CW SIGNAL.

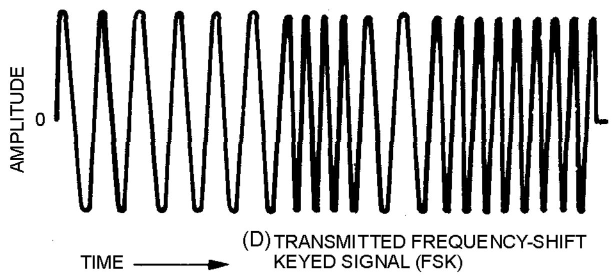

Figure 2-1D.—Comparison of ON-OFF and frequency-shift keying. TRANSMITTED FREQUENCY-SHIFT KEYED SIGNAL (FSK).

In fsk the output is abruptly changed between two differing frequencies by opening and closing the key. This is shown in view (D). For illustrative purposes, the spacing frequency in view (D) is shown as double the marking frequency. However, in practice the difference is usually less than 1,000 hertz, even when operating at several megahertz. You should also note that the limit of frequency shift is determined without reference to the amplitude of the keying signal in the fsk system. The frequency shift may be set at plus or minus 425 hertz from the allocated channel frequency. The total shift between mark and space would be 850 hertz. Either the mark or space may use the higher of the two frequencies. The upper frequency of the transmitted signal is usually the spacing interval and the lower frequency is the marking interval.

COMPARING FSK AND CW SIGNALS.—A comparison of on-off keyed cw (figure 2-2), (view (A), view (B), view (C)), and fsk (figure 2-3), (view (A), view (B), view (C)), signals will show clearly the principal features of fsk and give us a basis on which frequency modulation can be discussed. Let's use views (A), (B), and (C) of both figures to show the Morse code character "F" for an example. Figures 2-2 and 2-3 are graphic drawings of the two types of keying. Time and amplitude are known dimensions of AM; but to explain fsk properly, we have added the third dimension of frequency.

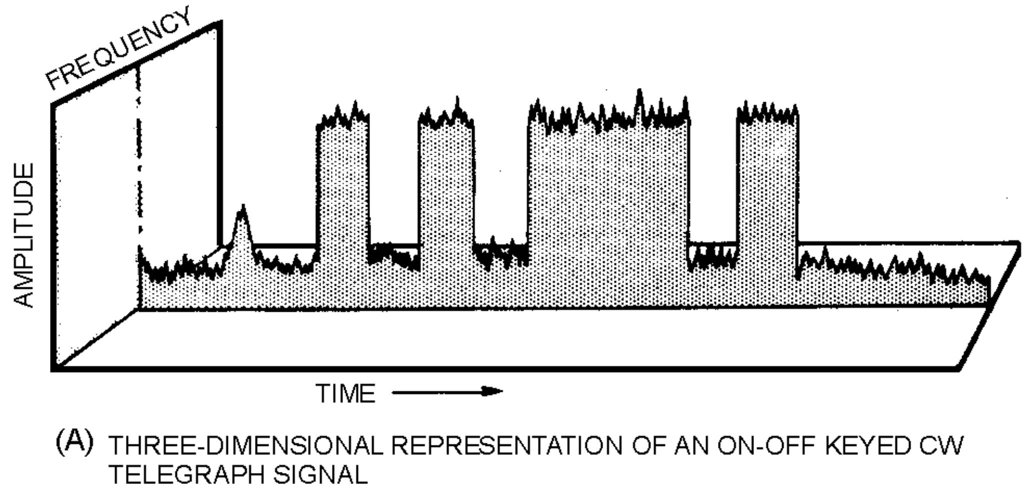

Figure 2-2A.—Comparison of AM and fm receiver response to an AM signal. THREE-DIMENSIONAL REPRESENTATION OF AN ON-OFF KEYED CW TELEGRAPH SIGNAL.

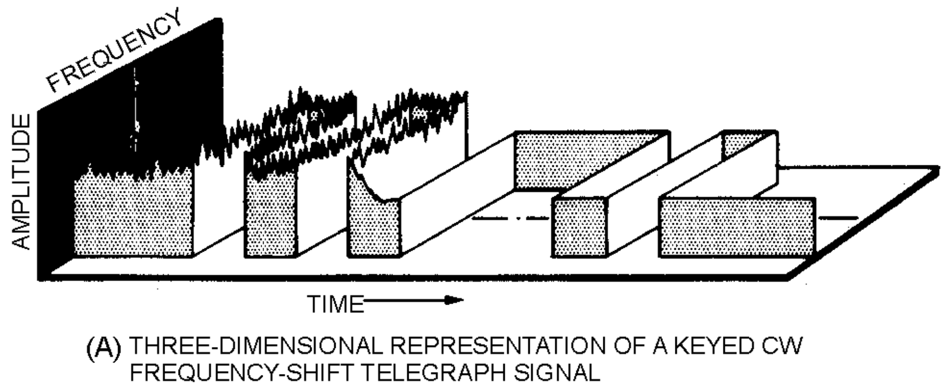

Figure 2-3A.—Comparison of AM and fm receiver response to an fm signal. THREE-DIMENSIONAL REPRESENTATION OF A FREQUENCY-SHIFT KEYED TELEGRAPH SIGNAL.

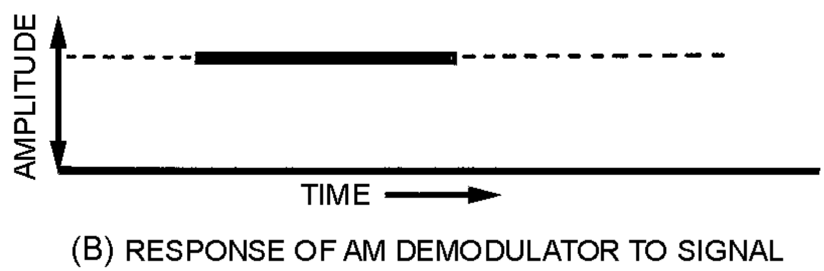

Figure 2-3B.—Comparison of AM and fm receiver response to an fm signal. RESPONSE OF AM DEMODULATOR TO SIGNAL.

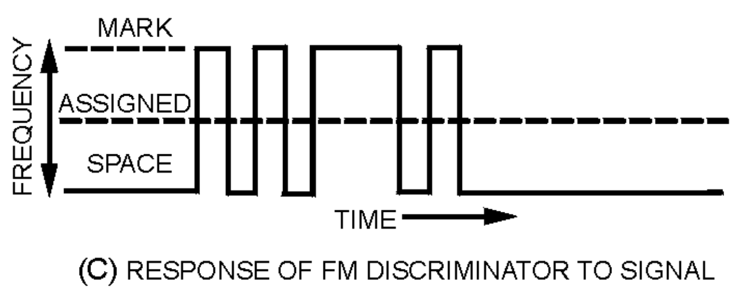

Figure 2-3C.—Comparison of AM and fm receiver response to an fm signal. RESPONSE OF FM DISCRIMINATOR TO SIGNAL.

CW SIGNALS.—Since cw signals are of essentially constant frequency, there is no variation along the frequency axis in view (A) of figure 2-2. The complete intelligence is carried as variations in the amplitude of the signal. To receive the intelligence carried by such a signal, the receiving equipment must be able to scan the signal along the time and amplitude axes, which carry the information. When scanned along the time and amplitude axes [shown in view (B)], the intelligence appears as large changes in amplitude. If the circuit were perfect, these variations would be from 0 amplitude to some maximum value (established by transmitter power, distance, and so forth) depending on whether the key were open or closed. However, interfering components of energy caused by atmospherics, interfering stations, and electrical machinery appear as additional variations along the amplitude axis. When these amplitude variations approach or exceed the variation caused by the keyed intelligence, the signal is blanked out by interference. We have all heard this happen on our AM radios during storms or when near operating machinery.

View (C) of figure 2-2 represents the same signal when scanned along the time and frequency axes as it would be in an fm receiver. Variations in signal amplitude have no effect on the frequency and no intelligence can be received. Note that the noise and interference components have also been suppressed so that they have little effect on the received signal. Thus, if the intelligence variations were impressed as changes along the frequency axis, and the receiving equipment were designed to respond to this type of signal, then the effects of noise and interference would be practically eliminated. Frequency-shift keyed circuits fulfill these conditions.

FSK SIGNALS.—In fsk the rf signal is shifted in frequency (not amplitude) between "key-open" and "key-closed" conditions. The signal amplitude remains essentially constant. View (A) of figure 2-3 represents the letter "F" keyed as a shift in frequency between mark and space. The normal frequency condition with the key open is a space. Recall that this may be either the lower or higher frequency. When the key is closed, the frequency instantly changes to the mark value and remains constant during the marking interval. Opening the key again returns the frequency to the space frequency. Midway between the mark and space frequencies is the assigned channel frequency.

Also shown in view (A) is the variation along the amplitude axis caused by the same noise and interference mentioned earlier. The right-hand portion of view (A) illustrates the elimination of this noise by the receiving equipment. View (B) clearly shows that scanning the signal along the amplitude and time axes reproduces no amplitude variations from signal interference. However, if the scanning is accomplished along the frequency and time axes, the intelligence is reproduced, as shown in view (C). By this system, the intelligence can be recovered at the receiving station in its original form; it will be nearly unaffected by conditions in the radio path other than fading. As a matter of fact, fsk resists the effects of fading better than cw.

FREQUENCY-SHIFT KEYING.—In its simplest form, frequency-shift keying of a transmitter can be accomplished by shunting a capacitor (or an inductor) and key (in series) across the oscillator circuit. By locking the normal key of the transmitter and operating only the oscillator circuit key, you can change the oscillator frequency. The shift in frequency between mark (key-closed) and space (key-open) conditions is determined by the effect of the additional capacitance (or inductance) on the oscillator frequency. The frequency multiplication factor in the transmitter amplifiers must be taken into consideration when determining the oscillator frequency shift. Thus, if the desired shift is the conventional 850 hertz at the transmission frequency, and this frequency is four times the oscillator frequency (that is, doubled in two stages), then the effect of the additional capacitance (or inductance) on the oscillator must be limited to 212.5 hertz as shown below:

$$\text{total frequency shift desired} = 850 \text{ hertz}$$

$$\text{multiplication factor per stage} = \times 2$$

$$\text{number of amplifier stages} = 2$$

$$\text{total multiplication factor} = 2 \times 2$$

$$\begin{aligned}\text{limiting value of capacitance/inductance} & \\ \text{in terms of frequency variation)} &= 4\,\overline{)\,850 \text{ hertz}} \\ &= 212.5 \text{ hertz}\end{aligned}$$

Frequency-shift keyers are, of course, more complicated than this simple illustration would seem to show, but the basic principles are the same. Still, the keyer does change the oscillator frequency by a certain number of cycles. Further, this change must be correlated with the multiplication factor of the transmitter to cause the desired shift between mark and space frequencies.

METHODS OF FREQUENCY SHIFTING.—Frequency-shift keyers operate on either of two general principles. First, the keyer may take the output of the transmitter's master oscillator and modulate it with the output of another oscillator that is frequency-shift keyed. This action will result in two frequencies that are used to excite the first amplifier stage of the transmitter. This system is illustrated in view (A) of figure 2-4. View (B) illustrates the second method of frequency-shift keyer operation. In this method the transmitter's master oscillator is itself shifted in frequency by the mark and space impulses from the keyer unit.

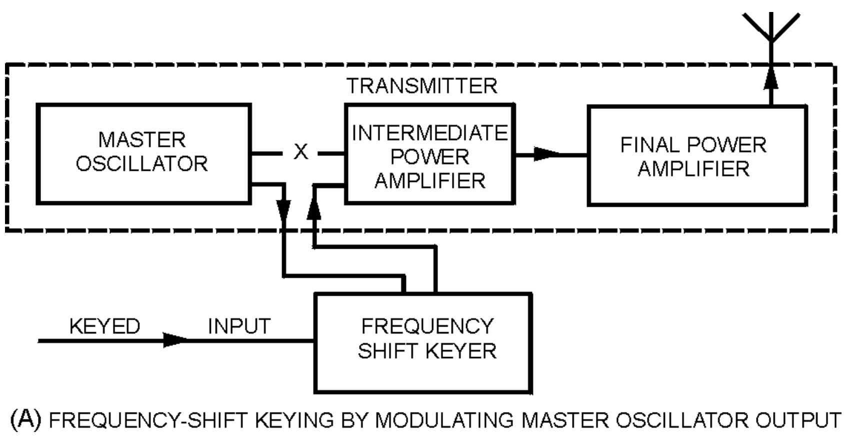

Figure 2-4A.—Two methods of frequency-shift keying (fsk). FREQUENCY-SHIFT KEYING BY MODULATING MASTER OSCILLATOR OUTPUT.

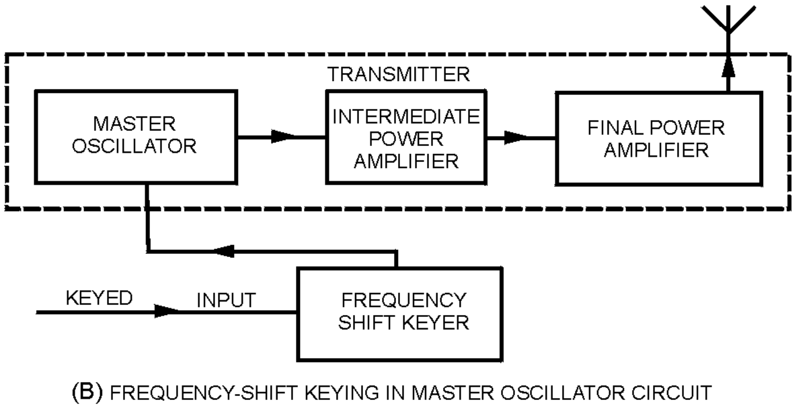

Figure 2-4B.—Two methods of frequency-shift keying (fsk). FREQUENCY-SHIFT KEYING IN MASTER OSCILLATOR CIRCUIT.

ADVANTAGES OF FSK OVER AM.—Frequency-shift keying is used in all single-channel, radiotelegraph systems that use automatic printing systems. The advantage of fsk over on-off keyed cw is that it rejects unwanted signals (noise) that are weaker than the desired signal. This is true of all fm systems. Also, since a signal is always present in the fsk receiver, automatic volume control methods may be used to minimize the effects of signal fading caused by ionospheric variations. The amount of inherent signal-to-noise ratio improvement of fsk over AM is approximately 3 to 4 dB. This improvement is because the signal energy of fsk is always present while signal energy is present for only one-half the time in AM systems. Noise is continuously present in both fsk and AM, but is eliminated in fsk reception. Under the rapid fading and high-noise conditions that commonly exist in the high frequency (hf) region, fsk shows a marked advantage over AM. Overall improvement is sometimes expressed as the RATIO OF TRANSMITTED POWERS required to give equivalent transmission results over the two systems. Such a ratio varies widely, depending on the prevailing conditions. With little fading, the ratio may be entirely the result of the improvement in signal-to-noise ratio and may be under 5 dB. However, under severe fading conditions, large amounts of power often fail to give good results for AM transmission. At the same time, fsk may be satisfactory at nominal power. The power ratio (fsk versus AM) would become infinite in such a case.

Another application of fsk is at low and very low frequencies (below 300 kilohertz). At these frequencies, keying speeds are limited by the "flywheel" effect of the extremely large capacitance and inductance of the antenna circuits. These circuits tend to oscillate at their resonant frequencies. Frequency-shifting the transmitter and changing the antenna resonance by the same keying impulses will result in much greater keying speeds. As a result, the use of these expensive channels is much more efficient.

Q-1. What are the two types of angle modulation?

Q-2. Name the modulation system in which the frequency alternates between two discrete values in response to the opening and closing of a key?

Q-3. What is the primary advantage of an fsk transmission system?

Frequency Modulation

In frequency modulation, the instantaneous frequency of the radio-frequency wave is varied in accordance with the modulating signal, as shown in view (A) of figure 2-5. As mentioned earlier, the amplitude is kept constant. This results in oscillations similar to those illustrated in view (B). The number of times per second that the instantaneous frequency is varied from the average (carrier frequency) is controlled by the *frequency* of the modulating signal. The amount by which the frequency departs from the average is controlled by the *amplitude* of the modulating signal. This variation is referred to as the FREQUENCY DEVIATION of the frequency-modulated wave. We can now establish two clear-cut rules for frequency deviation rate and amplitude in frequency modulation:

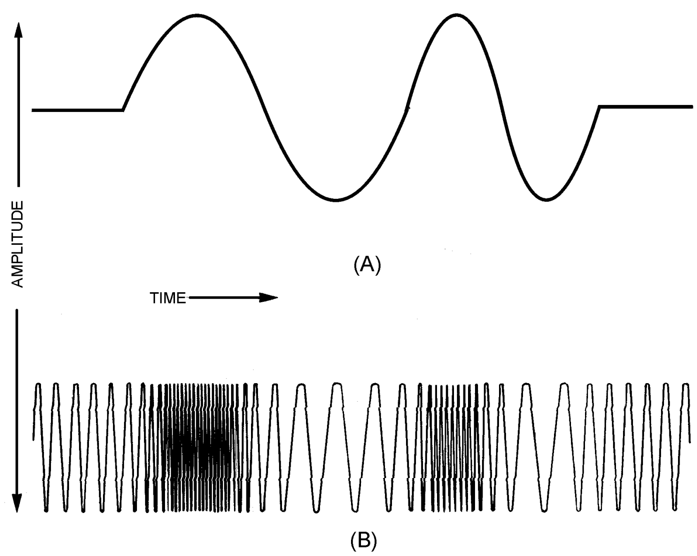

Figure 2-5.—Effect of frequency modulation on an rf carrier.

- *AMOUNT* OF FREQUENCY SHIFT IS PROPORTIONAL TO THE AMPLITUDE OF THE MODULATING SIGNAL

(This rule simply means that if a 10-volt signal causes a frequency shift of 20 kilohertz, then a 20-volt signal will cause a frequency shift of 40 kilohertz.)

- RATE OF FREQUENCY SHIFT IS PROPORTIONAL TO THE FREQUENCY OF THE MODULATING SIGNAL

(This second rule means that if the carrier is modulated with a 1-kilohertz tone, then the carrier is changing frequency 1,000 times each second.)

Figure 2-6 illustrates a simple oscillator circuit with the addition of a condenser microphone (M) in shunt with the oscillator tank circuit. Although the condenser microphone capacitance is actually very low, the capacitance of this microphone will be considered near that of the tuning capacitor (C). The frequency of oscillation in this circuit is, of course, determined by the LC product of all elements of the circuit; but, the product of the inductance (L) and the combined capacitance of C and M are the primary frequency components. When no sound waves strike M, the frequency is the rf carrier frequency. Any excitation of M will alter its capacitance and, therefore, the frequency of the oscillator circuit. Figure 2-7 illustrates what happens to the capacitance of the microphone during excitation. In view (A), the audio-frequency wave has three levels of intensity, shown as **X**, a whisper; **Y**, a normal voice; and **Z**, a loud voice. In view (B), the same conditions of intensity are repeated, but this time at a frequency twice that of view (A). Note in each case that the capacitance changes both positively and negatively; thus the frequency of oscillation alternates both above and below the resting frequency. The amount of change is determined by the change in capacitance of the microphone. The change is caused by the amplitude of the sound wave exciting the microphone. The rate at which the change in frequency occurs is determined by the rate at which the capacitance of the microphone changes. This rate of change is caused by the frequency of the sound wave. For example, suppose a 1,000-hertz tone of a certain loudness strikes the microphone. The frequency of the carrier will then shift by a certain amount, say plus and minus 40 kilohertz. The carrier will be shifted 1,000 times per second. Now assume that with its loudness unchanged, the frequency of the tone is changed to 4,000 hertz. The carrier frequency will still shift plus and minus 40 kilohertz; but now it will shift at a rate of 4,000 times per second. Likewise, assume that at the same loudness, the tone is reduced to 200 hertz. The carrier will continue to shift plus and minus 40 kilohertz, but now at a rate of 200 times per second. If the loudness of any of these modulating tones is reduced by one-half, the frequency of the carrier will be shifted plus and minus 20 kilohertz. The carrier will then shift at the same rate as before. This fulfills all requirements for frequency modulation. Both the frequency and the amplitude of the modulating signal are translated into variations in the frequency of the rf carrier.

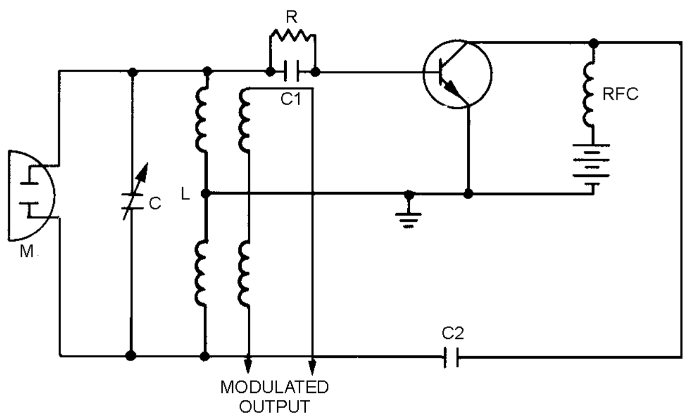

Figure 2-6.—Oscillator circuit illustrating frequency modulation.

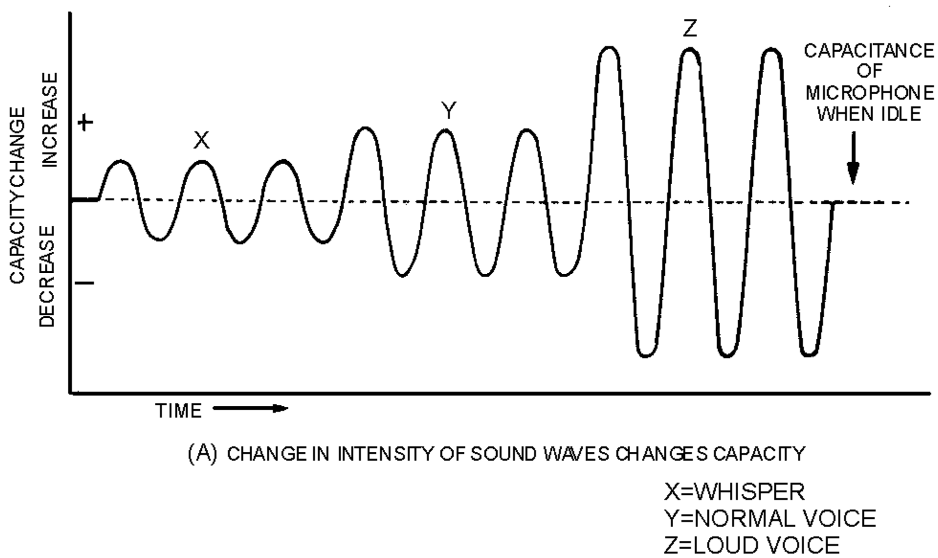

Figure 2-7A.—Capacitance change in an oscillator circuit during modulation. CHANGE IN INTENSITY OF SOUND WAVES CHANGES CAPACITY.

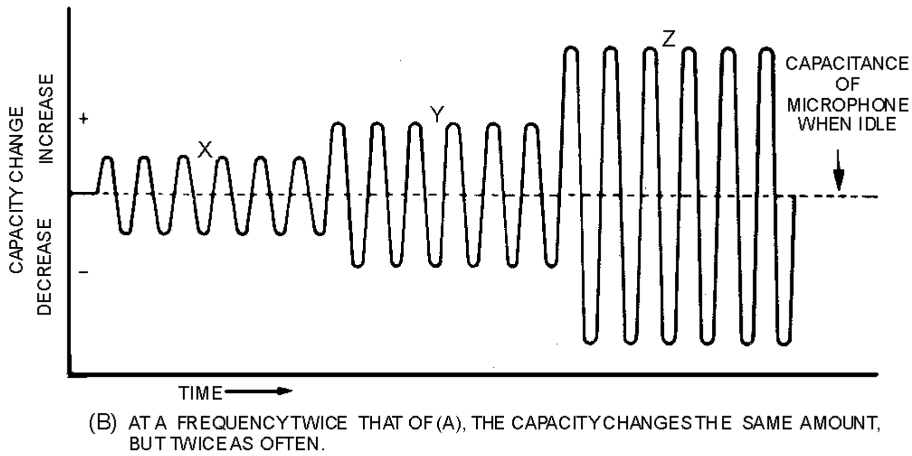

Figure 2-7B.—Capacitance change in an oscillator circuit during modulation. AT A FREQUENCY TWICE THAT OF (A), THE CAPACITY CHANGES THE SAME AMOUNT, BUT TWICE AS OFTEN.

Figure 2-8 shows how the frequency shift of an fm signal goes through the same variations as does the modulating signal. In this figure the dimension of the constant amplitude is omitted. (As these remaining waveforms are presented, be sure you take plenty of time to study and digest what the figures tell you. Look each one over carefully, noting everything you can about them. Doing this will help you understand this material.) If the maximum frequency deviation is set at 75 kilohertz above and below the carrier, the audio amplitude of the modulating wave must be so adjusted that its peaks drive the frequency only between these limits. This can then be referred to as 100-PERCENT MODULATION, although the term is only remotely applicable to fm. Projections along the vertical axis represent deviations in frequency from the resting frequency (carrier) in terms of audio amplitude. Projections along the horizontal axis represent time. The distance between **A** and **B** represents 0.001 second. This means that carrier deviations from the resting frequency to plus 75 kilohertz, then to minus 75 kilohertz, and finally back to rest would occur 1,000 times per second. This would equate to an audio frequency of 1,000 hertz. Since the carrier deviation for this period (**A** to **B**) extends to the full allowable limits of plus and minus 75 kilohertz, the wave is fully modulated. The distance from **C** to **D** is the same as that from **A** to **B**, so the time interval and frequency are the same as before. Notice, however, that the amplitude of the modulating wave has been decreased so that the carrier is driven to only plus and minus 37.5 kilohertz, one-half the allowable deviation. This would correspond to only 50-percent modulation if the system were AM instead of fm. Between **E** and **F**, the interval is reduced to 0.0005 second. This indicates an increase in frequency of the modulating signal to 2,000 hertz. The amplitude has returned to its maximum allowable value, as indicated by the deviation of the carrier to plus and minus 75 kilohertz. Interval **G** to **H** represents the same frequency at a lower modulation amplitude (66 percent). Notice the GUARD BANDS between plus and minus 75 kilohertz and plus and minus 100 kilohertz. These bands isolate the modulation extremes of this particular channel from that of adjacent channels.

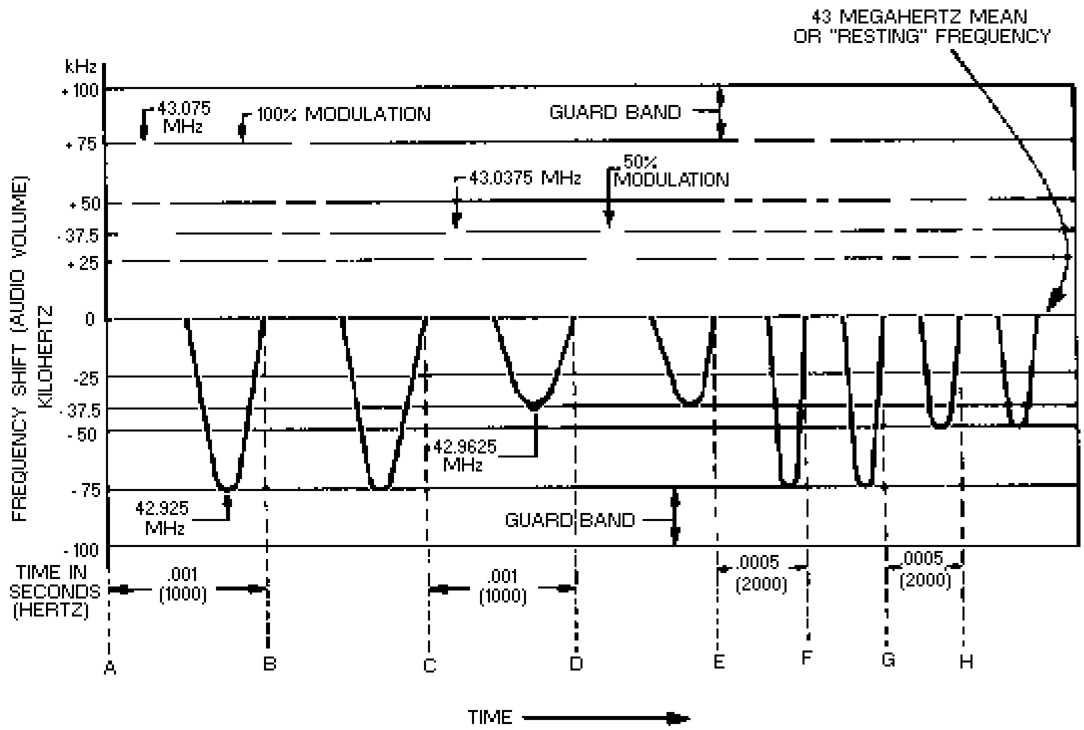

Figure 2-8.—Frequency-modulating signal.

PERCENT OF MODULATION.—Before we explain 100-percent modulation in an fm system, let's review the conditions for 100-percent modulation of an AM wave. Recall that 100-percent modulation for AM exists when the amplitude of the modulation envelope varies between 0 volts and twice its normal unmodulated value. At 100-percent modulation there is a power increase of 50 percent. Because the modulating wave is not constant in voice signals, the degree of modulation constantly varies. In this case the vacuum tubes in an AM system cannot be operated at maximum efficiency because of varying power requirements.

In frequency modulation, 100-percent modulation has a meaning different from that of AM. The modulating signal varies only the frequency of the carrier. Therefore, tubes do not have varying power requirements and can be operated at maximum efficiency and the fm signal has a constant power output. In fm a modulation of 100 percent simply means that the carrier is deviated in frequency by the full permissible amount. For example, an 88.5-megahertz fm station operates at 100-percent modulation when the modulating signal deviation frequency band is from 75 kilohertz above to 75 kilohertz below the carrier (the maximum allowable limits). This maximum deviation frequency is set arbitrarily and will vary according to the applications of a given fm transmitter. In the case given above, 50-percent modulation would mean that the carrier was deviated 37.5 kilohertz above and below the resting frequency (50 percent of the 150-kilohertz band divided by 2). Other assignments for fm service may limit the allowable deviation to 50 kilohertz, or even 10 kilohertz. Since there is no fixed value for comparison, the term "percent of modulation" has little meaning for fm. The term MODULATION INDEX is more useful in fm modulation discussions. Modulation index is frequency deviation divided by the frequency of the modulating signal.

MODULATION INDEX.—This ratio of frequency deviation to frequency of the modulating signal is useful because it also describes the ratio of amplitude to tone for the audio signal. These factors determine the number and spacing of the side frequencies of the transmitted signal. The modulation index formula is shown below:

$$\text{modulation index} = \frac{\Delta f}{f_m}$$

Where:

Δf = frequency deviation
f_m = modulating frequency

Views (A) and (B) of figure 2-9 show the frequency spectrum for various fm signals. In the four examples of view (A), the modulating frequency is constant; the deviation frequency is changed to show the effects of modulation indexes of 0.5, 1.0, 5.0, and 10.0. In view (B) the deviation frequency is held constant and the modulating frequency is varied to give the same modulation indexes.

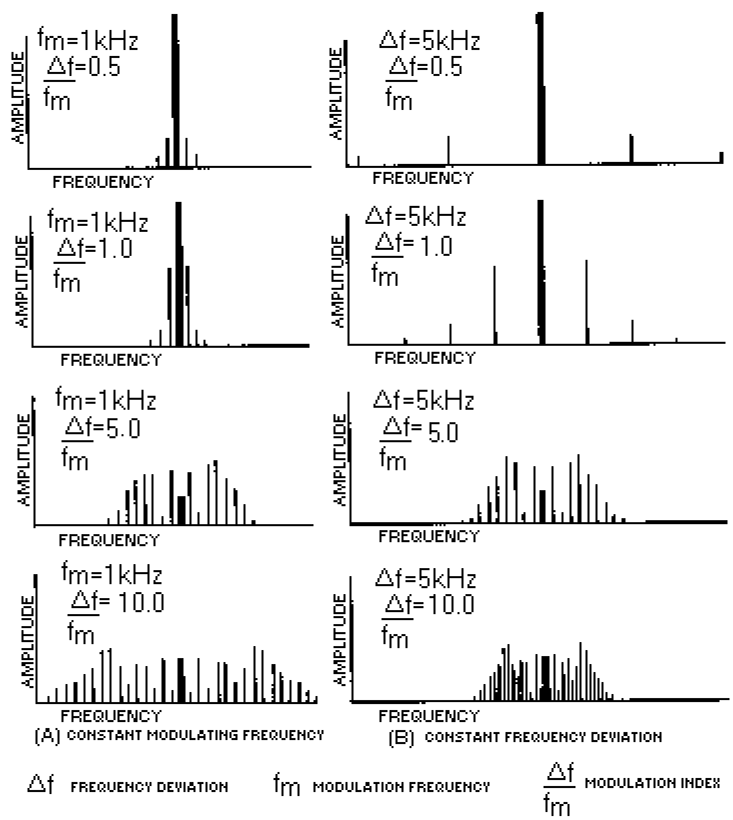

Figure 2-9.—Frequency spectra of fm waves under various conditions.

You can determine several facts about fm signals by studying the frequency spectrum. For example, table 2-1 was developed from the information in figure 2-9. Notice in the top spectrums of both views (A) and (B) that the modulation index is 0.5. Also notice as you look at the next lower spectrums that the modulation index is 1.0. Next down is 5.0, and finally, the bottom spectrums have modulation indexes of

10.0. This information was used to develop table 2-1 by listing the modulation indexes in the left column and the number of significant sidebands in the right. SIGNIFICANT SIDEBANDS (those with significantly large amplitudes) are shown in both views of figure 2-9 as vertical lines on each side of the carrier frequency. Actually, an infinite number of sidebands are produced, but only a small portion of them are of sufficient amplitude to be important. For example, for a modulation index of 0.5 [top spectrums of both views (A) and (B)], the number of significant sidebands counted is 4. For the next spectrums down, the modulation index is 1.0 and the number of sidebands is 6, and so forth. This holds true for any combination of deviating and modulating frequencies that yield identical modulating indexes.

Table 2-1.—Modulation index table

MODULATION INDEX	SIGNIFICANT SIDEBANDS
.01	2
.4	2
.5	4
1.0	6
2.0	8
3.0	12
4.0	14
5.0	16
6.0	18
7.0	22
8.0	24
9.0	26
10.0	28
11.0	32
12.0	32
13.0	36
14.0	38
15.0	38

You should be able to see by studying figure 2-9, views (A) and (B), that the modulating frequency determines the spacing of the sideband frequencies. By using a significant sidebands table (such as table 2-1), you can determine the bandwidth of a given fm signal. Figure 2-10 illustrates the use of this table. The carrier frequency shown is 500 kilohertz. The modulating frequency is 15 kilohertz and the deviation frequency is 75 kilohertz.

$$\Delta f = 75kHz$$

$$f_m = 15kHz$$

$$MI = \frac{\Delta f}{f_m}$$

$$MI = \frac{75kHz}{15kHz}$$

$$MI = 5$$

77

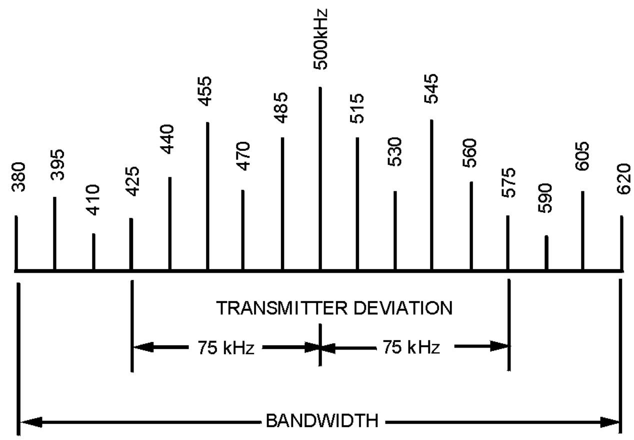

Figure 2-10.—Frequency deviation versus bandwidth.

From table 2-1 we see that there are 16 significant sidebands for a modulation index of 5. To determine total bandwidth for this case, we use:

$$bw = \text{modulating frequency} \times \text{no. of significant sidebands}$$

$$bw = 15kHz \times 16$$

$$bw = 240kHz$$

The use of this math is to illustrate that the actual bandwidth of an fm transmitter (240 kHz) is greater than that suggested by its maximum deviation bandwidth (±75 kHz or 150 kHz). This is important to know when choosing operating frequencies or designing equipment.

Q-4. What characteristic of a carrier wave is varied in frequency modulation?

Q-5. How is the degree of modulation expressed in an fm system?

Q-6. What two values may be used to determine the bandwidth of an fm wave?

METHODS OF FREQUENCY MODULATION.—The circuit shown earlier in figure 2-6 and the discussion in previous paragraphs were for illustrative purposes only. In reality, such a circuit would not be practical. However, the basic principle involved (the change in reactance of an oscillator circuit in accordance with the modulating voltage) constitutes one of the methods of developing a frequency-modulated wave.

Reactance-Tube Modulation.—In direct modulation, an oscillator is frequency modulated by a REACTANCE TUBE that is in parallel (SHUNT) with the oscillator tank circuit. (The terms "shunt" or "shunting" will be used in this module to mean the same as "parallel" or "to place in parallel with" components.) This is illustrated in figure 2-11. The oscillator is a conventional Hartley circuit with the reactance-tube circuit in parallel with the tank circuit of the oscillator tube. The reactance tube is an ordinary pentode. It is made to act either capacitively or inductively; that is, its grid is excited with a voltage which either leads or lags the oscillator voltage by 90 degrees.

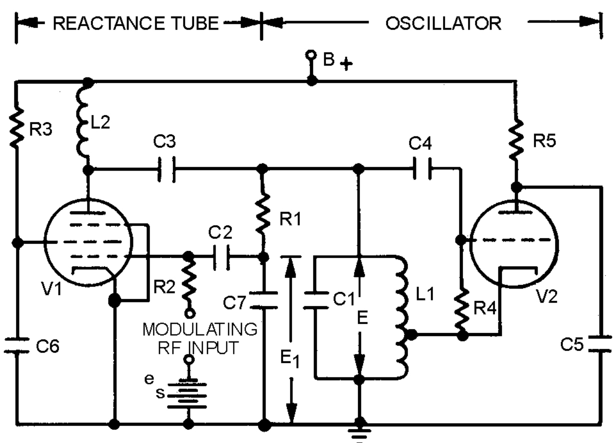

Figure 2-11.—Reactance-tube fm modulator.

When the reactance tube is connected across the tank circuit with no modulating voltage applied, it will affect the frequency of the oscillator. The voltage across the oscillator tank circuit (L1 and C1) is also in parallel with the series network of R1 and C7. This voltage causes a current flow through R1 and C7. If R1 is at least five times larger than the capacitive reactance of C7, this branch of the circuit will be essentially resistive. Voltage E_1, which is across C7, will lag current by 90 degrees. E_1 is applied to the control grid of reactance tube V1. This changes plate current (I_p), which essentially flows only through the LC tank circuit. This is because the value of R1 is high compared to the impedance of the tank circuit. Since current is inversely proportional to impedance, most of the plate current coupled through C3 flows through the tank circuit.

At resonance, the voltage and current in the tank circuit are in phase. Because E_1 lags E by 90 degrees and I is in phase with grid voltage E_1, the superimposed current through the tank circuit lags the original tank current by 90 degrees. Both the resultant current (caused by I_p) and the tank current lag tank voltage and current by some angle depending on the relative amplitudes of the two currents. Because this resultant current is a lagging current, the impedance across the tank circuit cannot be at its maximum unless something happens within the tank to bring current and voltage into phase. Therefore, this situation continues until the frequency of oscillations in the tank circuit changes sufficiently so that the voltages across the tank and the current flowing into it are again in phase. This action is the same as would be produced by adding a reactance in parallel with the L1C1 tank. Because the superimposed current lags voltage E by 90 degrees, the introduced reactance is inductive. In *NEETS*, Module 2, *Introduction to*

Alternating Current and Transformers, you learned that total inductance decreases as additional inductors are added in parallel. Because this introduced reactance effectively reduces inductance, the frequency of the oscillator increases to a new fixed value.

Now let's see what happens when a modulating signal is applied. The magnitude of the introduced reactance is determined by the magnitude of the superimposed current through the tank. The magnitude of I_p for a given E_1 is determined by the transconductance of V1. (Transconductance was covered in *NEETS*, Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies.*) Therefore, the value of reactance introduced into the tuned circuit varies directly with the transconductance of the reactance tube. When a modulating signal is applied to the grid of V1, both E_1 and I change, causing transconductance to vary with the modulating signal. This causes a variable reactance to be introduced into the tuned circuit. This variable reactance either adds to or subtracts from the fixed value of reactance that is introduced in the absence of the modulating signal. This action varies the reactance across the oscillator which, in turn, varies the instantaneous frequency of the oscillator. These variations in the oscillator frequency are proportional to the instantaneous amplitude of the modulating voltage. Reactance-tube modulators are usually operated at low power levels. The required output power is developed in power amplifier stages that follow the modulators.

The output of a reactance-tube modulated oscillator also contains some unwanted amplitude modulation. This unwanted modulation is caused by stray capacitance and the resistive component of the RC phase splitter. The resistance is much less significant than the desired X_C, but the resistance does allow some plate current to flow which is not of the proper phase relationship for good tube operation. The small amplitude modulation that this produces is easily removed by passing the oscillator output through a limiter-amplifier circuit.

Semiconductor Reactance Modulator.—The SEMICONDUCTOR-REACTANCE MODULATOR is used to frequency modulate low-power semiconductor transmitters. Figure 2-12 shows a typical frequency-modulated oscillator stage operated as a reactance modulator. Q1, along with its associated circuitry, is the oscillator. Q2 is the modulator and is connected to the circuit so that its collector-to-emitter capacitance (C_{CE}) is in parallel with a portion of the rf oscillator coil, L1. As the modulator operates, the output capacitance of Q2 is varied. Thus, the frequency of the oscillator is shifted in accordance with the modulation the same as if C1 were varied.

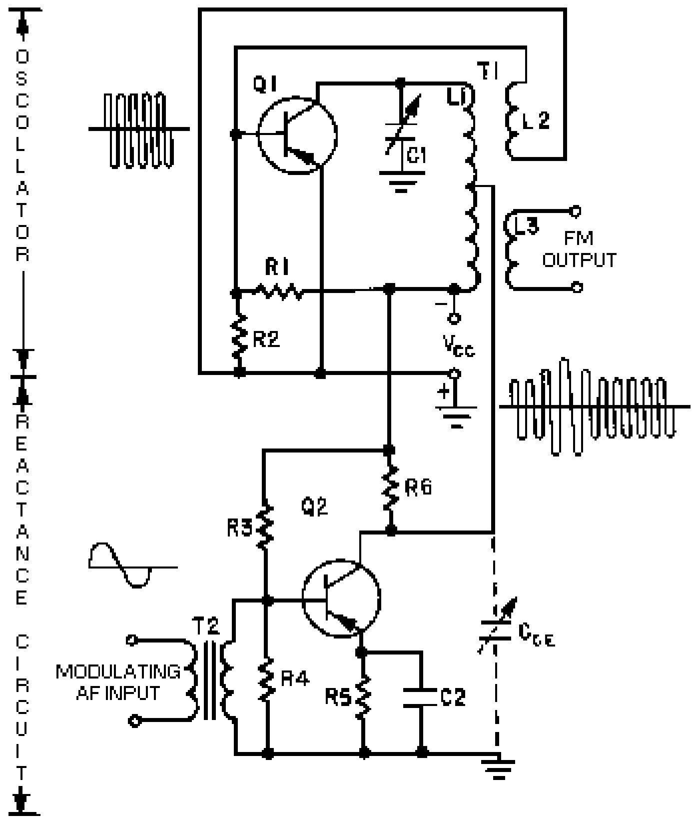

Figure 2-12.—Reactance-semiconductor fm modulator.

When the modulating signal is applied to the base of Q2, the emitter-to-base bias varies at the modulation rate. This causes the collector voltage of Q2 to vary at the same modulating rate. When the collector voltage increases, output capacitance C_{CE} decreases; when the collector voltage decreases, C_{CE} increases. An *increase* in collector voltage has the effect of spreading the plates of C_{CE} farther apart by increasing the width of the barrier. A *decrease* of collector voltage reduces the width of the pn junction and has the same effect as pushing the capacitor plates together to provide more capacitance.

When the output capacitance *decreases*, the instantaneous frequency of the oscillator tank circuit increases (acts the same as if C1 were decreased). When the output capacitance *increases*, the instantaneous frequency of the oscillator tank circuit decreases. This decrease in frequency produces a lower frequency in the output because of the shunting effect of C_{CE}. Thus, the frequency of the oscillator tank circuit increases and decreases at an audio frequency (af) modulating rate. The output of the oscillator, therefore, is a frequency modulated rf signal.

Since the audio modulation causes the collector voltage to increase and decrease, an AM component is induced into the output. This produces both an fm and AM output. The amplitude variations are then removed by placing a limiter stage after the reactance modulator and only the frequency modulation remains.

Frequency multipliers or mixers (discussed in chapter 1) are used to increase the oscillator frequency to the desired output frequency. For high-power applications, linear rf amplifiers are used to increase the steady-amplitude signal to a higher power output. With the initial modulation occurring at low levels, fm represents a savings of power when compared to conventional AM. This is because fm noise-reducing properties provide a better signal-to-noise ratio than is possible with AM.

Multivibrator Modulator.—Another type of frequency modulator is the astable multivibrator illustrated in figure 2-13. Inserting the modulating af voltage in series with the base-return of the multivibrator transistors causes the gate length, and thus the fundamental frequency of the multivibrator, to vary. The amount of variation will be in accordance with the amplitude of the modulating voltage. One requirement of this method is that the fundamental frequency of the multivibrator be high in relation to the highest modulating frequencies. A factor of at least 100 provides the best results.

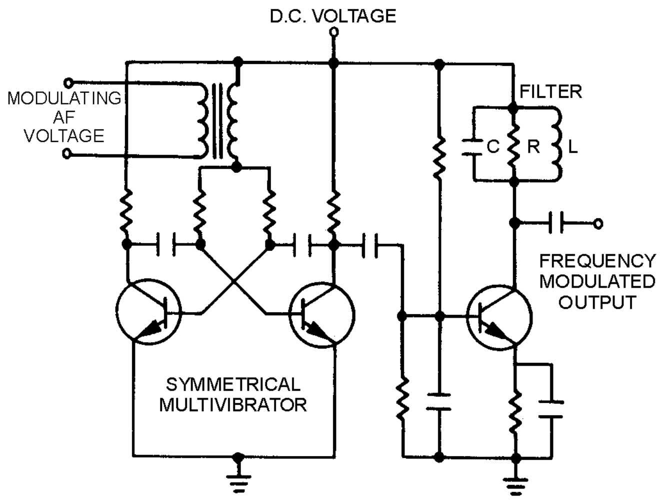

Figure 2-13.—Astable multivibrator and filter circuit for generating an fm carrier.

Recall that a multivibrator output consists of the fundamental frequency and all of its harmonics. Unwanted even harmonics are eliminated by using a SYMMETRICAL MULTIVIBRATOR circuit, as shown in figure 2-13. The desired fundamental frequency, or desired odd harmonics, can be amplified after all other odd harmonics are eliminated in the LCR filter section of figure 2-13. A single frequency-modulated carrier is then made available for further amplification and transmission.

Proper design of the multivibrator will cause the frequency deviation of the carrier to faithfully follow (referred to as a "linear" function) the modulating voltage. This is true up to frequency deviations which are considerable fractions of the fundamental frequency of the multivibrator. The principal design consideration is that the RC coupling from one multivibrator transistor base to the collector of the other has a time constant which is greater than the actual gate length by a factor of 10 or more. Under these conditions, a rise in base voltage in each transistor is essentially linear from cutoff to the bias at which the transistor is switched on. Since this rise in base voltage is a linear function of time, the gate length will change as an inverse function of the modulating voltage. This action will cause the frequency to change as a linear function of the modulating voltage.

The multivibrator frequency modulator has the advantage over the reactance-type modulator of a greater linear frequency deviation from a given carrier frequency. However, multivibrators are limited to frequencies below about 1 megahertz. Both systems are subject to drift of the carrier frequency and must, therefore, be stabilized. Stabilization may be accomplished by modulating at a relatively low frequency and translating by heterodyne action to the desired output frequency, as shown in figure 2-14. A 1-megahertz signal is heterodyned with 49 megahertz from the crystal-controlled oscillator to provide a stable 50-megahertz output from the mixer. If a suitably stable heterodyning oscillator is used, the frequency stability can be greatly improved. For instance, at the frequencies shown in figure 2-14, the stability of the unmodulated 50-megahertz carrier would be 50 times better than that which harmonic multiplication could provide.

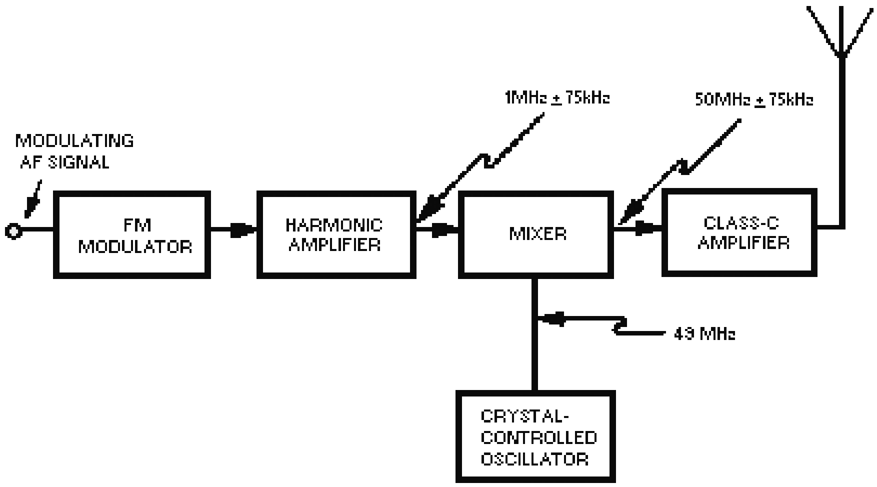

Figure 2-14.—Method for improving frequency stability of fm system.

Varactor FM Modulator.—Another fm modulator which is widely used in transistorized circuitry uses a voltage-variable capacitor (VARACTOR). The varactor is simply a diode, or pn junction, that is designed to have a certain amount of capacitance between junctions. View (A) of figure 2-15 shows the varactor schematic symbol. A diagram of a varactor in a simple oscillator circuit is shown in view (B). This is not a working circuit, but merely a simplified illustration. The capacitance of a varactor, as with regular capacitors, is determined by the area of the capacitor plates and the distance between the plates. The depletion region in the varactor is the dielectric and is located between the p and n elements, which serve as the plates. Capacitance is varied in the varactor by varying the reverse bias which controls the thickness of the depletion region. The varactor is so designed that the change in capacitance is linear with the change in the applied voltage. This is a special design characteristic of the varactor diode. The varactor must not be forward biased because it cannot tolerate much current flow. Proper circuit design prevents the application of forward bias.

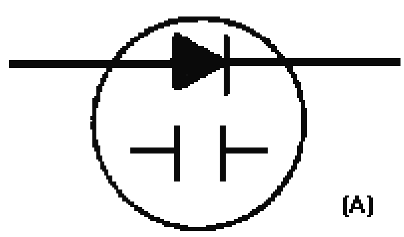

Figure 2-15A.—Varactor symbol and schematic. SCHEMATIC SYMBOL.

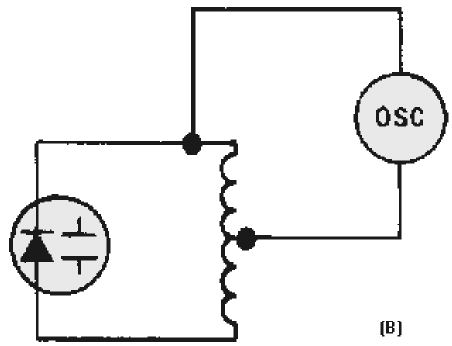

Figure 2-15B.—Varactor symbol and schematic. SIMPLIFIED CIRCUIT.

Notice the simplicity of operation of the circuit in figure 2-16. An af signal that is applied to the input results in the following actions: (1) On the positive alternation, reverse bias increases and the dielectric (depletion region) width increases. This decreases capacitance which increases the frequency of the oscillator. (2) On the negative alternation, the reverse bias decreases, which results in a decrease in oscillator frequency.

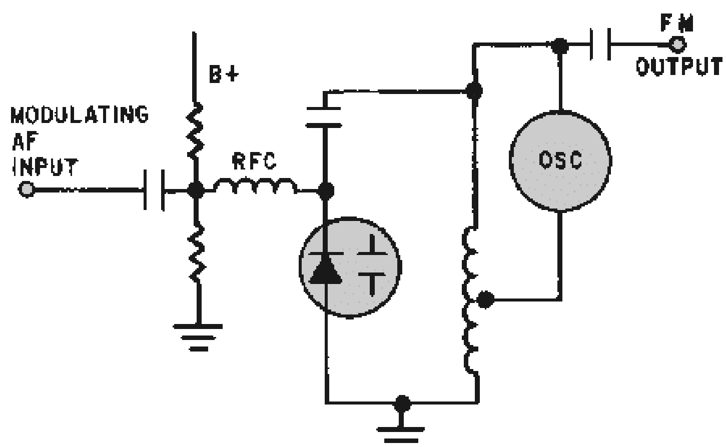

Figure 2-16.—Varactor fm modulator.

Many different fm modulators are available, but they all use the basic principles you have just studied. The main point to remember is that an oscillator must be used to establish the reference (carrier) frequency. Secondly, some method is needed to cause the oscillator to change frequency in accordance with an af signal. Anytime this can be accomplished, we have a frequency modulator.

Q-7. How does the reactance-tube modulator impress intelligence onto an rf carrier?

Q-8. What characteristic of a transistor is varied in a semiconductor-reactance modulator?

Q-9. What circuit section is required in the output of a multivibrator modulator to eliminate unwanted output frequencies?

Q-10. What characteristic of a varactor is used in an fm modulator?

PHASE MODULATION

Frequency modulation requires the oscillator frequency to deviate both above and below the carrier frequency. During the process of frequency modulation, the peaks of each successive cycle in the modulated waveform occur at times other than they would if the carrier were unmodulated. This is actually an incidental phase shift that takes place along with the frequency shift in fm. Just the opposite action takes place in phase modulation. The af signal is applied to a PHASE MODULATOR in pm. The resultant wave from the phase modulator shifts in phase, as illustrated in figure 2-17. Notice that the time period of each successive cycle varies in the modulated wave according to the audio-wave variation. Since frequency is a function of time period per cycle, we can see that such a phase shift in the carrier will cause its frequency to change. The frequency change in fm is vital, but in pm it is merely incidental. The amount of frequency change has nothing to do with the resultant modulated wave shape in pm. At this point the comparison of fm to pm may seem a little hazy, but it will clear up as we progress.

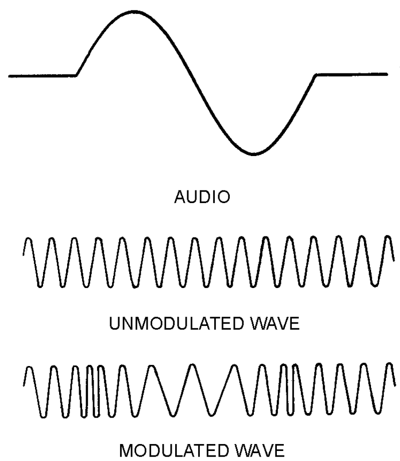

Figure 2-17.—Phase modulation.

Let's review some voltage phase relationships. Look at figure 2-18 and compare the three voltages (**A**, **B**, and **C**). Since voltage **A** begins its cycle and reaches its peak before voltage **B**, it is said to *lead* voltage **B**. Voltage **C**, on the other hand, *lags* voltage **B** by 30 degrees. In phase modulation the phase of the carrier is caused to shift at the rate of the af modulating signal. In figure 2-19, note that the unmodulated carrier has constant phase, amplitude, and frequency. The dotted wave shape represents the modulated carrier. Notice that the phase on the second peak leads the phase of the unmodulated carrier. On the third peak the shift is even greater; however, on-the fourth peak, the peaks begin to realign phase with each other. These relationships represent the effect of 1/2 cycle of an af modulating signal. On the negative alternation of the af intelligence, the phase of the carrier would lag and the peaks would occur at times later than they would in the unmodulated carrier.

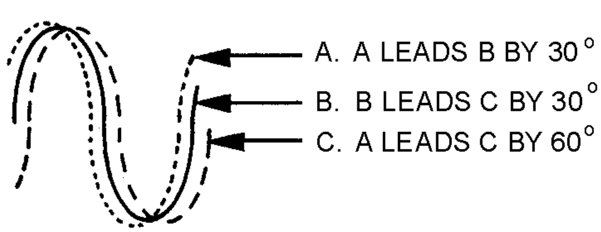

Figure 2-18.—Phase relationships.

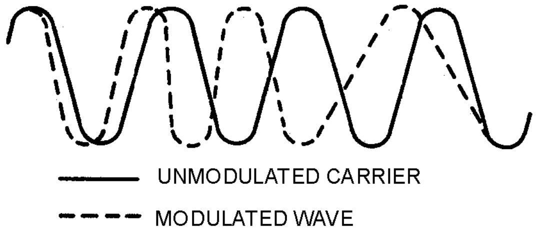

Figure 2-19.—Carrier with and without modulation.

The presentation of these two waves together does not mean that we transmit a modulated wave together with an unmodulated carrier. The two waveforms were drawn together only to show how a modulated wave looks when compared to an unmodulated wave.

Now that you have seen the phase and frequency shifts in both fm and pm, let's find out exactly how they differ. First, only the phase shift is important in pm. It is proportional to the af modulating signal. To visualize this relationship, refer to the wave shapes shown in figure 2-20. Study the composition of the fm and pm waves carefully as they are modulated with the modulating wave shape. Notice that in fm, the carrier frequency deviates when the modulating wave changes polarity. With each alternation of the modulating wave, the carrier advances or retards in frequency and remains at the new frequency for the duration of that cycle. In pm you can see that between one alternation and the next, the carrier phase must change, and the frequency shift that occurs does so *only* during the transition time; the frequency then returns to its normal rate. Note in the pm wave that the frequency shift occurs only when the modulating wave is changing polarity. The frequency during the constant amplitude portion of each alternation is the REST FREQUENCY.

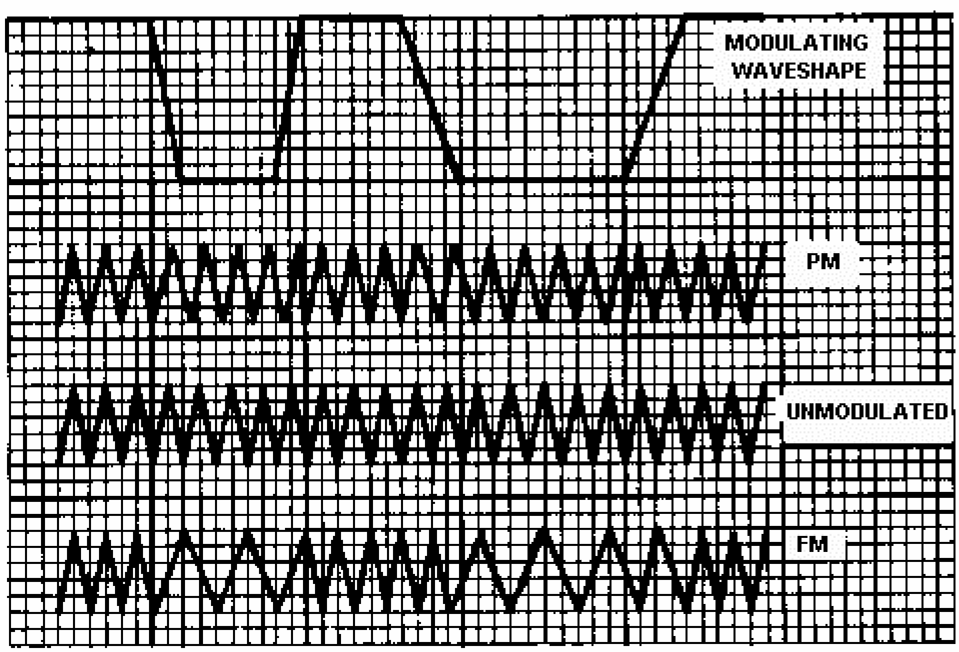

Figure 2-20.—Pm versus fm.

The relationship, in pm, of the modulating af to the change in the phase shift is easy to see once you understand AM and fm principles. Again, we can establish two clear-cut rules of phase modulation:

- AMOUNT OF PHASE SHIFT IS PROPORTIONAL TO THE AMPLITUDE OF THE MODULATING SIGNAL.

(If a 10-volt signal causes a phase shift of 20 degrees, then a 20-volt signal causes a phase shift of 40 degrees.)

- RATE OF PHASE SHIFT IS PROPORTIONAL TO THE FREQUENCY OF THE MODULATING SIGNAL.

(If the carrier were modulated with a 1-kilohertz tone, the carrier would advance and retard in phase 1,000 times each second.)

Phase modulation is also similar to frequency modulation in the number of sidebands that exist within the modulated wave and the spacing between sidebands. Phase modulation will also produce an infinite number of sideband frequencies. The spacing between these sidebands will be equal to the frequency of the modulating signal. However, one factor is very different in phase modulation; that is, the distribution of power in pm sidebands is not similar to that in fm sidebands, as will be explained in the next section.

Modulation Index

Recall from frequency modulation that modulation index is used to calculate the number of significant sidebands existing in the waveform. The higher the modulation index, the greater the number of sideband pairs. The modulation index is the ratio between the amount of oscillator deviation and the frequency of the modulating signal:

$$MI = \frac{\text{transmitter deviation}}{\text{modulating frequency}}$$

In frequency modulation, we saw that as the frequency of the modulating signal increased (assuming the deviation remained constant) the number of significant sideband pairs decreased. This is shown in views (A) and (B) of figure 2-21. Notice that although the total number of significant sidebands decreases with a higher frequency-modulating signal, the sidebands spread out relative to each other; the total bandwidth increases.

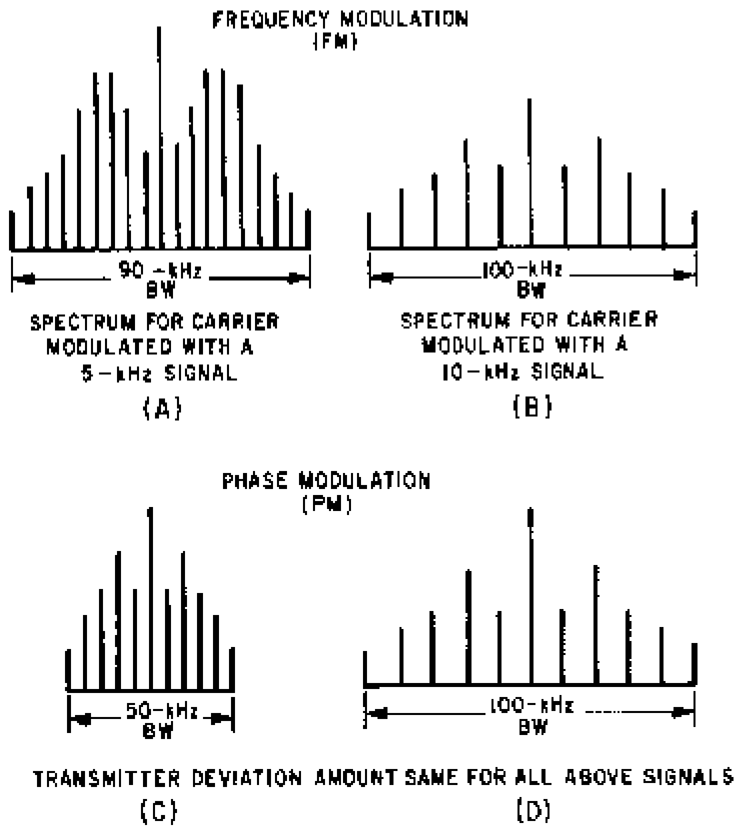

Figure 2-21.—Fm versus pm spectrum distribution.

In phase modulation the oscillator does not deviate, and the power in the sidebands is a function of the amplitude of the modulating signal. Therefore, two signals, one at 5 kilohertz and the other at 10 kilohertz, used to modulate a carrier would have the same sideband power distribution. However, the 10-kilohertz sidebands would be farther apart, as shown in views (C) and (D) of figure 2-21. When compared to fm, the bandwidth of the pm transmitted signal is greatly increased as the frequency of the modulating signal is increased.

As we pointed out earlier, phase modulation cannot occur without an incidental change in frequency, nor can frequency modulation occur without an incidental change in phase. The term fm is loosely used when referring to any type of angle modulation, and phase modulation is sometimes incorrectly referred to as "indirect fm." This is a definition that you should disregard to avoid confusion. Phase modulation is just what the words imply — phase modulation of a carrier by an af modulating signal. You will develop a better understanding of these points as you advance in your study of modulation.

Basic Modulator

In phase modulation you learned that varying the phase of a carrier at an intelligence rate caused that carrier to contain variations which could be converted back into intelligence. One circuit that can cause this phase variation is shown in figure 2-22.

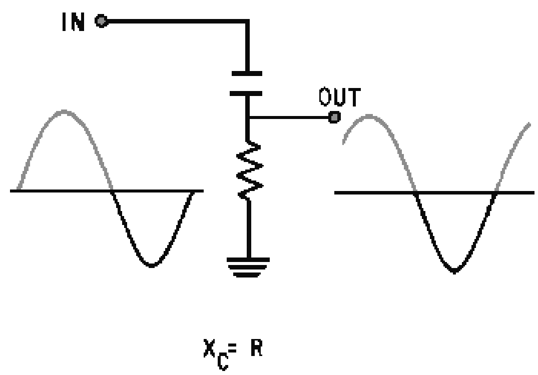

Figure 2-22.—Phase shifting a sine wave.

The capacitor in series with the resistor forms a phase-shift circuit. With a constant frequency rf carrier applied at the input, the output across the resistor would be 45 degrees out of phase with the input if $X_C = R$.

Now, let's vary the resistance and observe how the output is affected in figure 2-23. As the resistance reaches a value greater than 10 times X_C, the phase difference between input and output is nearly 0 degrees. For all practical purposes, the circuit is resistive. As the resistance is decreased to 1/10 the value of X_C, the phase difference approaches 90 degrees. The circuit is now almost completely capacitive. By replacing the resistor with a vacuum tube, as shown in view (A) of figure 2-24, we can vary the resistance (vacuum-tube impedance) by varying the voltage applied to the grid of the tube. The frequency applied to the circuit (from a crystal-controlled master oscillator) will be shifted in phase by 45 degrees with no audio input [view (B)]. With the application of an audio signal, the phase will shift as the impedance of the tube is varied.

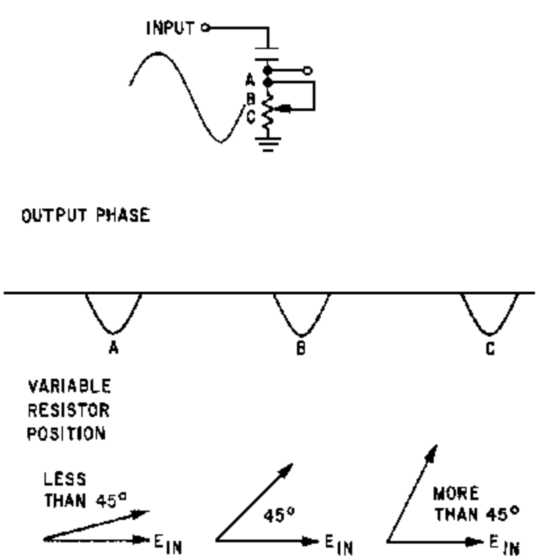

Figure 2-23.—Control over the amount of phase shift.

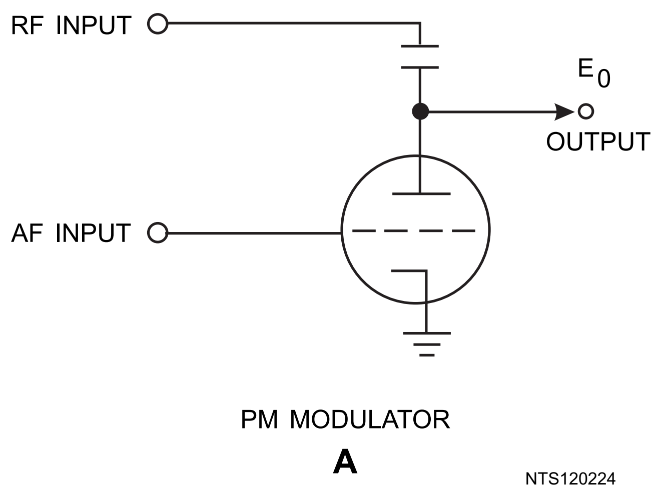

Figure 2-24A.—Phase modulator.

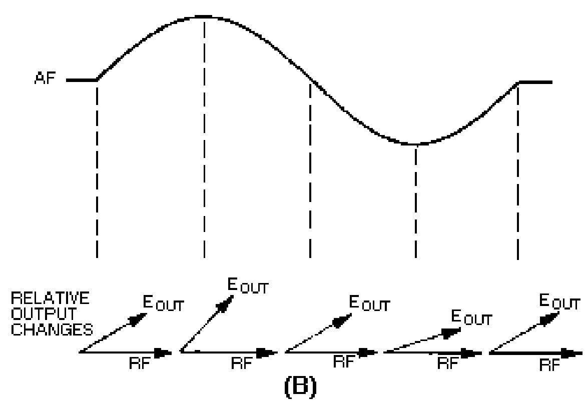

Figure 2-24B.—Phase modulator.

In practice, a circuit like this could not provide enough phase shift to produce the desired results in the output. Several of these circuits are arranged in cascade to provide the desired amount of phase shift. Also, since the output of this circuit will vary in amplitude, the signal is fed to a limiter to remove amplitude variations.

The major advantage of this type modulation circuit over frequency modulation is that this circuit uses a crystal-controlled oscillator to maintain a stable carrier frequency. In fm the oscillator cannot be crystal controlled because it is actually required to vary in frequency. That means that an fm oscillator will require a complex automatic frequency control (afc) system. An afc system ensures that the oscillator stays on the same carrier frequency and achieves a high degree of stability. The afc circuit will be covered in a later module.

Phase-Shift Keying

Phase-shift keying (psk) is similar to ON-OFF cw keying in AM systems and frequency-shift keying in fm systems. Psk is most useful when the code elements are all of equal length; that is, all marks and spaces, whether message elements or synchronizing signals, occupy identical elements of time. It is not fully suitable for use on start-stop teletypewriter circuits where the stop pulse is 1.42 times longer than the other pulses. Neither is it applicable to those pulsed systems in which the duration or position of the pulses are varied by the modulation frequency. In its simplest form, psk operates on the principle of phase reversal of the carrier. Each time a mark is received, the phase is reversed. No phase reversal takes place when a space is received. In binary systems, marks and spaces are called ONES and ZEROS, respectively, so that a ONE causes a 180-degree phase shift, and a ZERO has no effect on the incoming signal. Figure 2-25 shows the application of phase-shift keying to an unmodulated carrier [view (A)] in the af range. For transmission over other than a conductive path, the wave shown in view (D) must be used as the modulating signal for some other system of modulating an rf carrier.

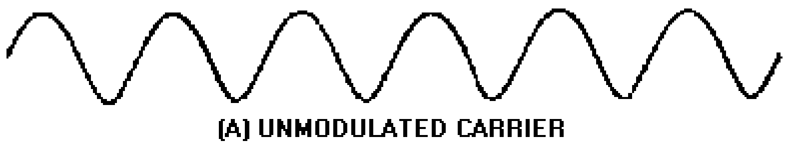

Figure 2-25A.—Phase-shift keying. UNMODULATED CARRIER.

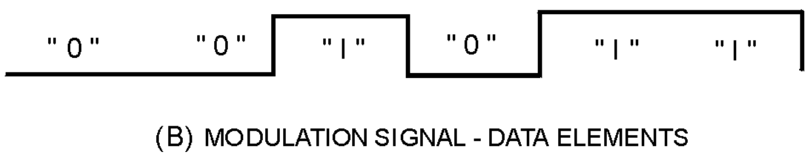

Figure 2-25B.—Phase-shift keying. MODULATION SIGNAL - DATA ELEMENTS.

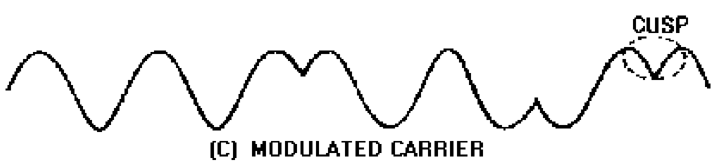

Figure 2-25C.—Phase-shift keying. MODULATED CARRIER.

Figure 2-25D.—Phase-shift keying. MODULATED CARRIER AFTER FILTERING.

The modulating signal in view (B) consists of a bit stream of ZEROS and ONES. A ZERO does not affect the carrier frequency which is usually set to equal the bit rate. For example, a data stream of 1,200 bits per second would have a carrier of 1,200 hertz. When a data bit ONE occurs, the phase of the carrier frequency is shifted 180 degrees. In view (C) we find that the third, fifth, and sixth cycles (all ONE) have been reversed in phase. This phase reversal produces CUSPS (sharp phase reversals) which are usually removed by filtering before transmission or further modulation. This filtering action limits the bandwidth of the output signal frequencies. The resulting wave is shown in view (D).

The exact waveform of figure 2-25, view (D), can be obtained by logic operations of timing and data. This is illustrated in figure 2-26, where a timing signal [view (A)] is used rather than a carrier frequency. The data (intelligence) is shown in view (B) and is combined with the timing signal to produce a combination digital modulation signal, as shown in view (C). The square-wave pattern of the digital modulation is filtered to limit the bandwidth of the signal frequencies, as shown in view (D). This system has been used in some high-speed data equipment, but it offers no particular advantage over other systems of modulation, particularly the pulse-modulated systems for high-speed data transmission.

Q-11. What type of modulation depends on the carrier-wave phase shift?

Q-12. What components may be used to build a basic phase modulator?

Q-13. Phase-shift keying is similar to what other two types of modulation?

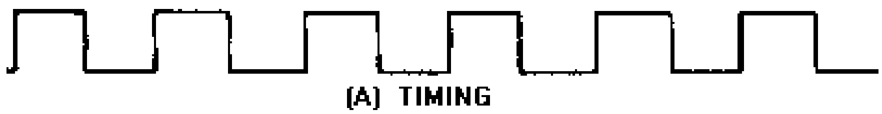

Figure 2-26A.—Simulated phase-shift keying. TIMING.

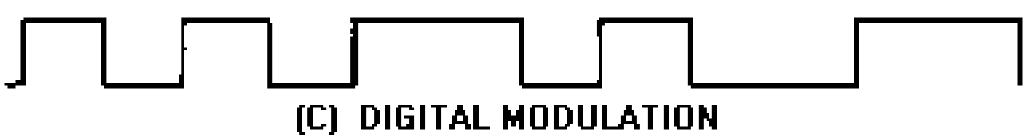

Figure 2-26C.—Simulated phase-shift keying. DIGITAL MODULATION.

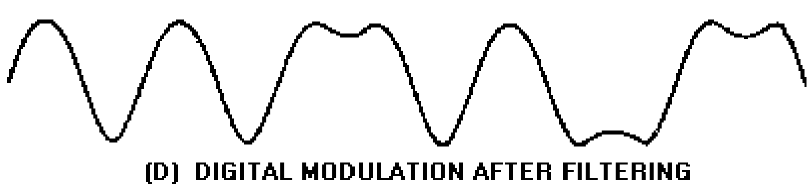

Figure 2-26D.—Simulated phase-shift keying. DIGITAL MODULATION AFTER FILTERING.

PULSE MODULATION

Another type of modulation is PULSE MODULATION. Pulse modulation has many uses, including telegraphy, radar, telemetry, and multiplexing. Far too many applications of pulse modulation exist to elaborate on any one of them, but in this section we will cover the basic principles of pulse modulation.

CHARACTERISTICS

Amplitude modulating a simple rf carrier to a point where it becomes drastically overmodulated could produce a waveform similar to that required in pulse modulation. A modulating signal [view (A) of figure 2-27] that is much larger than the carrier results in the modulation envelope shown in view (B). The modulation envelope would be the same if the modulating wave shape were not sinusoidal; that is, like the one shown in view (C).

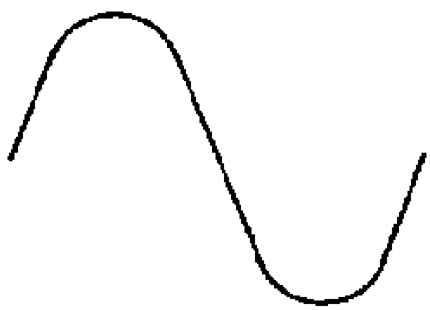

Figure 2-27A.—Overmodulation of a carrier. MODULATING WAVE.

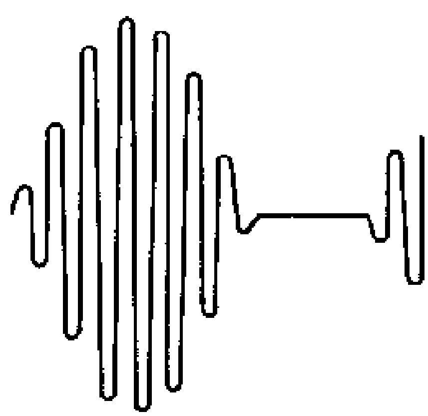

Figure 2-27B.—Overmodulation of a carrier. MODULATION ENVELOPE.

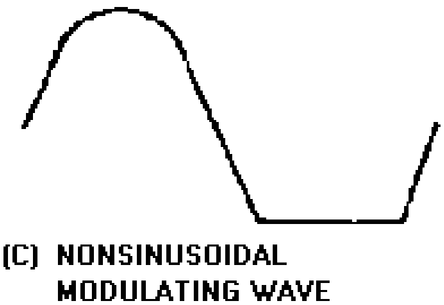

Figure 2-27C.—Overmodulation of a carrier. NONSINUSOIDAL MODULATING WAVE.

Observe the modulating square wave in figure 2-28. Remember that it contains an infinite number of odd harmonics in addition to its fundamental frequency. Assume that a carrier has a frequency of 1 megahertz. The fundamental frequency of the modulating square wave is 1 kilohertz. When these signals heterodyne, two new frequencies will be produced: a sum frequency of 1.001 megahertz and a difference frequency of 0.999 megahertz. The fundamental frequency heterodynes with the carrier. This is also true of all harmonics contained in the square wave. Side frequencies associated with those harmonics will be produced as a result of this process. For example, the third harmonic of the square wave heterodynes with the carrier and produces sideband frequencies at 1.003 and 0.997 megahertz. Another set will be produced by the fifth, seventh, ninth, eleventh, thirteenth, fifteenth, seventeenth, and nineteenth harmonics of the square wave, and so on to infinity.

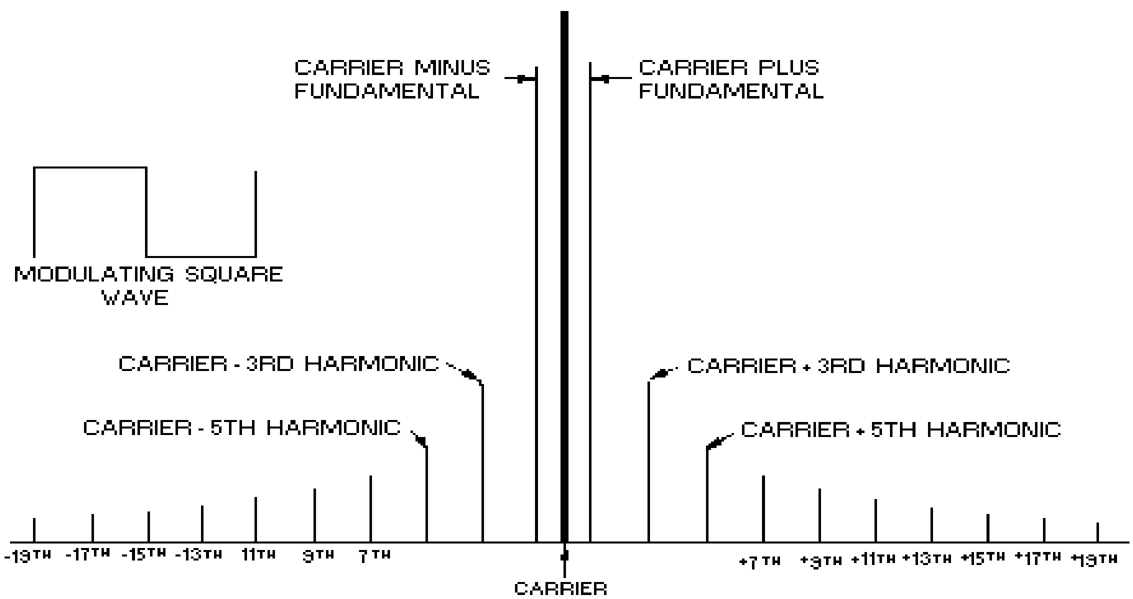

Figure 2-28.—Spectrum distribution when modulating with a square wave.

Look at figure 2-28 and observe the relative amplitudes of the sidebands as they relate to the amplitudes of the harmonics contained in the square wave. Note that the first set of sidebands is directly related to the amplitude of the square wave. The second set of sidebands is related to the third harmonic content of the square wave and is 1/3 the amplitude of the first set. The third set is related to the amplitude of the first set of sidebands and is 115 the amplitude of the first set. This relationship will apply to each additional set of sidebands.

View (A) of figure 2-29 shows the carrier modulated with a square wave. In view (B) the modulating square wave is increased in amplitude; note that the rf peaks increase in amplitude during the positive alternation of the square wave and decrease during the negative half of the square wave. In view (C) the amplitude of the square wave is further increased and the amplitude of the rf wave is almost 0 during the negative alternation of the square wave.

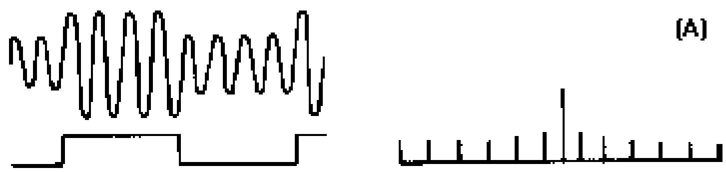

Figure 2-29A.—Various square-wave modulation levels with frequency-spectrum carrier and sidebands.

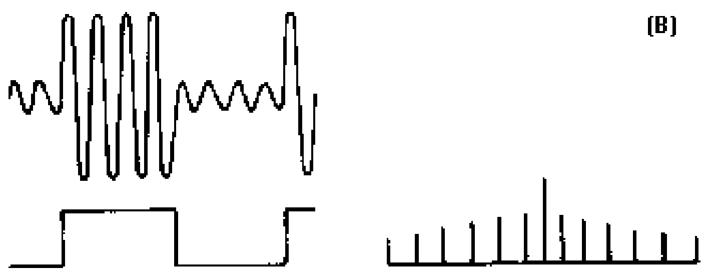

Figure 2-29B.—Various square-wave modulation levels with frequency-spectrum carrier and sidebands.

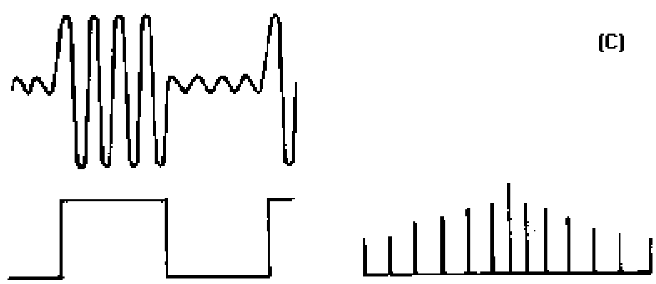

Figure 2-29C.—Various square-wave modulation levels with frequency-spectrum carrier and sidebands.

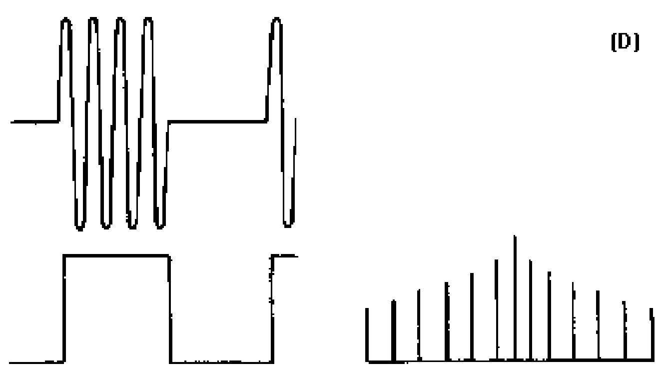

Figure 2-29D.—Various square-wave modulation levels with frequency-spectrum carrier and sidebands.

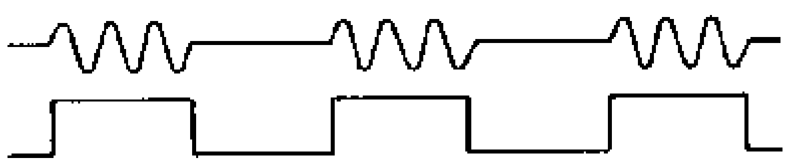
Note the frequency spectrum associated with each of these conditions. The carrier amplitude remains constant, but the sidebands increase in amplitude in accordance with the amplitude of the modulating square wave.

So far in pulse modulation, the same general rules apply as in AM. In view (C) the amplitude of the square wave of voltage is equal to the peak voltage of the unmodulated carrier wave. This is 100-percent modulation, just as in conventional AM. Note in the frequency spectrum that the sideband distribution is also the same as in AM. Keep in mind that the total sideband power is 1/2 of the total power when the modulator signal is a square wave. This is in contrast to 1/3 the total power with sine-wave modulation.

Now refer to view (D). The increase of the square-wave modulating voltage is greater in amplitude than the unmodulated carrier. Notice that the sideband distribution does not change; but, as the sidebands take on more of the transmitted power, so will the carrier.

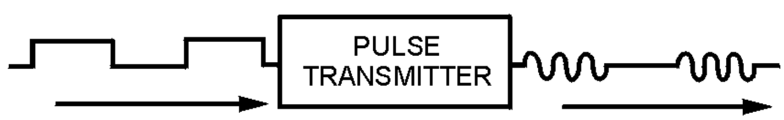
Pulse Timing

Thus far, we have established a carrier and have caused its peaks to increase and decrease as a modulating square wave is applied. Some pulse-modulation systems modulate a carrier in this manner. Others produce no rf until pulsed; that is, rf occurs only during the actual pulse as shown in view (A) of figure 2-30. For example, let's start with an rf carrier frequency of 1 megahertz. Each cycle of the rf requires a certain amount of time to complete. If we allow oscillations to occur for a given period of time only during selected intervals, as in view (B), we are PULSING the system. Note that the pulse transmitter does not produce an rf signal until one of the positive-going modulating pulses is applied. The transmitter then produces the rf carrier until the positive input pulse ends and the input waveform again becomes a negative potential.



(A)

Figure 2-30A.—Pulse transmission.



(B)

Figure 2-30B.—Pulse transmission.

Refer back to figure 1-41 and the over-modulation discussion in chapter 1. You will notice that the overmodulation wave shape of view (D) in figure 2-29 and the pulse-modulation wave shape of figure 2-30, view (B), are very similar to figure 1-41.

Actually, both figure 1-41 and view (D) of figure 2-29 result from overmodulation. Even though the output of the pulse transmitter in figure 2-30 looks like overmodulation, it is not; rather, it is pulsed.

However, the frequency spectrums are similar. Sideband distributions are similar, but not identical, since the pulse transmitter in figure 2-30 is gated on and off instead of being modulated by a square wave as was the case in view (D) of figure 2-29.

Remember, in pulse modulation the sidebands produced to accompany the carrier during transmission are directly related to the harmonic content of the modulating wave shape. In figure 2-31, (view A, view B and view C), observe the square and rectangular wave shapes used to pulse modulate the same carrier frequency in each of the three views.

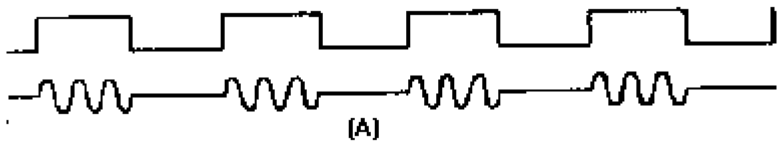


Figure 2-31A.—Varying pulse-modulating waves.

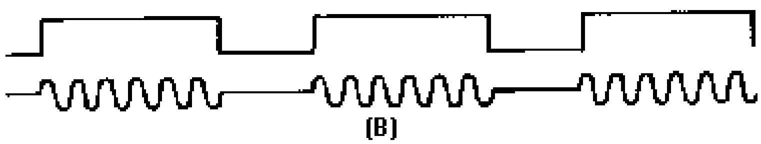

Figure 2-31B.—Varying pulse-modulating waves.

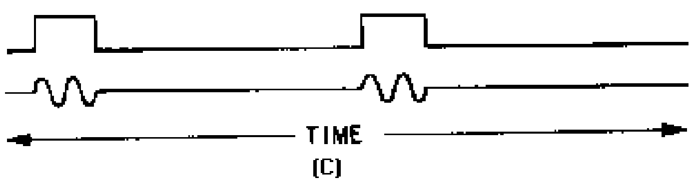

Figure 2-31C.—Varying pulse-modulating waves.

Let's take note of some timing relationships in the three modulating sequences in figure 2-31:

- the time for the rf cycle is the same in each case
- the number of cycles occurring in each group is different
- the ratio between transmitting and non-transmitting time varies
- the transmitter produces an rf wave four times in view (A), three transmission groups in view (B), and only two in view (C)
- rf is generated only during the positive pulses

In figure 2-32, observe the relative time for individual rf cycles. The time for each cycle is the same in views (A) and (B). Since this time is the same, we can assume that the carrier frequency is the same. But in view (C) the time for each cycle is about half that in views (A) and (B). Therefore, the frequency of the carrier in view (C) is nearly twice that of the other two. This illustration shows that carrier frequencies in pulse systems can vary.

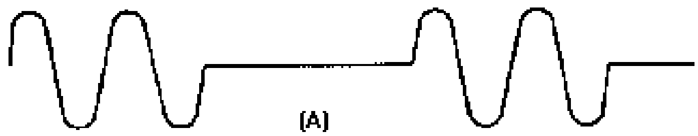

Figure 2-32A.—Carrier frequency.

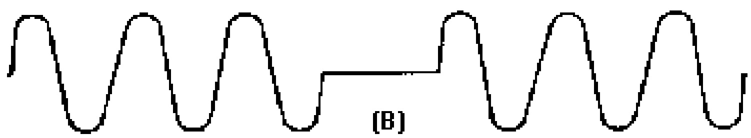

Figure 2-32B.—Carrier frequency.

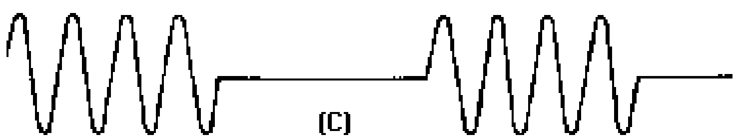

Figure 2-32C.—Carrier frequency.

The carrier frequency is not the only frequency we must concern ourselves with in pulse systems. We must also be concerned with the frequency that is associated with the repetition rate of groups of pulses. Figure 2-33 shows that a specific time period exists between each group of rf pulses. This time is the same for each repetition of the pulse and is called the PULSE-REPETITION TIME (prt). To find out how often these groups of pulses occur, compute PULSE-REPETITION FREQUENCY (prf) using the formula:

$$prf = \frac{1}{prt}$$

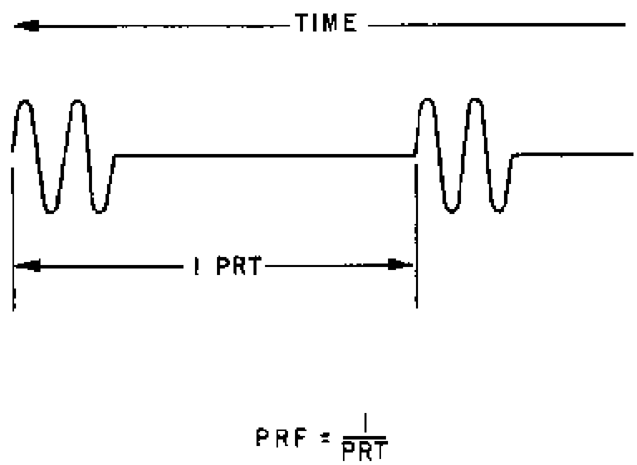

Figure 2-33.—Pulse-repetition time (prt).

Just remember that the pulse-repetition time is the time it takes for a pulse to recur, as shown in figure 2-34. The duration of time of the pulse (**a**) plus the time when no pulse occurs (**b**) equals the total pulse-repetition time.

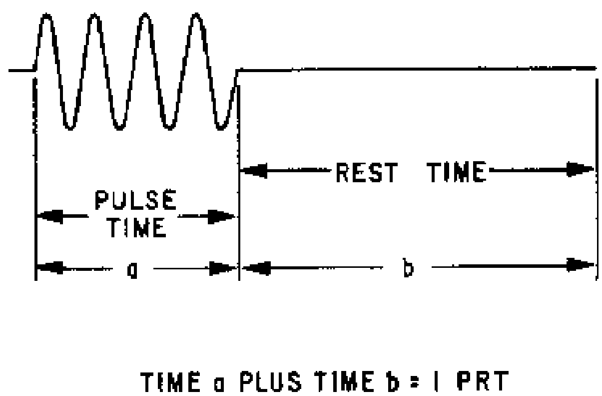

Figure 2-34.—Pulse cycles.

The time during which the pulse is occurring is called PULSE DURATION (pd) or PULSE WIDTH (pw), as shown in figure 2-35. As you will soon see, pulse width is important in pulse modulation.

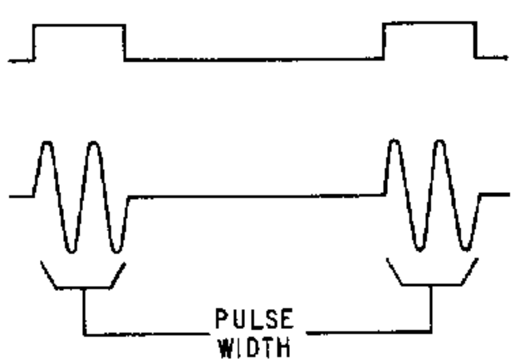

Figure 2-35.—Pulse width (pw).

The time we have been referring to as the time of no pulse, or nonpulse time, is referred to as REST TIME (rt). The duration of this rest time will determine certain capabilities of the pulse-modulation system. The pulse width is the time that the transmitter produces rf oscillations and is the actual pulse transmission time. During the nonpulse time, shown in figure 2-36, the transmitter produces no oscillations and the oscillator is cut off.

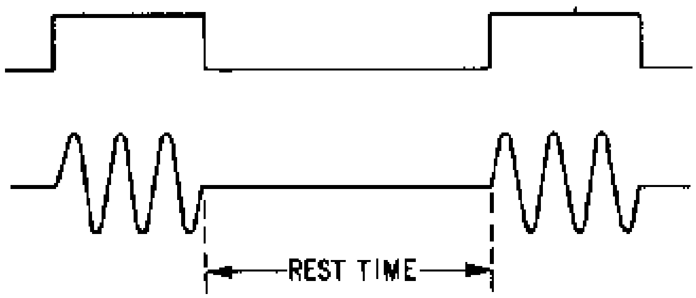

Figure 2-36.—Rest time (rt).

Some pulse transmitter-receiver systems transmit the pulse and then rest, awaiting the return of an echo. Rest time provides the system time for the receive cycle of operation.

Power in a Pulse System

When discussing power in a pulse-modulation system, we have to consider PEAK POWER and AVERAGE POWER. Peak power is the maximum value of the transmitted pulse; average power is the peak power value averaged over the pulse-repetition time. Peak power is very easy to see in a pulse system. In figure 2-37, all pulsed wave shapes have a peak power of 100 watts. Also note that in views (A), (B), and (C) the pulse width is the same, even though the carrier frequency is different. In these three cases average power would be the same. This is because average power is actually equal to the peak power of a pulse averaged over 1 operating cycle. However, the pulse width is increased in view (D) and we have a greater average power with the same prt. In view (E) the decreased pulse width has decreased average power over the same prt.

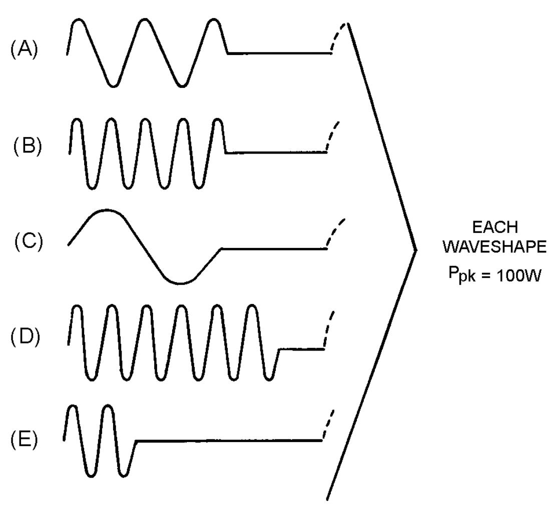

Figure 2-37.—Peak and average power.

Use these simple rules to determine power in a pulsed-wave shape:

- Peak power is the maximum power reached by the transmitter during the pulse.

- Average power equals the peak power averaged over one cycle.

Duty Cycle

In pulse modulation you will need to know the percentage of time the system is actually producing rf. For example, let's say that a pulse system is transmitting 25 percent of the time. This would mean that the pw is 1/4 the prt. For every 60 minutes we operate the pulse system, we actually transmit a total of only 15 minutes.

The DUTY CYCLE is the ratio of working time to total time for intermittently operated devices. Thus, duty cycle represents a ratio of actual transmitting time to transmitting time plus rest time. To establish the duty cycle, divide the pw by the prt of the system. This yields the duty cycle and is expressed as a decimal figure. With this information, we can figure percentage of transmitting time by multiplying the duty cycle by 100.

Applications of Pulse Modulation

Pulse modulation has many applications in the transmission of intelligence information. In telemetry, for example, the width of successive pulses may tell us humidity; the changing of the rest time may tell us pressure. In other applications, as you will see later in this text, the changing of the average power can provide us with intelligence information.

In radar a pulse is transmitted and travels some distance to a target where it is then reflected back to the system. The amount of time it takes provides us with information that can be converted to distance.

Telemetry and radar systems use the principles of pulse modulation described in this section. Let's quickly review what has been presented:

- **Pulse width (pw)** — the duration of time rf frequency is transmitted

- **Rest time (rt)** — the time the transmitter is resting (not transmitting)

- **Carrier frequency** — the frequency of the rf wave generated in the oscillator of the transmitter

- **Pulse-repetition time (prt)** — the total time of 1 complete pulse cycle of operation (rest time plus pulse width)

- **Pulse-repetition frequency (prf)** — the rate, in pulses per second, that the pulse occurs

- **Power peak** — the maximum power contained in the pulse

- **Average power** — the peak power averaged over 1 complete operating cycle

- **Duty cycle** — a decimal number that expresses a ratio in a pulse modulation system of transmit time to total time

Pulse modulation will play a major part in your electronics career. In one way or another, you will encounter it in some form. The function of the particular system may involve many variations of the characteristics presented here. We will now look at some specific applications of pulse modulation in radar and communications systems.

Q-14. Overmodulating an rf carrier in amplitude modulation produces a waveform which is similar to what modulated waveform?

Q-15. What is prt?

Q-16. What is nonpulse time?

Q-17. What is average power in a pulsed system?

RADAR MODULATION

Radio frequency energy in radar is transmitted in short pulses with time durations that may vary from 1 to 50 microseconds or more. If the transmitter is cut off before any reflected energy returns from a target, the receiver can distinguish between the transmitted pulse and the reflected pulse. After all reflections have returned, the transmitter can again be cut on and the process repeated. The receiver output is applied to an indicator which measures the time interval between the transmission of energy and its return as a reflection. Since the energy travels at a constant velocity, the time interval becomes a measure of the distance traveled (RANGE). Since this method does not depend on the relative frequency of the returned signal, or on the motion of the target, difficulties experienced in cw or fm methods are not encountered. The pulse modulation method is used in many military radar applications.

Most radar oscillators operate at pulse voltages between 5 and 20 kilovolts. They require currents of several amperes during the actual pulse which places severe requirements on the modulator. The function of the high-vacuum tube modulator is to act as a switch to turn a pulse ON and OFF at the transmitter in response to a control signal. The best device for this purpose is one which requires the least signal power for control and allows the transfer of power from the transmitter power source to the oscillator with the least loss. The pulse modulator circuits discussed in this section are typical pulse modulators used in radar equipment.

Spark-Gap Modulator

The SPARK-GAP MODULATOR consists of a circuit for storing energy, a circuit for rapidly discharging the storage circuit (spark gap), a pulse transformer, and an ac power source. The circuit for storing energy is essentially a short section of artificial transmission line which is known as the PULSE-FORMING NETWORK (pfn). The pulse-forming network is discharged by a spark gap. Two types of spark gaps are used: FIXED GAPS and ROTARY GAPS. The fixed gap, discussed in this section, uses a trigger pulse to ionize the air between the contacts of the spark gap and to initiate the discharge of the pulse-forming network. The rotary gap is similar to a mechanically driven switch.

A typical fixed, spark-gap modulator circuit is shown in figure 2-38. Between trigger pulses the spark gap is an open circuit. Current flows through the pulse transformer (T1), the pulse-forming network (C1, C2, C3, C4, and L2), the diode (V1), and the inductor (L1) to the plate supply voltage (E_b). These components form the charging circuit for the pulse-forming network.

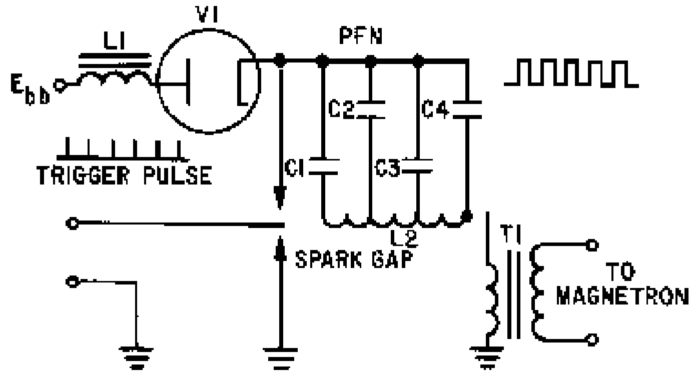

Figure 2-38.—Fixed spark-gap modulator.

The spark gap is actually triggered (ionized) by the combined action of the charging voltage across the pulse-forming network and the trigger pulse. (Ionization was discussed in *NEETS*, Module 6, *Introduction to Electronic Emission, Tubes and Power Supplies*.) The air between the trigger pulse injection point and ground is ionized by the trigger voltage. This, in turn, initiates the ionization of the complete gap by the charging voltage. This ionization allows conduction from the charged pulse-forming network through pulse transformer T1. The output pulse is then applied to an oscillating device, such as a magnetron.

Thyratron Modulator

The hydrogen THYRATRON MODULATOR is an electronic switch which requires a positive trigger of only 150 volts. The trigger potential must rise at the rate of 100 volts per microsecond to cause the modulator to conduct. In contrast to spark gap devices, the hydrogen thyratron (figure 2-39) operates over a wide range of anode voltages and pulse-repetition rates. The grid has complete control over the initiation of cathode emission for a wide range of voltages. The anode is completely shielded from the cathode by the grid. Thus, effective grid action results in very smooth firing over a wide range of anode voltages and repetition frequencies. Unlike most other thyratrons, the positive grid-control characteristic ensures stable operation. In addition, deionization time is reduced by using the hydrogen-filled tube.

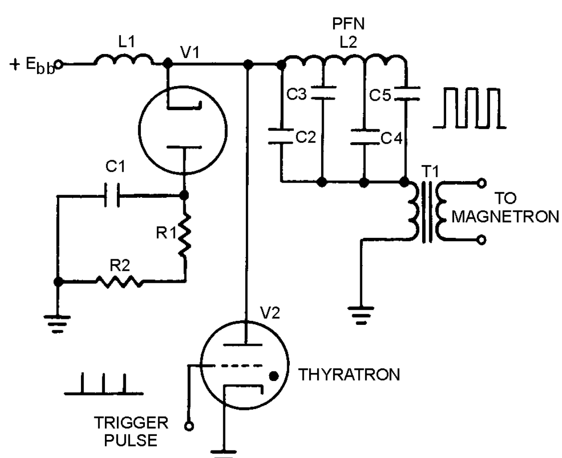

Figure 2-39.—Typical thyratron gas-tube modulator.

The hydrogen thyratron modulator provides improved timing because the synchronized trigger pulse is applied to the control grid of the thyratron (V2) and instantaneous firing is obtained. In addition, only one gas tube is required to discharge the pulse-forming network, and a low amplitude trigger pulse is sufficient to initiate discharge. A damping diode is used to prevent breakdown of the thyratron by reverse-voltage transients. The thyratron requires a sharp leading edge for a trigger pulse and depends on a sudden drop in anode voltage (controlled by the pulse-forming network) to terminate the pulse and cut off the tube.

As shown in figure 2-39, the typical thyratron modulator is very similar to the spark-gap modulator. It consists of a power source (E_b), a circuit for storing energy (L2, C2, C3, C4, and C5), a circuit for discharging the storage circuit (V2), and a pulse transformer (T1). In addition this circuit has a damping diode (V1) to prevent reverse-polarity signals from being applied to the plate of V2 which could cause V2 to breakdown.

With no trigger pulse applied, the pfn charges through T1, the pfn, and the charging coil L1 to the potential of E_b. When a trigger pulse is applied to the grid of V2, the tube ionizes causing the pulse-forming network to discharge through V2 and the primary of T1. As the voltage across the pfn falls below the ionization point of V2, the tube shuts off. Because of the inductive properties of the pfn, the positive discharge voltage has a tendency to swing negative. This negative overshoot is prevented from damaging the thyratron and affecting the output of the circuit by V1, R1, R2, and C1. This is a damping circuit and provides a path for the overshoot transient through V1. It is dissipated by R1 and R2 with C1 acting as a high-frequency bypass to ground, preserving the sharp leading and trailing edges of the pulse. The hydrogen thyratron modulator is the most common radar modulator.

Pulse modulation is also useful in communications systems. The intelligence-carrying capability and power requirements for communications systems differ from those of radar. Therefore, other methods of achieving pulse modulation that are more suitable for communications systems will now be studied.

Q-18. What is the primary component for a spark-gap modulator?

Q-19. What are the basic components of a thyratron modulator?

COMMUNICATIONS PULSE MODULATORS

To transmit intelligence using pulse modulation, you must provide a method to vary some characteristic of the pulse train in accordance with the modulating signal. Figure 2-40 illustrates a simple pulse train. The characteristics of these pulses that can be varied are amplitude, pulse width, pulse-repetition time, and the pulse position as compared to a reference. In addition to these three characteristics, pulses may be transmitted according to a code to represent the different levels of the modulating signal. To ensure maximum fidelity (accuracy in reproducing a modulating wave), the modulating signal has to be represented by enough pulses to restore the original wave shape. Logically, the higher the sampling rate (the more often sampled) of the pulse modulator, the more accurately the original modulating wave can be reproduced. Figure 2-41 illustrates the effectiveness of three pulse-sampling rates. View (A) shows a sampling rate of more than two times the modulating frequency. As you can see, this reproduces the modulating signal very accurately. However, the high sampling rate requires a wide bandwidth and increases the average power required of the transmitter. If less than two samples per cycle are made, you are not able to reproduce the original modulating signal, as shown in view (B). View (C) shows a sampling rate that is two times the highest modulating frequency. This is the minimum sampling rate that will give a sufficiently accurate reproduction of the modulating wave. The standard sampling rate is 2.5 times the highest frequency that is to be transmitted. This ensures the ability to accurately reproduce the modulating waveform. In military voice systems the bandwidth for voice signals is limited to 300 to 3,000 hertz, requiring a sampling frequency of 8 kilohertz. Although the pulse characteristic that is changed may vary for each type of pulse modulation, the sampling frequency will remain constant. We will now briefly discuss common types of pulse modulation.

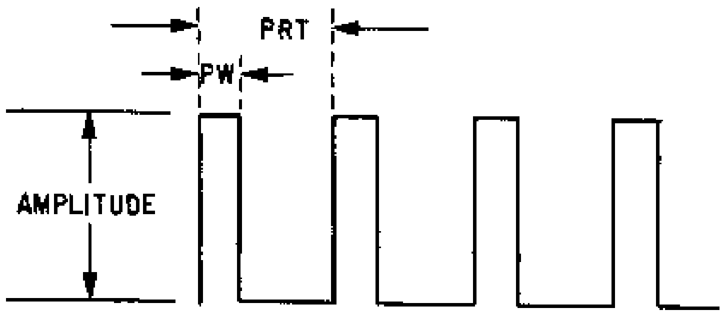

Figure 2-40.—Pulse train.

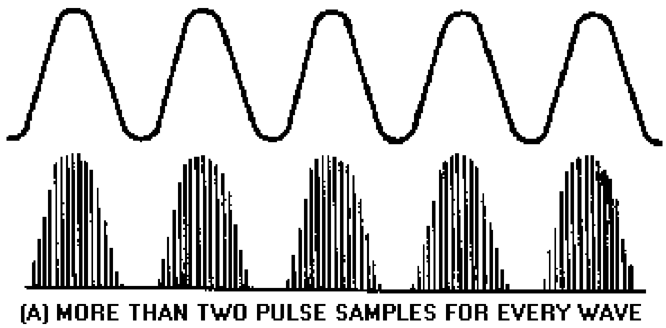

Figure 2-41A.—Pulse sampling rates. MORE THAN TWO PULSE SAMPLES FOR EVERY WAVE.

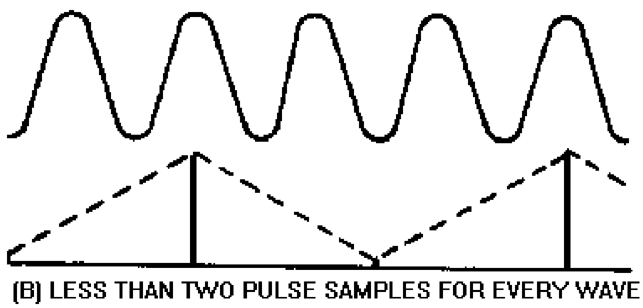

Figure 2-41B.—Pulse sampling rates. LESS THAN TWO PULSE SAMPLES FOR EVERY WAVE.

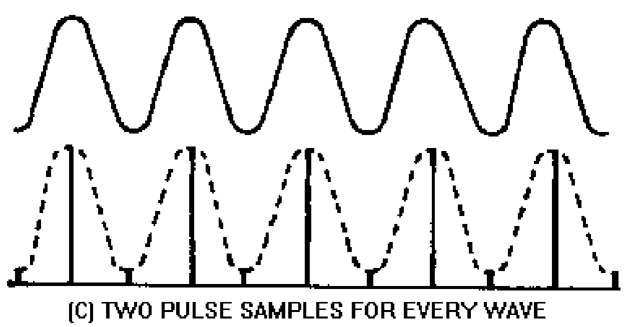

Figure 2-41C.—Pulse sampling rates. TWO PULSE SAMPLES FOR EVERY WAVE.

Pulse-Amplitude Modulation

Some characteristic of the sampling pulses must be varied by the modulating signal for the intelligence of the signal to be present in the pulsed wave. Figure 2-42 shows three typical waveforms in which the pulse amplitude is varied by the amplitude of the modulating signal. View (A) represents a sine wave of intelligence to be modulated on a transmitted carrier wave. View (B) shows the timing pulses which determine the sampling interval. View (C) shows PULSE-AMPLITUDE MODULATION (pam) in which the amplitude of each pulse is controlled by the instantaneous amplitude of the modulating signal at the time of each pulse.

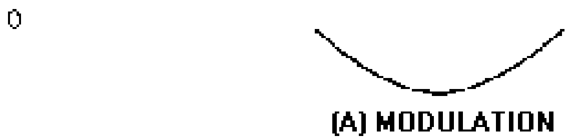

Figure 2-42A.—Pulse-amplitude modulation (pam). MODULATION.

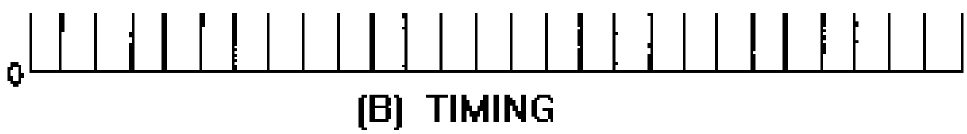

Figure 2-42B.—Pulse-amplitude modulation (pam). TIMING.

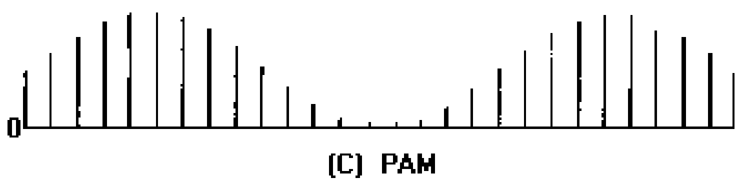

Figure 2-42C.—Pulse-amplitude modulation (pam). PAM.

Pulse-amplitude modulation is the simplest form of pulse modulation. It is generated in much the same manner as analog-amplitude modulation. The timing pulses are applied to a pulse amplifier in which the gain is controlled by the modulating waveform. Since these variations in amplitude actually represent the signal, this type of modulation is basically a form of AM. The only difference is that the signal is now in the form of pulses. This means that pam has the same built-in weaknesses as any other AM signal - high susceptibility to noise and interference. The reason for susceptibility to noise is that any interference in the transmission path will either add to or subtract from any voltage already in the circuit (signal voltage). Thus, the amplitude of the signal will be changed. Since the amplitude of the voltage represents the signal, any unwanted change to the signal is considered a SIGNAL DISTORTION. For this reason, pam is not often used. When pam is used, the pulse train is used to frequency modulate a carrier for transmission. Techniques of pulse modulation other than pam have been developed to overcome problems of noise interference. The following sections will discuss other types of pulse modulation.

Q-20. What action is necessary to impress intelligence on the pulse train in pulse modulation?

Q-21. To ensure the accuracy of a transmission, what is the minimum number of times a modulating wave should be sampled in pulse modulation?

Q-22. What, if any, noise susceptibility advantage exists for pulse-amplitude modulation over analog-amplitude modulation?

Pulse-Time Modulation

In pulse-modulated systems, as in an analog system, the intelligence may be impressed on the carrier by varying any of its characteristics. In the preceding paragraphs the method of modulating a pulse train by varying its amplitude was discussed. Time characteristics of pulses may also be modulated with intelligence information. Two time characteristics may be affected: (1) the *time duration of the pulses*, referred to as PULSE-DURATION MODULATION (pdm) or PULSE-WIDTH MODULATION (pwm); and (2) the *time of occurrence of the pulses*, referred to as PULSE-POSITION MODULATION (ppm), and a special type of PULSE-TIME MODULATION (ptm) referred to as PULSE-FREQUENCY MODULATION (pfm). Figure 2-43 shows these types of ptm in views (C), (D), and (E). Views (A) and (B) show the modulating signal and timing, respectively.

Figure 2-43A.—Pulse-time modulation (ptm). MODULATION.

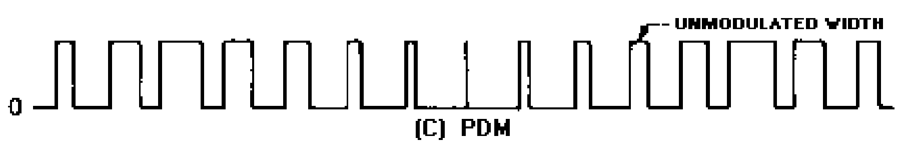

Figure 2-43C.—Pulse-time modulation (ptm). PDM.

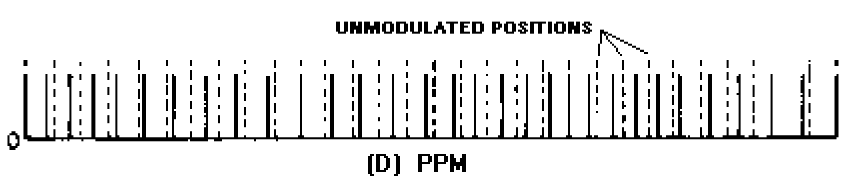

Figure 2-43D.—Pulse-time modulation (ptm). PPM.

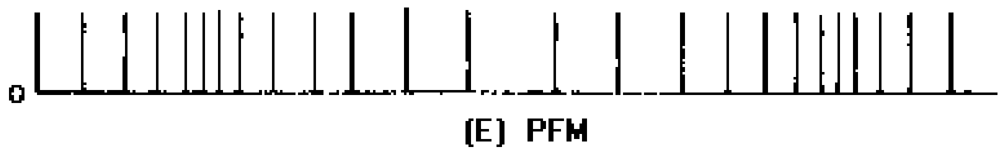

Figure 2-43E.—Pulse-time modulation (ptm). PFM

PULSE-DURATION MODULATION.—Pdm and pwm are designations for a single type of modulation. The width of each pulse in a train is made proportional to the instantaneous value of the modulating signal at the instant of the pulse. Either the leading edges, the trailing edges, or both edges of the pulses may be modulated to produce the variation in pulse width. Pdm can be obtained in a number of ways, one of which is illustrated in views (A) through (D) in figure 2-44. A circuit to produce pdm is shown in figure 2-45. Adding the modulating signal [figure 2-44, view (A)] to a repetitive sawtooth [view (B)] will result in the waveform shown in view (C). This waveform is then applied to a circuit which changes state when the input signal exceeds a specific threshold level. This action produces pulses with widths that are determined by the length of time that the input waveform exceeds the threshold level. The resulting waveform is shown in view (D).

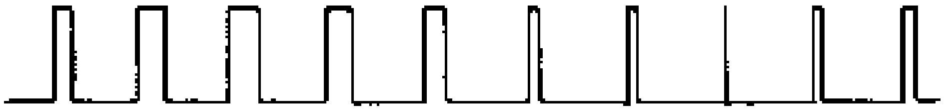

Figure 2-44D.—Pulse-duration modulation (pdm). WIDTH MODULATED PULSES FROM CIRCUIT OF FIGURE 2-45.

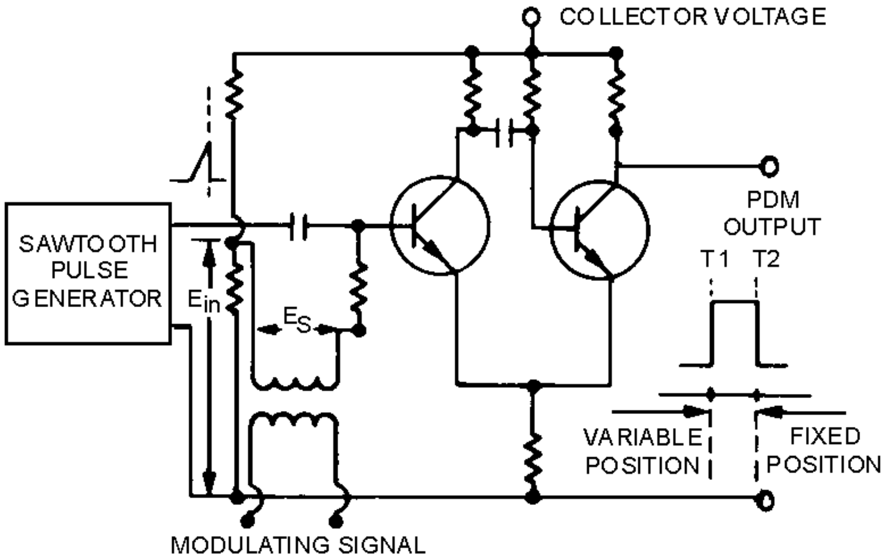

Figure 2-45.—Circuit for producing pdm.

In the circuit of figure 2-45, a series of sawtooth pulses, occurring at the sampling rate, is applied to a one-shot multivibrator. The multivibrator has the signal voltage $E_s$superimposed on the bias voltage E_{in}. Each pulse triggers a cycle of multivibrator operation which terminates after a time interval and varies linearly with the voltage E_s. The pulse of plate voltage produced by the multivibrator will have a leading edge at T1. The leading edge will vary in position with the signal voltage, while the trailing edge at T2 is fixed by the termination of the sawtooth pulse. The length of the output pulse is thus duration or width modulated. If the sawtooth has an instantaneous buildup and a sloping trailing edge, then the leading edge (T1) is fixed and the trailing edge (T2) varies. If the sawtooth generator produces a slope on both leading and trailing edges, both T1 and T2 are variable in position, but the result is still pdm. Pdm is often used because it is of a constant amplitude and is, therefore, less susceptible to noise. When compared with ppm, pdm has the disadvantage of a varying pulse, width and, therefore, of varying power content. This means that the transmitter must be powerful enough to handle the maximum-width pulses, although the average power transmitted is much less than peak power. On the other hand, pdm will still work if the synchronization between the transmitter and receiver fails; in ppm it will not, as will be seen in the next section.

PULSE-POSITION MODULATION.—The amplitude and width of the pulse is kept constant in the system. The position of each pulse, in relation to the position of a recurrent reference pulse, is varied by each instantaneous sampled value of the modulating wave. Ppm has the advantage of requiring constant transmitter power since the pulses are of constant amplitude and duration. It is widely used but has the disadvantage of depending on transmitter-receiver synchronization.

Ppm can be generated in several ways, but we will discuss one of the simplest. Figure 2-46 shows three waveforms associated with developing ppm from pdm. The pdm pulse train is applied to a differentiating circuit. (Differentiation was presented in *NEETS*, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*.) This provides positive- and negative-polarity pulses that correspond to the leading and trailing edges of the pdm pulses. Considering pdm and its generation, you can see that each pulse has a leading and trailing edge. In this case the position of the leading edge is fixed, whereas the trailing edge is not, as shown in view (A) of figure 2-46. The resultant pulses after the differentiation are shown in view (B). The negative pulses are position-modulated in accordance with the modulating waveform. Both the negative and positive pulse are then applied to a rectification circuit. This application eliminates the positive, non-modulated pulses and develops a ppm pulse train, as shown in view (C).

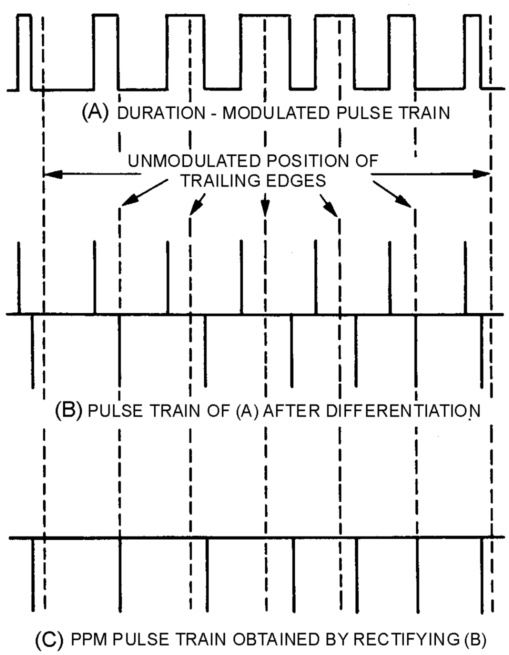

Figure 2-46.—Pulse-position modulation (ppm).

PULSE-FREQUENCY MODULATION.—Pfm is a method of pulse modulation in which the modulating wave is used to frequency modulate a pulse-generating circuit. For example, the pulse rate may be 8,000 pulses per second (pps) when the signal voltage is 0. The pulse rate may step up to 9,000 pps for maximum positive signal voltage, and down to 7,000 pps for maximum negative signal voltage. Figure 2-47, views (A), (B), and (C) show three typical waveforms for pfm. This method of modulation is not used extensively because of complicated pfm generation methods. It requires a stable oscillator that is frequency modulated to drive a pulse generator. Since the other forms of ptm are easier to achieve, they are commonly used.

Q-26. What is pulse-frequency modulation?

Pulse-Code Modulation

PULSE-CODE MODULATION (pcm) refers to a system in which the standard values of a QUANTIZED WAVE (explained in the following paragraphs) are indicated by a series of coded pulses. When these pulses are decoded, they indicate the standard values of the original quantized wave. These codes may be *binary*, in which the symbol for each quantized element will consist of pulses and spaces: *ternary*, where the code for each element consists of any one of three distinct kinds of values (such as positive pulses, negative pulses, and spaces); or *n-ary*, in which the code for each element consists of nay number (n) of distinct values. This discussion will be based on the binary pcm system.

All of the pulse-modulation systems discussed previously provide methods of converting analog wave shapes to digital wave shapes (pulses occurring at discrete intervals, some characteristic of which is varied as a continuous function of the analog wave). The entire range of amplitude (frequency or phase) values of the analog wave can be arbitrarily divided into a series of standard values. Each pulse of a pulse train [figure 2-48, view (B)] takes the standard value nearest its actual value when modulated. The modulating wave can be faithfully reproduced, as shown in views (C) and (D). The amplitude range has been divided into 5 standard values in view (C). Each pulse is given whatever standard value is nearest its actual instantaneous value. In view (D), the same amplitude range has been divided into 10 standard levels. The curve of view (D) is a much closer approximation of the modulating wave, view (A), than is the 5-level quantized curve in view (C). From this you should see that the greater the number of standard levels used, the more closely the quantized wave approximates the original. This is also made evident by the fact that an infinite number of standard levels exactly duplicates the conditions of nonquantization (the original analog waveform).

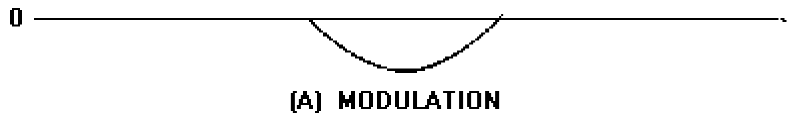

Figure 2-48A.—Quantization levels. MODULATION.

Figure 2-48B.—Quantization levels. TIMING.

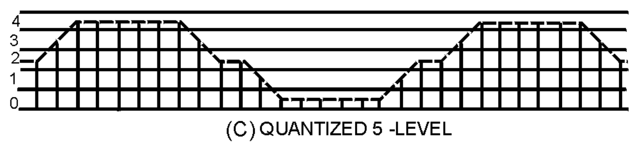

Figure 2-48C.—Quantization levels. QUANTIZED 5-LEVEL.

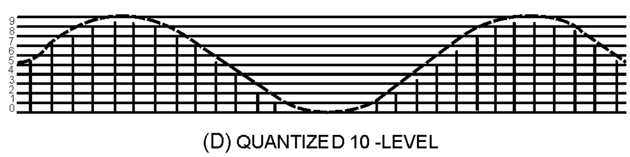

Figure 2-48D.—Quantization levels. QUANTIZED 10-LEVEL.

Although the quantization curves of figure 2-48 are based on 5- and 10-level quantization, in actual practice the levels are usually established at some exponential value of 2, such as $4(2^2)$, $8(2^3)$, $16(2^4)$, $32(2^5)$ . . . $N(2^n)$. The reason for selecting levels at exponential values of 2 will become evident in the discussion of pcm. Quantized fm is similar in every way to quantized AM. That is, the range of frequency deviation is divided into a finite number of standard values of deviation. Each sampling pulse results in a deviation equal to the standard value nearest the actual deviation at the sampling instant. Similarly, for phase modulation, quantization establishes a set of standard values. Quantization is used mostly in amplitude- and frequency-modulated pulse systems.

Figure 2-49 shows the relationship between decimal numbers, binary numbers, and a pulse-code waveform that represents the numbers. The table is for a 16-level code; that is, 16 standard values of a quantized wave could be represented by these pulse groups. Only the presence or absence of the pulses are important. The next step up would be a 32-level code, with each decimal number represented by a series of five binary digits, rather than the four digits of figure 2-49. Six-digit groups would provide a 64-level code, seven digits a 128-level code, and so forth. Figure 2-50 shows the application of pulse-coded groups to the standard values of a quantized wave.

DECIMAL NUMBER	BINARY EQUIVALENT 2^3	2^2	2^1	2^0

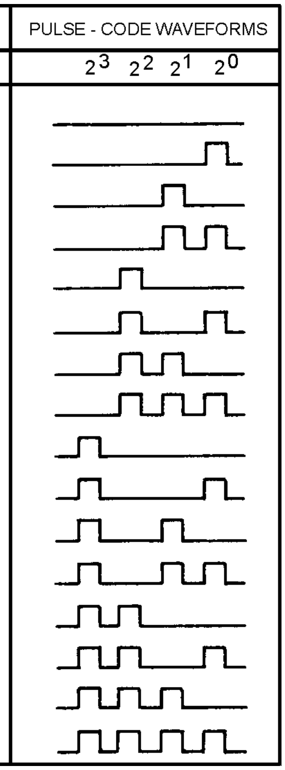

Figure 2-49.—Binary numbers and pulse-code equivalents.

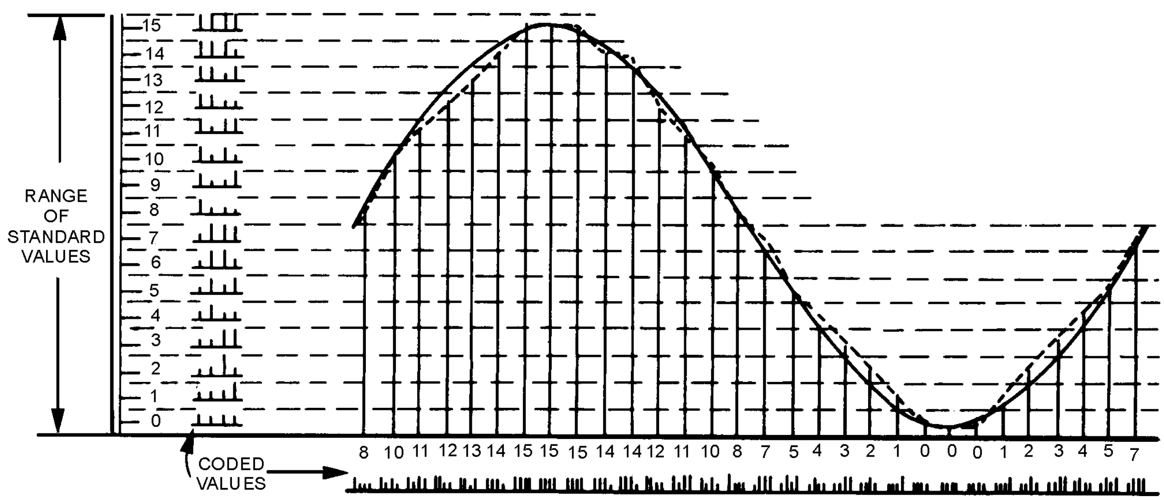

Figure 2-50.—Pulse-code modulation of a quantized wave (128 bits).

In figure 2-50 the solid curve represents the unquantized values of a modulating sinusoid. The dashed curve is reconstructed from the quantized values taken at the sampling interval and shows a very close agreement with the original curve. Figure 2-51 is identical to figure 2-50 except that the sampling interval is four times as great and the reconstructed curve is not faithful to the original. As previously stated, the sampling rate of a pulsed system must be at least twice the highest modulating frequency to get a usable reconstructed modulation curve. At the sampling rate of figure 2-50 and with a 4-element binary code, 128 bits (presence or absence of pulses) must be transmitted for each cycle of the modulating frequency. At the sampling rate of figure 2-51, only 32 bits are required; at the minimum sampling rate, only 8 bits are required.

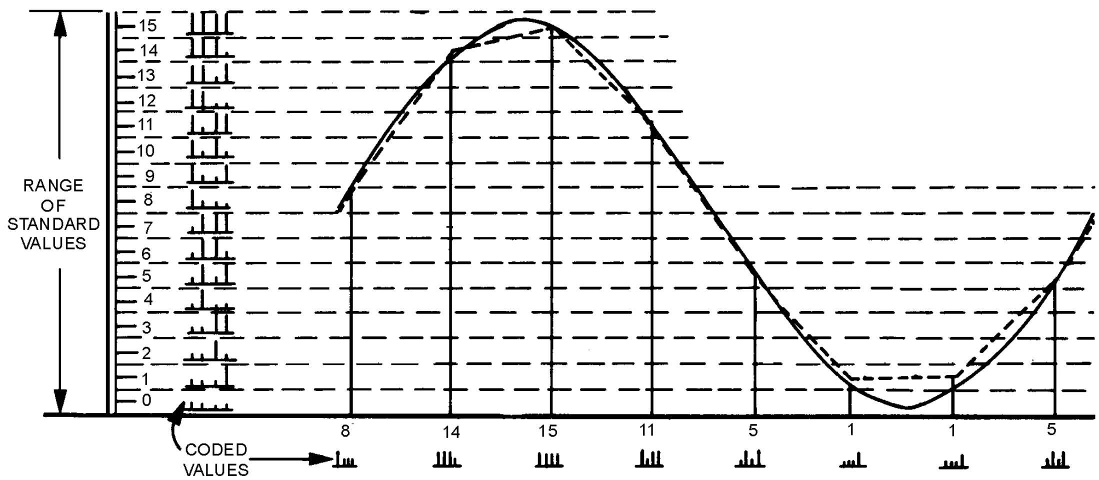

Figure 2-51.—Pulse-code modulation of a quantized wave (32 bits).

As a matter of convenience, especially to simplify the demodulation of pcm, the pulse trains actually transmitted are reversed from those shown in figures 2-49, 2-50, and 2-51; that is, the pulse with the lowest binary value (least significant digit) is transmitted first and the succeeding pulses have increasing binary values up to the code limit (most significant digit). Pulse coding can be performed in a number of ways using conventional circuitry or by means of special cathode ray coding tubes. One form of coding circuit is shown in figure 2-52. In this case, the pulse samples are applied to a holding circuit (a capacitor which stores pulse amplitude information) and the modulator converts pam to pdm. The pdm pulses are then used to gate the output of a precision pulse generator that controls the number of pulses applied to a binary counter. The duration of the gate pulse is not necessarily an integral number of the repetition pulses from the precisely timed clock-pulse generator. Therefore, the clock pulses gated into the binary counter by the pdm pulse may be a number of pulses plus the leading edge of an additional pulse. This "partial" pulse may have sufficient duration to trigger the counter, or it may not. The counter thus responds only to integral numbers, effectively quantizing the signal while, at the same time, encoding it. Each bistable stage of the counter stores ZERO or a ONE for each binary digit it represents (binary 1110 or decimal 14 is shown in figure 2-52). An electronic commutator samples the 2^0, 2^1, 2^2, and 2^3 digit positions in sequence and transmits a mark or space bit (pulse or no pulse) in accordance with the state of each counter stage. The holding circuit is always discharged and reset to zero before initiation of the sequence for the next pulse sample.

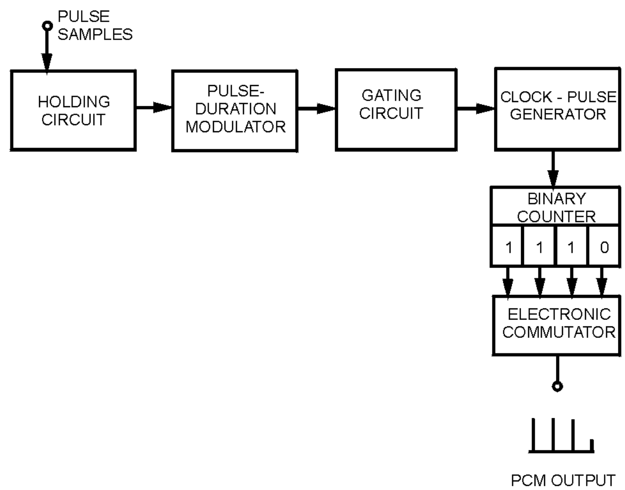

Figure 2-52.—Block diagram of quantizer and pcm coder.

The pcm demodulator will reproduce the correct standard amplitude represented by the pulse-code group. However, it will reproduce the correct standard only if it is able to recognize correctly the presence or absence of pulses in each position. For this reason, noise introduces no error at all if the signal-to-noise ration is such that the largest peaks of noise are not mistaken for pulses. When the noise is random (circuit and tube noise), the probability of the appearance of a noise peak comparable in amplitude to the pulses can be determined. This probability can be determined mathematically for any ration of signal-to-average-noise power. When this is done for 10^5 pulses per second, the approximate error rate for three values of signal power to average noise power is:

17 dB — 10 errors per second

20 dB — 1 error every 20 minutes

22 dB — 1 error every 2,000 hours

Above a threshold of signal-to-noise ration of approximately 20 dB, virtually no errors occur. In all other systems of modulation, even with signal-to-noise ratios as high as 60 dB, the noise will have some effect. Moreover, the pcm signal can be retransmitted, as in a multiple relay link system, as many times as desired, without the introduction of additional noise effects; that is, noise is not cumulative at relay stations as it is with other modulation systems.

The system does, of course, have some distortion introduced by quantizing the signal. Both the standard values selected and the sampling interval tend to make the reconstructed wave depart from the original. This distortion, called QUANTIZING NOISE, is initially introduced at the quantizing and coding modulator and remains fixed throughout the transmission and retransmission processes. Its magnitude can be reduced by making the standard quantizing levels closer together. The relationship of the quantizing noise to the number of digits in the binary code is given by the following standard relationship:

Where:

n is the number of digits in the binary code

$$\frac{\text{peak signal power}}{\text{average quantizing noise power}} = (10.8 + 6n)\ \text{dB}$$

Thus, with the 4-digit code of figure 2-50 and 2-51, the quantizing noise will be about 35 dB weaker than the peak signal which the channel will accommodate.

The advantages of pcm are two-fold. First, noise interference is almost completely eliminated when the pulse signals exceed noise levels by a value of 20 dB or more. Second, the signal may be received and retransmitted as many times as may be desired without introducing distortion into the signal.

Q-27. Pulse-code modulation requires the use of approximations of value that are obtained by what process?

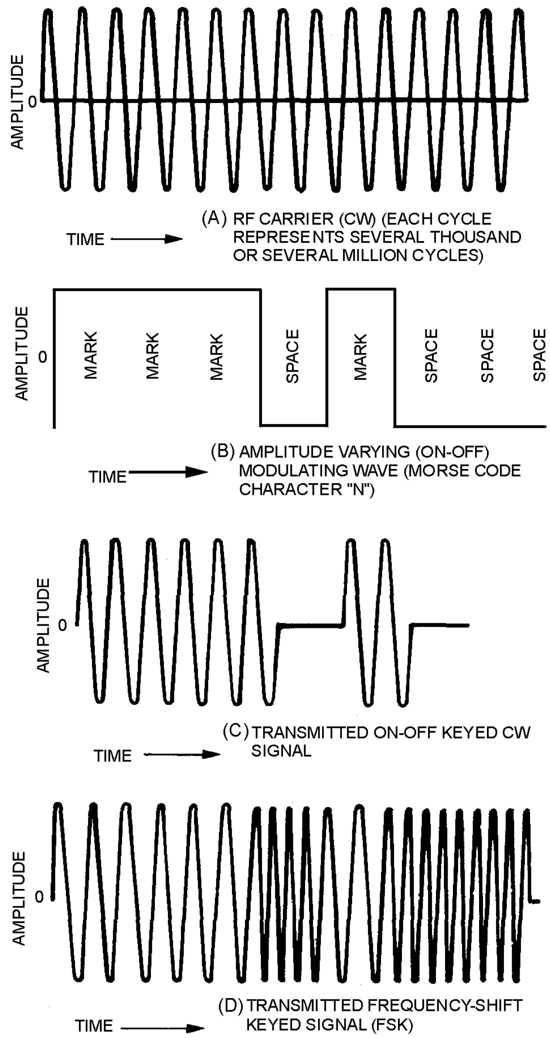
Q-28. If a modulating wave is sampled 10 times per cycle with a 5-element binary code, how many bits of information are required to transmit the signal?

Q-29. What is the primary advantage of pulse-modulation systems?

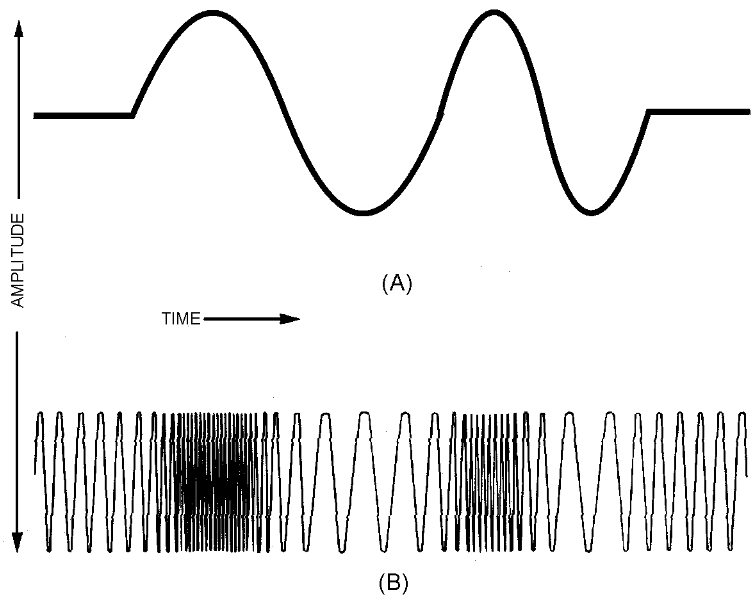
SUMMARY

Now that you have completed this chapter, a short review of what you have learned is in order. The following review will refresh your memory of angle modulation and pulse modulation.

FREQUENCY-SHIFT KEYING (fsk) is similar to cw keying in amplitude modulation and is a form of angle modulation. The carrier frequency is changed between two discrete values by the opening and closing of a key.



In **FREQUENCY MODULATION (fm)** the instantaneous frequency of the radio-frequency wave is varied in accordance with the modulating signal; the amplitude of the radio-frequency wave is kept constant.

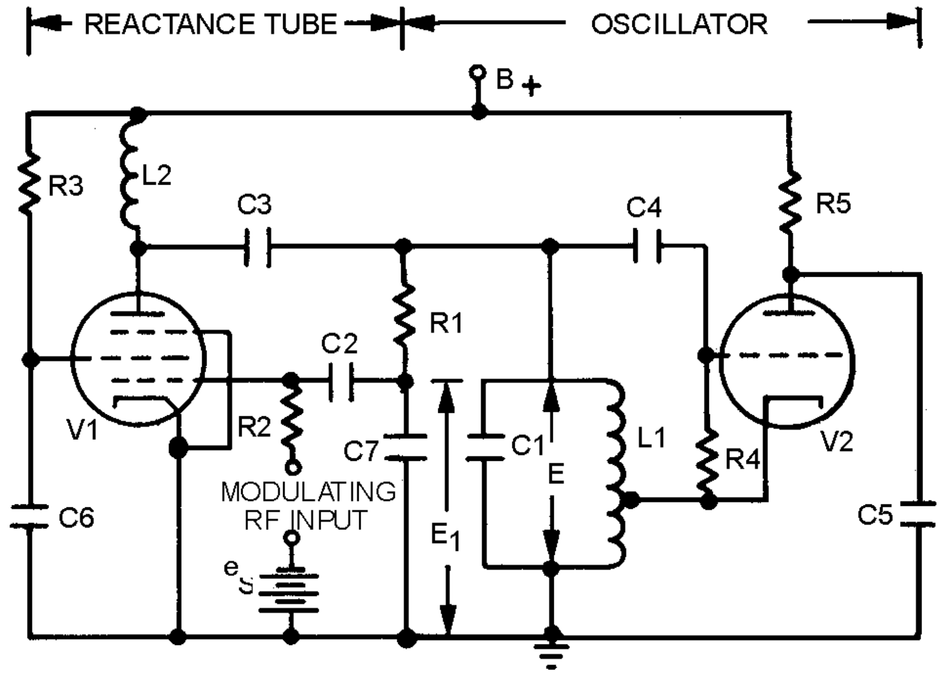


MODULATION INDEX is the ratio of the maximum frequency difference between the modulated and the unmodulated carrier, or between the deviation frequency and the modulation frequency.

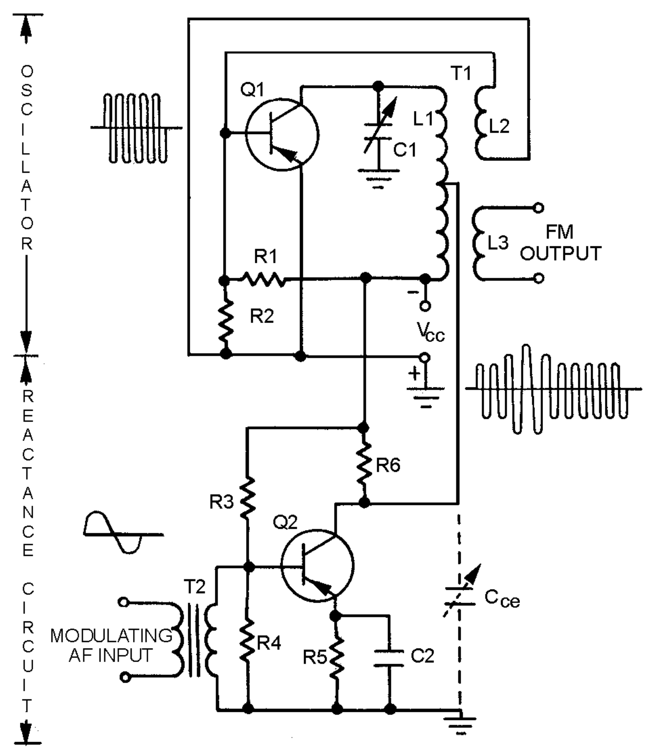
The number of SIGNIFICANT SIDEBANDS and the modulating frequency will determine the bandwidth of the fm wave. The number of significant sidebands can be determined from the modulation index.

MODULATION INDEX	SIGNIFICANT SIDEBANDS
.01	2
.4	2
.5	4
1.0	6
2.0	8
3.0	12
4.0	14
5.0	16
6.0	18
7.0	22
8.0	24
9.0	26
10.0	28
11.0	32
12.0	32
13.0	36
14.0	38
15.0	38

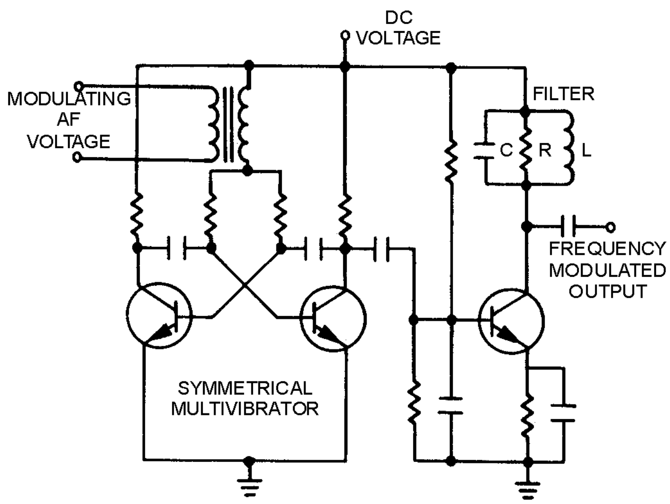
The **REACTANCE-TUBE MODULATOR** is frequency modulated by using a reactance tube in shunt with the tank circuit.



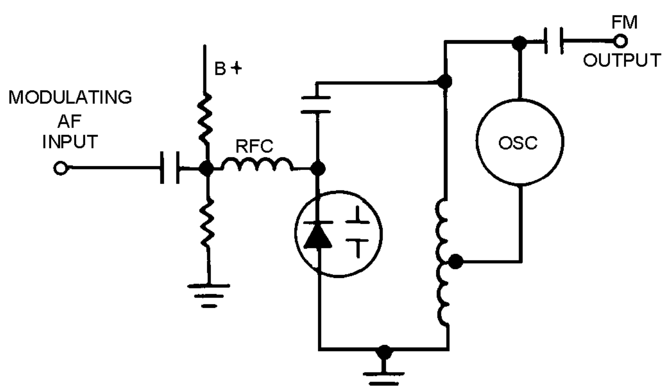
The **SEMICONDUCTOR-REACTANCE MODULATOR** is used to frequency modulate low-power semiconductor transmitters.



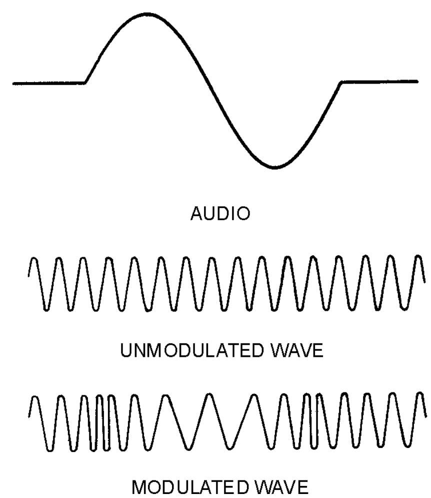
The **MULTIVIBRATOR MODULATOR** uses an astable multivibrator with a modulating voltage inserted in series with the base return of the multivibrator transistors.



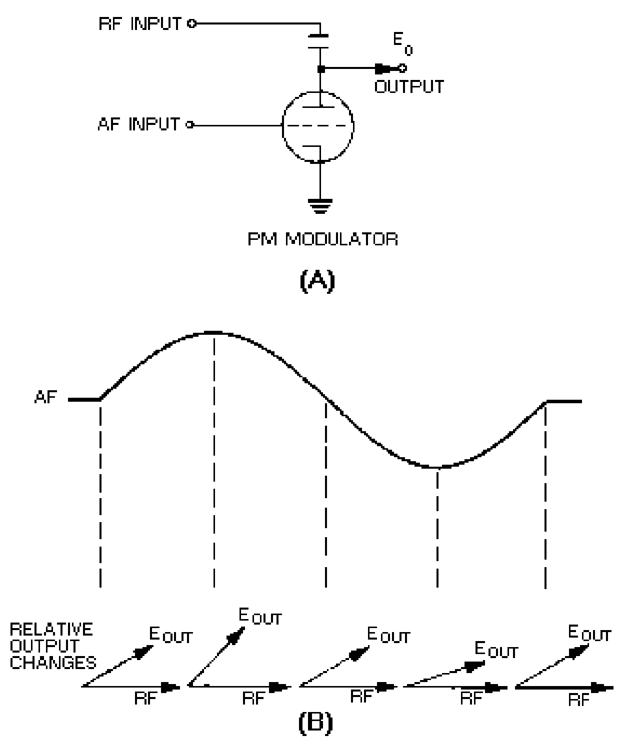
The **VARACTOR FM MODULATOR** uses a VARACTOR. This is a specially designed diode that has a certain amount of capacitance between the junction that can be controlled by reverse biasing.



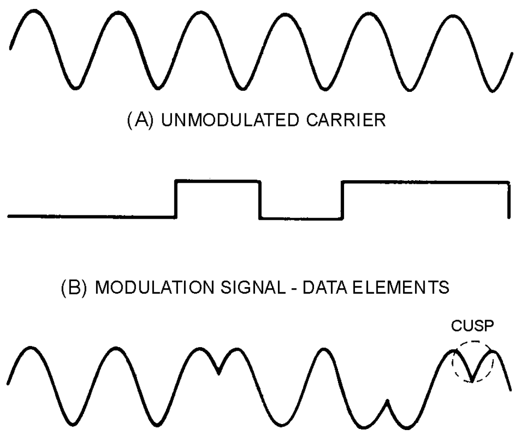
In **PHASE MODULATION** the carrier's phase is caused to shift at the rate of the modulating audio. The amount of phase shift is controlled by the amplitude of the modulating wave.



A **BASIC PHASE MODULATOR** may be a single tube in series with a capacitor to form a phase-shift network. As the impedance of the tube changes, the phase of the output shifts.

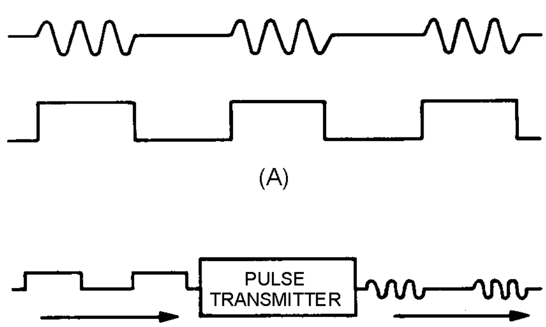


PHASE-SHIFT KEYING (psk) is similar to cw and fsk. It consists of phase reversals of the carrier frequency as modulating signal data elements open and close the modulator key.

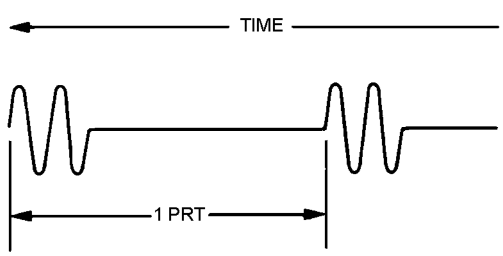


(A) UNMODULATED CARRIER
(B) MODULATION SIGNAL - DATA ELEMENTS
(C) MODULATED CARRIER
(D) MODULATED CARRIER AFTER FILTERING

PULSE MODULATION is modulation in which we allow oscillations to occur for a given period of time only during selected intervals.

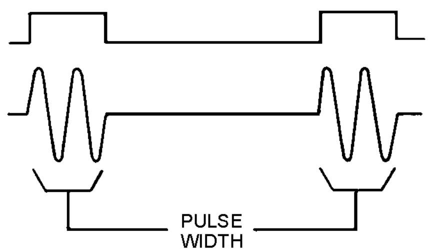


PULSE-REPETITION TIME (prt) is the specific time period between each group of rf pulses.

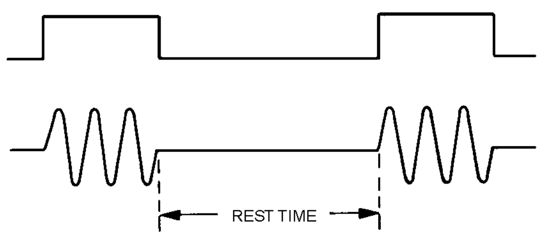


PULSE-REPETITION FREQUENCY (prf) is found by dividing the pulse repetition time into 1. This defines how often the groups of pulses occur.

PULSE WIDTH (pw) or **PULSE DURATION (pd)** is the time that a pulse is occurring.



REST TIME (rt) is the time referred to as nonpulse time.

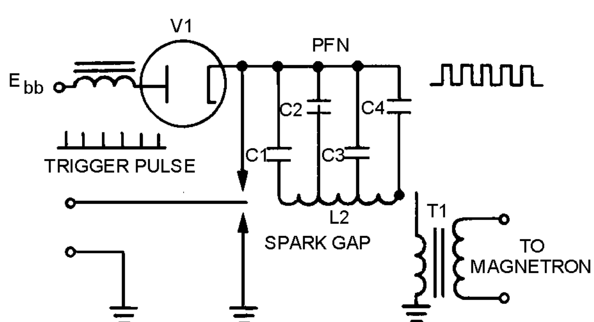


PEAK POWER is the maximum power during a pulse.

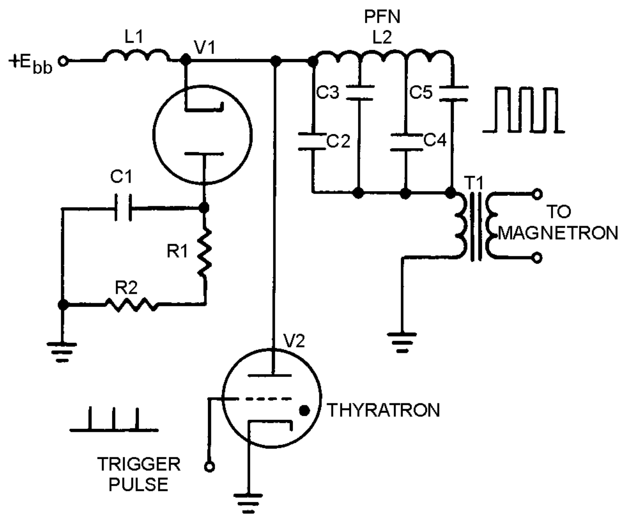
AVERAGE POWER equals the peak power averaged over one complete cycle.

DUTY CYCLE is the ratio of working time to total time, or the ratio of actual transmit time to transmit time plus rest time, for intermittently operated devices.

The **SPARK-GAP MODULATOR** consists of a circuit for storing energy, a circuit for rapidly discharging the storage circuit, a pulse transformer, and a power source.

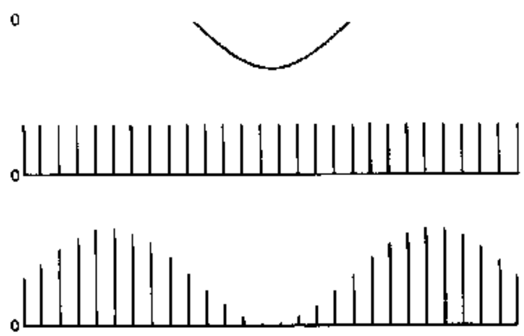


The **THYRATRON MODULATOR** is an electronic switch which requires a positive trigger of only 150 volts. The trigger must rise at the rate of 100 volts per microsecond to fire or cause the modulator to conduct.



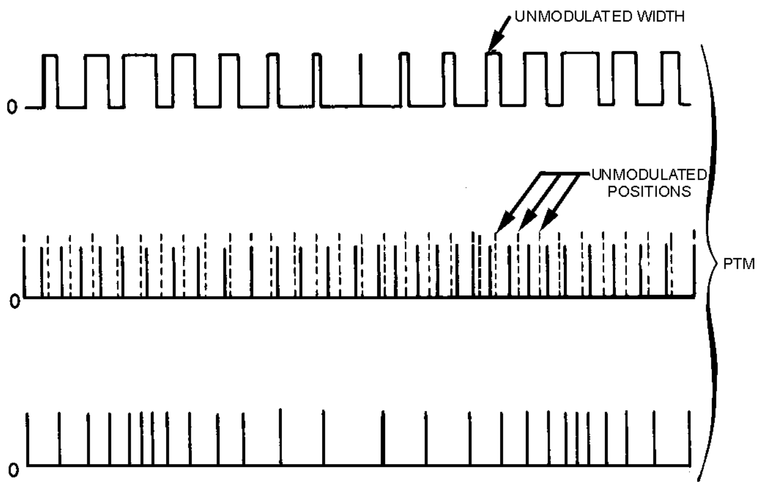
In communications **PULSE-MODULATION SYSTEMS**, the modulating wave must be SAMPLED at 2.5 times the highest modulating frequency to ensure accuracy.

PULSE-AMPLITUDE MODULATION (pam) is modulation in which the amplitude of each pulse is controlled by the instantaneous amplitude of the modulation signal at the time of each pulse.



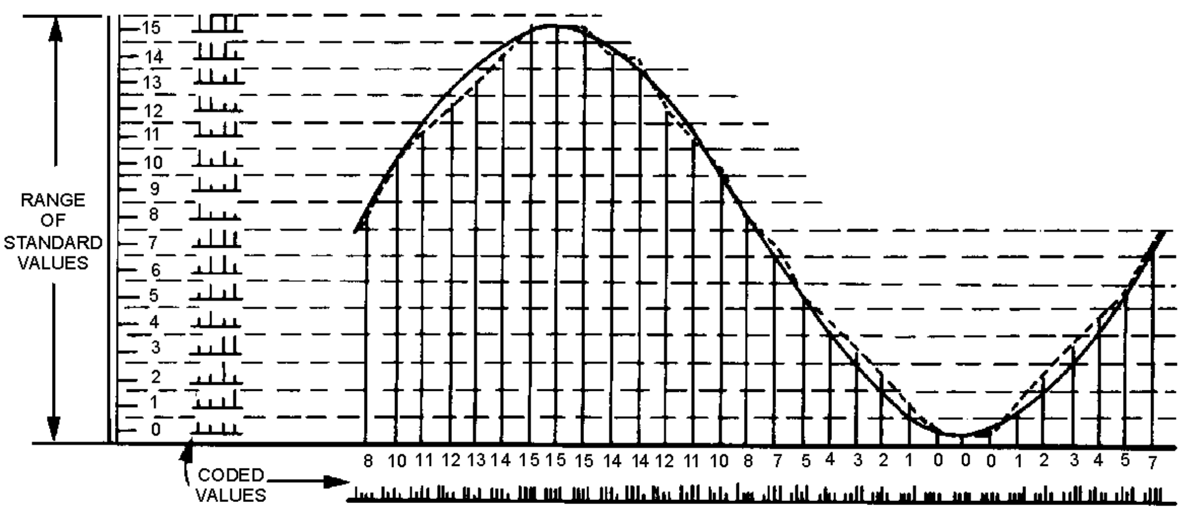
PULSE-DURATION MODULATION (pdm) or **PULSE-WIDTH MODULATION (pwm)** are both designations for a type of modulation. The width of each pulse in a train is made proportional to the instantaneous value of the modulating signal at the instant of the pulse.

PULSE-POSITION MODULATION (ppm) has the advantage of requiring constant transmitter power. The amplitude and width of the pulses are kept constant. At the same time, the position of each pulse, in relation to the position of a recurrent reference pulse, is varied by each instantaneous sampled value of the modulating wave.



PULSE-FREQUENCY MODULATION (pfm) is a method of pulse modulation in which the modulating wave is used to frequency modulate a pulse-generating circuit.

PULSE-CODE MODULATION (pcm) refers to a system in which the standard value of a quantized wave is indicated by a series of coded pulses that give the modulating wave's value at the instant of the sample.



ANSWERS TO QUESTIONS Q1. THROUGH Q29.

A-1. Frequency and phase.

A-2. Frequency-shift keying.

A-3. Resistance to noise interference.

A-4. Instantaneous frequency.

A-5. As the ratio of the frequency deviation to the maximum frequency deviation allowable.

A-6. The number of significant sidebands and the modulating frequency.

A-7. By changing the reactance of an oscillator circuit in consonance with the modulating voltage.

A-8. Collector-to-emitter capacitance.

A-9. An LCR filter.

A-10. Capacitance.

A-11. Phase.

A-12. A phase-shift network such as a variable resistor and capacitor in series.

A-13. Cw and frequency-shift keying.

A-14. Pulse modulation.

A-15. Pulse-repetition time.

A-16. Rest time.

A-17. Peak power during a pulse averaged over pulse time plus rest time.

A-18. Either a fixed spark gap that uses a trigger pulse to ionize the air between the contacts, or a rotary gap that is similar to a mechanical switch.

A-19. Power source, a circuit for storing energy, a circuit for discharging the storage circuit, and a pulse transformer.

A-20. Some characteristic of the pulses has to be varied.

A-21. 2.5 times the highest modulating frequency.

A-22. Both are susceptible to noise and interference.

A-23. The time duration of the pulses or the time of occurrence of the pulses.

A-24. Either, or both at the same time.

A-25. It requires synchronization between the transmitter and receiver.

A-26. A method of pulse modulation in which a modulating wave is used to frequency modulate a pulse-generating circuit.

A-27. Quantization.

A-28. 50.

A-29. Low susceptibility to noise.

CHAPTER 3

DEMODULATION

LEARNING OBJECTIVES

Upon completion of this chapter you will be able to:

1. Describe cw detector circuit operations for the heterodyne and regenerative detectors.
2. Discuss the requirements for recovery of intelligence from an AM signal and describe the theory of operation of the following AM demodulators: series-diode, shunt-diode, common-emitter, and common-base.
3. Describe fm demodulation circuit operation for the phase-shift and gated-beam discriminators and the ratio-detector demodulator.
4. Describe phase demodulation circuit operation for the peak, low-pass filter, and conversion detectors.

INTRODUCTION

In chapters 1 and 2 you studied how to apply intelligence (modulation) to an rf-carrier wave. Carrier modulation allows the transmission of modulating frequencies without the use of transmission wire as a medium. However, for the communication process to be completed or to be useful, the intelligence must be recovered in its original form at the receiving site. The process of re-creating original modulating frequencies (intelligence) from the rf carrier is referred to as DEMODULATION or DETECTION. Each type of modulation is different and requires different techniques to recover (demodulate) the intelligence. In this chapter we will discuss ways of demodulating AM, cw, fm, phase, and pulse modulation.

The circuit in which restoration is achieved is called the DETECTOR or DEMODULATOR (both of these terms are used in *NEETS*). The term demodulator is used because the demodulation process is considered to be the opposite of modulation. The output of an ideal detector must be an exact reproduction of the modulation existing on the rf wave. Failure to accurately recover this intelligence will result in distortion and degradation of the demodulated signal and intelligence will be lost. The distortion may be in amplitude, frequency, or phase, depending on the nature of the demodulator. A nonlinear device is required for demodulation. This nonlinear device is required to recover the modulating frequencies from the rf envelope. Solid-state detector circuits may be either a pn junction diode or the input junction of a transistor. In electron-tube circuits, either a diode or the grid or plate circuits of a triode electron tube may be used as the nonlinear device.

Q-1. What is demodulation?

Q-2. What is a demodulator?

CONTINUOUS-WAVE DEMODULATION

Continuous-wave (cw) modulation consists of on-off keying of a carrier wave. To recover on-off keyed information, we need a method of detecting the *presence or absence of rf oscillations*. The CW DEMODULATOR detects the presence of rf oscillations and converts them into a recognizable form. Figure 3-1 illustrates the received cw in view (A), the rectified cw from a diode detector in view (B), and the dc output from a filter that can be used to control a relay or light indicator in view (C).

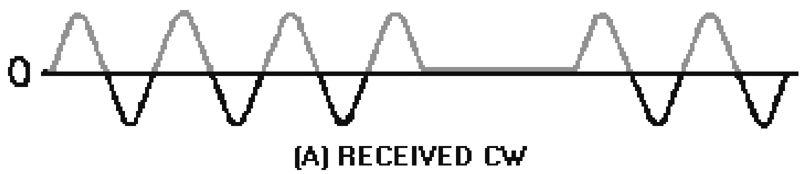


Figure 3-1A.—Cw demodulation. RECEIVED CW.

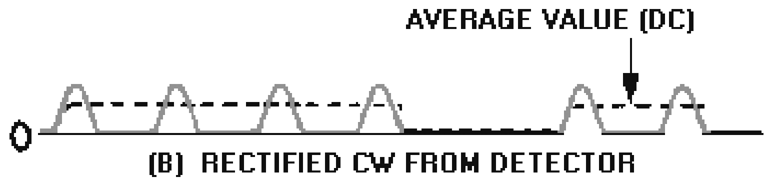

Figure 3-1B.—Cw demodulation. RECTIFIED CW FROM DETECTOR.

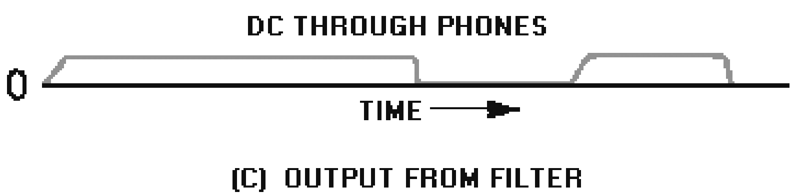

Figure 3-1C.—Cw demodulation. OUTPUT FROM FILTER.

Figure 3-2 is a, simplified circuit that could be used as a cw demodulator. The antenna receives the rf oscillations from the transmitter. The tank circuit, L and C1, acts as a frequency-selective network that is tuned to the desired rf carrier frequency. The diode rectifies the oscillations and C2 provides filtering to provide a constant dc output to control the headset. This demodulator circuit is the equivalent of a wire telegraphy circuit but it has certain disadvantages. For example, if two transmitters are very close in frequency, distinguishing which transmitting station you are receiving is often impossible without a method of fine tuning the desired frequency. Also, if the stations are within the frequency bandpass of the input tank circuit, the tank output will contain a mixture of both signals. Therefore, a method, such as HETERODYNE DETECTION, must be used which provides more than just the information on the presence or absence of a signal.

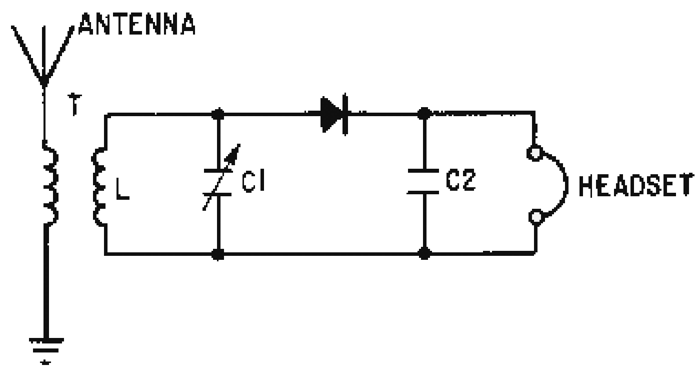

Figure 3-2.—Cw demodulator.

HETERODYNE DETECTION

The use of an af voltage in the detector aids the operator in distinguishing between various signals. Since the carrier is unmodulated, the af voltage can be developed by using the heterodyne procedure discussed in chapter 1. The procedure is to mix the incoming cw signal with locally generated oscillations. This provides a convenient difference frequency in the af range, such as 1,000 hertz. The af difference frequency then is rectified and smoothed by a detector. The af voltage is reproduced by a telephone headset or a loudspeaker.

Consider the heterodyne reception of the code letter **A**, as shown in figure 3-3, view (A). The code consists of a short burst of cw energy (dot) followed by a longer burst (dash). Assume that the frequency of the received cw signal is 500 kilohertz. The locally generated oscillations are adjusted to a frequency which is higher or lower than the incoming rf signal (501 kilohertz in this case), as shown in view (B). The voltage resulting from the heterodyning action between the cw signal [view (A)] and the local oscillator signal [view (B)] is shown in view (C) as the mixed-frequency signal. ENVELOPE (intelligence) amplitude varies at the BEAT (difference) frequency of 1,000 hertz (501,000 – 500,000). The negative half cycles of the mixed frequency are rectified, as shown in view (D). The peaks of the positive half cycles follow the 1,000-hertz beat frequency.

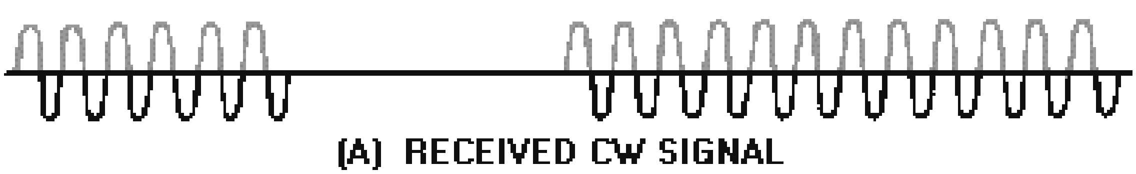

Figure 3-3A.—Heterodyne detection. RECEIVED CW SIGNAL.

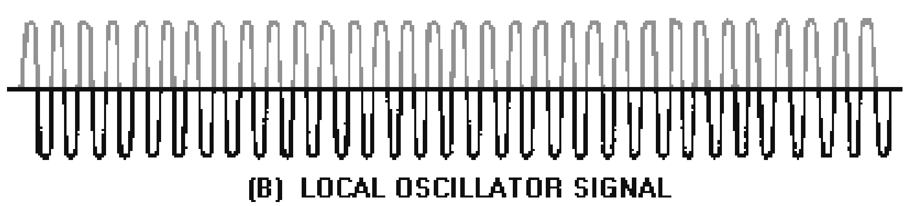

Figure 3-3B.—Heterodyne detection. LOCAL OSCILLATOR SIGNAL.

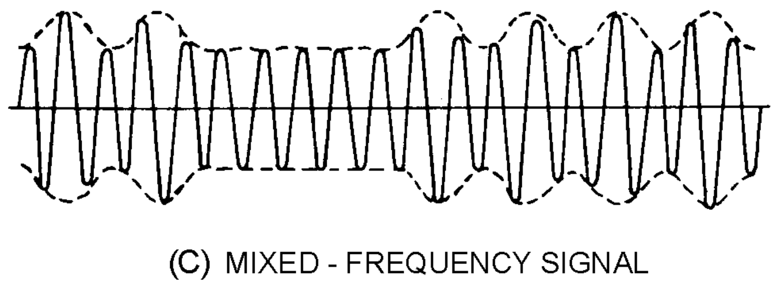

Figure 3-3C.—Heterodyne detection. MIXED-FREQUENCY SIGNAL.

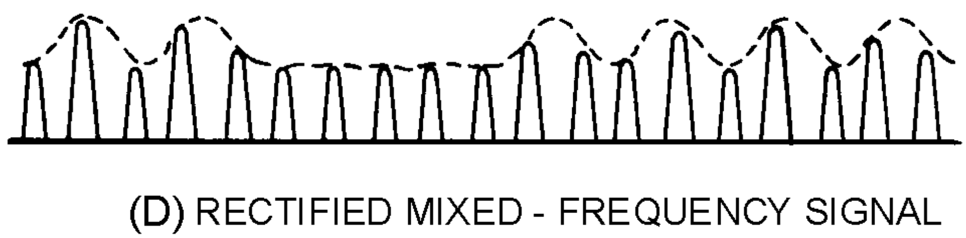

Figure 3-3D.—Heterodyne detection. RECTIFIED MIXED-FREQUENCY SIGNAL.

Figure 3-3E.—Heterodyne detection. AUDIO-BEAT NOTE FROM FILTER.

The cw signal pulsations are removed by the rf filter in the detector output and only the envelope of the rectified pulses remains. The envelope, shown in view (E), is a 1,000-hertz audio-beat note. This 1,000 hertz, dot-dash tone may be heard in a speaker or headphone and identified as the letter **A** by the operator.

The heterodyne method of reception is highly selective and allows little interference from adjacent cw stations. If a cw signal from a radiotelegraph station is operating at 10,000,000 hertz and at the same time an adjacent station is operating at 10,000,300 hertz, a simple detector cannot clearly discriminate between the two stations because the signals are just 300 hertz apart. This is because the bandpass of the tuning circuits is too wide and allows some of the other signal to interfere. The two carrier frequencies differ by only 0.003 percent and a tuned tank circuit cannot easily discriminate between them. However, if a heterodyne detector with a local-oscillator frequency of 10,001,000 hertz is used, then beat notes of 1,000 and 700 hertz are produced by the two signals. These are audio frequencies, which can be distinguished easily by a selective circuit because they differ by 30 percent (compared to the 0.003 percent above).

Even if two stations produce identical beat frequencies, they can be separated by adjusting the local-oscillator or BEAT-FREQUENCY OSCILLATOR (bfo) frequency. For example, if the second station in the previous example had been operating at 10,002,000 hertz, then both stations would have produced a 1,000-hertz beat frequency and interference would have occurred. Adjusting the local-oscillator frequency to 9,999,000 hertz would have caused the desired station at 10,000,000 hertz to produce a 1,000-hertz beat frequency. The other station, at 10,002,000 hertz, would have produced a beat frequency of 3,000 hertz. Either selective circuits or the operator can easily distinguish between these widely differing tones. A trained operator can use the variable local oscillator to distinguish between stations that vary in frequency by only a few hundred hertz.

Q-3. What is the simplest form of cw detector?

Q-4. What are the essential components of a cw receiver system?

Q-5. What principle is used to help distinguish between two cw signals that are close in frequency?

Q-6. How does heterodyning distinguish between cw signals?

REGENERATIVE DETECTOR

A simple, one-transistor REGENERATIVE DETECTOR circuit that uses the heterodyning principle for cw operation is shown in figure 3-4. The circuit can be made to oscillate by increasing the amount of energy fed back to the tank circuit from the collector-output circuit (by physically moving tickler coil L2 closer to L1 using the regeneration control). This feedback overcomes losses in the base-input circuit and causes self-oscillations which are controlled by tuning capacitor C1. The received signal from the antenna and the oscillating frequency are both present at the base of transistor Q1. These two frequencies are heterodyned by the nonlinearity of the transistor. The resulting beat frequencies are then rectified by the emitter-base junction and produce a beat note which is amplified in the collector-output circuit. The af currents in the collector circuit actuate the phones. The REGENERATIVE DETECTOR (figure 3-4) produces its own oscillations, heterodynes them with an incoming signal, and rectifies or detects them.

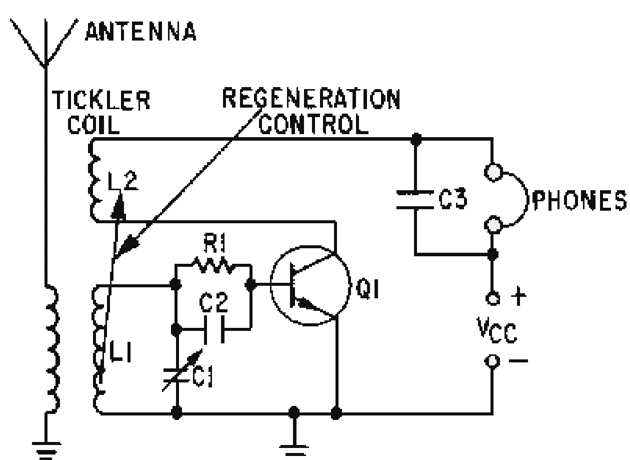

Figure 3-4.—Regenerative detector.

The regenerative detector is used to receive short-wave code signals because it is easy to adjust and has high sensitivity and good selectivity. At high frequencies, the amount of signal detuning necessary to produce an audio-beat note is a small percentage of the signal frequency and causes no trouble. The use of the regenerative detector for low-frequency code reception, however, is usually avoided. At low frequencies the detuning required to produce the proper audio-beat frequency is a considerable percentage of the signal frequency. Although this type detector may be used for AM signals, it has high distortion and is not often used.

Q-7. What simple, one-transistor detector circuit uses the heterodyne principle?

Q-8. What three functions does the transistor in a regenerative detector serve?

AM DEMODULATION

Amplitude modulation refers to any method of modulating an electromagnetic carrier frequency by varying its amplitude in accordance with the message intelligence that is to be transmitted. This is accomplished by heterodyning the intelligence frequency with the carrier frequency. The vector summation of the carrier, sum, and difference frequencies causes the modulation envelope to vary in amplitude at the intelligence frequency, as discussed in chapter 1. In this section we will discuss several circuits that can be used to recover this intelligence from the variations in the modulation envelope.

DIODE DETECTORS

The detection of AM signals ordinarily is accomplished by means of a diode rectifier, which may be either a vacuum tube or a semiconductor diode. The basic detector circuit is shown in its simplest form in view (A) of figure 3-5. Views (B), (C), and (D) show the circuit waveforms. The demodulator must meet three requirements: (1) It must be sensitive to the type of modulation applied at the input, (2) it must be nonlinear, and (3) it must provide filtering. Remember that the AM waveform appears like the diagram of view (B) and the *amplitude* variations of the peaks represent the original audio signal, but *no modulating signal frequencies* exist in this waveform. The waveform contains only three rf frequencies: (1) the *carrier* frequency, (2) the *sum* frequency, and (3) the *difference* frequency. The modulating intelligence is contained in the *difference* between these frequencies. The vector addition of these frequencies provides the modulation envelope which approximates the original modulating waveform. It is this modulation envelope that the DIODE DETECTORS use to reproduce the original modulating frequencies.

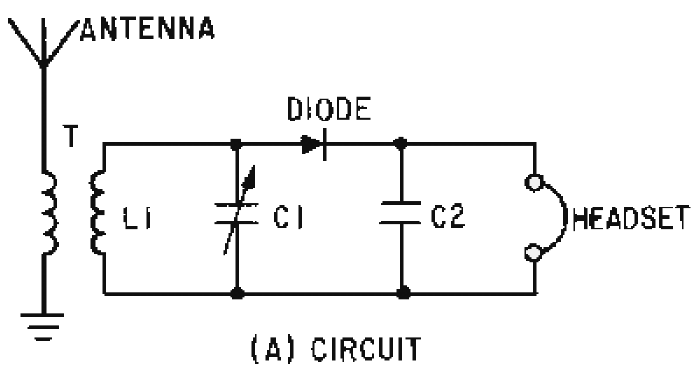

Figure 3-5A.—Series-diode detector and wave shapes. CIRCUIT.

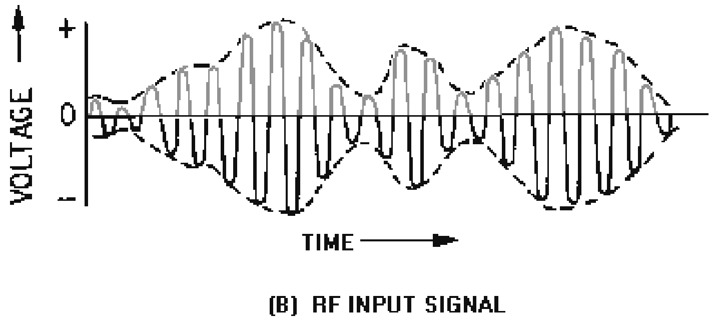

Figure 3-5B.—Series-diode detector and wave shapes. RF INPUT SIGNAL.

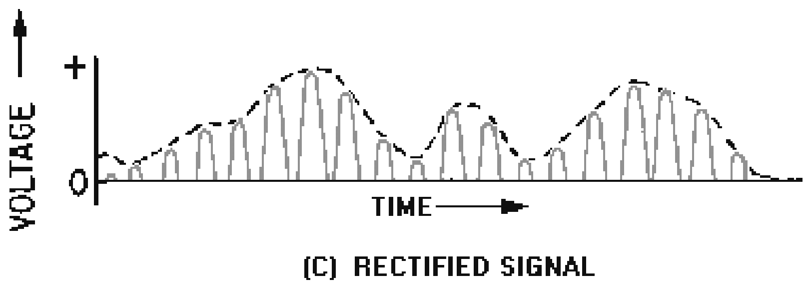

Figure 3-5C.—Series-diode detector and wave shapes. RECTIFIED SIGNAL.

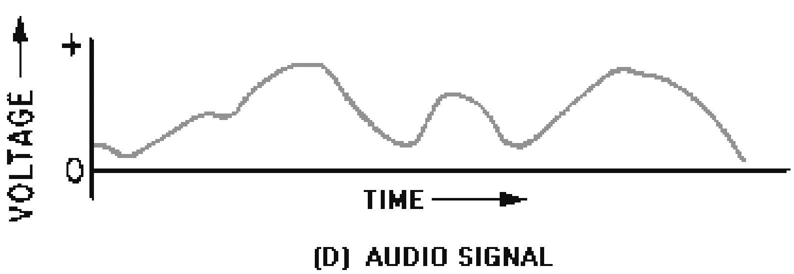

Figure 3-5D.—Series-diode detector and wave shapes. AUDIO SIGNAL.

Series-Diode Detector

Let's analyze the operation of the circuit shown in view (A) of figure 3-5. This circuit is the basic type of diode receiver and is known as a SERIES-DIODE DETECTOR. The circuit consists of an antenna, a tuned LC tank circuit, a semiconductor diode detector, and a headset which is bypassed by capacitor C2. The antenna receives the transmitted rf energy and feeds it to the tuned tank circuit. This tank circuit (L1 and C1) selects which rf signal will be detected. As the tank resonates at the selected frequency, the wave shape in view (B) is developed across the tank circuit. Because the semiconductor is a nonlinear device, it conducts in only one direction. This eliminates the negative portion of the rf carrier and produces the signal shown in view (C). The current in the circuit must be smoothed before the headphones can reproduce the af intelligence. This action is achieved by C2 which acts as a filter to provide an output that is proportional to the peak rf pulses. The filter offers a low impedance to rf and a relatively high impedance to af. (Filters were discussed in *NEETS*, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*.) This action causes C2 to develop the waveform in view (D). This varying af voltage is applied to the headset which then reproduces the original modulating frequency. This circuit is called a series-diode detector (sometimes referred to as a VOLTAGE-DIODE DETECTOR) because the semiconductor diode is in series with both the input voltage and the load impedance. Voltages in the circuit cause an output voltage to develop across the load impedance that is proportional to the input voltage peaks of the modulation envelope.

Q-9. What are the three requirements for an AM demodulator?

Q-10. What does the simplest diode detector use to reproduce the modulating frequency?

Q-11. What is the function of the diode in a series-diode detector?

Q-12. In figure 3-5, what is the function of C2?

Shunt-Diode Detector

The SHUNT-DIODE DETECTOR (figure 3-6) is similar to the series-diode detector except that the output variations are current pulses rather than voltage pulses. Passing this current through a shunt resistor develops the voltage output. The input is an rf modulated envelope. On the negative half cycles of the rf, diode CR1 is forward biased and shunts the signal to ground. On the positive half cycles, current flows from the output through L1 to the input. A field is built up around L1 that tends to keep the current flowing. This action integrates the rf current pulses and causes the output to follow the modulation envelope (intelligence) closely. (Integration was discussed in *NEETS*, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*.) Shunt resistor R1 develops the output voltage from this current flow. Although the shunt detector operates on the principle of current flow, it is the output voltage across the shunt resistor that is used to reproduce the original modulation signal. The shunt-diode detector is easily identified by noting that the detector diode is in parallel with both the input and load impedance. The waveforms associated with this detector are identical to those shown in views (B), (C), and (D) of figure 3-5.

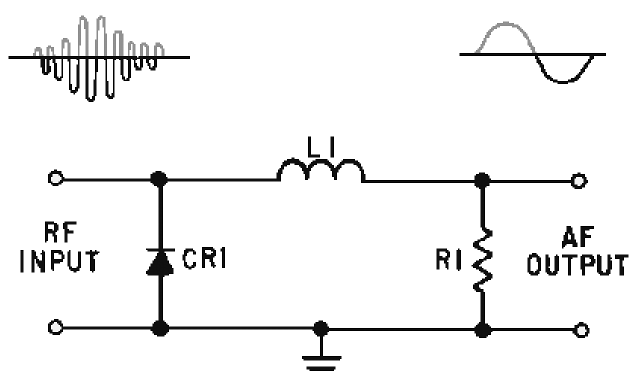

Figure 3-6.—Shunt-diode detector.

The series-diode detector is normally used where large input signals are supplied and a linear output is required. The shunt-diode detector is used where the voltage variations are too small to produce a full output from audio amplifier stages. Additional current amplifiers are required to bring the output to a usable level. Other methods of detection and amplification have been developed which will detect low-level signals. The next sections will discuss two of these circuits, the common-emitter and common-base detectors.

Q-13. How does the current-diode detector differ from the voltage-diode detector?

Q-14. Under what circuit conditions would the shunt detector be used?

COMMON-EMITTER DETECTOR

The COMMON-EMITTER DETECTOR is often used in receivers to supply an amplified detected output. The schematic for a typical transistor common-emitter detector is shown in figure 3-7. Input transformer T1 has a tuned primary that acts as a frequency-selective device. L2 inductively couples the input modulation envelope to the base of transistor Q1. Resistors R1 and R2 are fixed-bias voltage dividers that set the bias levels for Q1. Resistor R1 is bypassed by C2 to eliminate rf. This RC combination also acts as the load for the diode detector (emitter-base junction of Q1). The detected audio is in series with the biasing voltage and controls collector current. The output is developed across R4 which is also bypassed to remove rf by C4. R3 is a temperature stabilization resistor and C3 bypasses it for both rf and af.

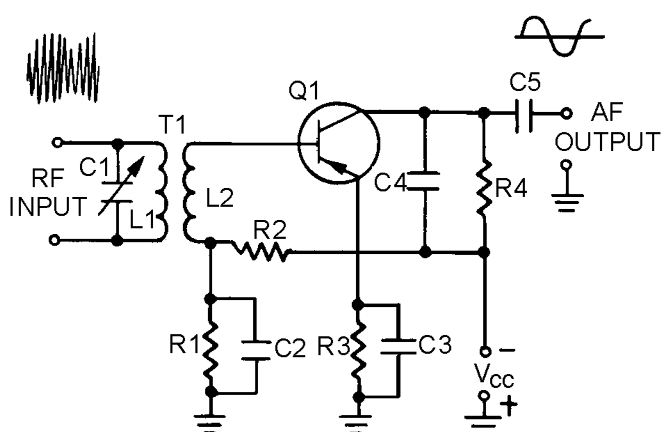

Figure 3-7.—Common-emitter detector.

Q1 is biased for slight conduction with no input signal applied. When an input signal appears on the base of Q1, it is rectified by the emitter-base junction (operating as a diode) and is developed across R1 as a dc bias voltage with a varying af component. This voltage controls bias and collector current for Q1. The output is developed by collector current flow through R4. Any rf ripple in the output is bypassed across the collector load resistor by capacitor C4. The af variations are not bypassed. After the modulation envelope is detected in the base circuit, it is amplified in the output circuit to provide suitable af output. The output of this circuit is higher than is possible with a simple detector. Because of the amplification in this circuit, weaker signals can be detected than with a simple detector. A higher, more usable output is thus developed.

Q-15. Which junction of the transistor in the common-emitter detector detects the modulation envelope?

Q-16. Which component in figure 3-7 develops the af signal at the input?

Q-17. How is the output signal developed in the common-emitter detector?

COMMON-BASE DETECTOR

Another amplifying detector that is used in portable receivers is the COMMON-BASE DETECTOR. In this circuit detection occurs in the emitter-base junction and amplification occurs at the output of the collector junction. The output developed is the equivalent of a diode detector which is followed by a stage of audio amplification, but with more distortion. Figure 3-8 is a schematic of a typical common-base detector. Transformer T1 is tuned by capacitor C3 to the frequency of the incoming modulated envelope. Resistor R1 and capacitor C1 form a self-biasing network which sets the dc operating point of the emitter junction. The af output is taken from the collector circuit through audio transformer T2. The primary of T2 forms the detector output load and is bypassed for rf by capacitor C2.

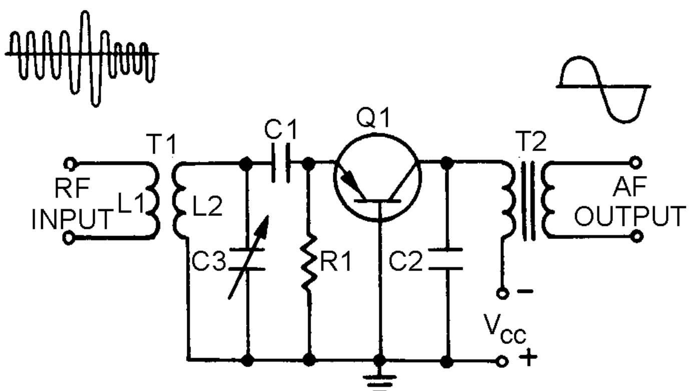

Figure 3-8.—Common-base detector.

The input signal is coupled through T1. When capacitor C3 is tuned to the proper frequency, the signal is passed to the emitter of Q1. When no input signal is present, bias is determined by resistor R1. When the input signal becomes positive, current flows through the emitter-base junction causing it to be forward biased. C1 and R1 establish the dc operating point by acting as a filter network. This action provides a varying dc voltage that follows the peaks of the rf modulated envelope. This action is identical to the diode detector with the emitter-base junction doing the detecting. The varying dc voltage on the emitter changes the bias on Q1 and causes collector current to vary in accordance with the detected voltage. Transformer T2 couples these af current changes to the output. Thus, Q1 detects the AM wave and then provides amplification for the detected waveform.

The four AM detectors just discussed are not the only types that you will encounter. However, they are representative of most AM detectors and the same characteristics will be found in all AM detectors. Now let's study some ways of demodulating frequency-modulated (fm) signals.

Q-18. Which junction acts as the detector in a common-base detector?

Q-19. To what circuit arrangement is a common-base detector equivalent?

Q-20. In figure 3-8, which components act as the filter network in the diode detector?

FM DEMODULATION

In fm demodulators, the intelligence to be recovered is not in amplitude variations; it is in the *variation of the instantaneous frequency* of the carrier, either above or below the center frequency. The detecting device must be constructed so that its output amplitude will vary linearly according to the instantaneous frequency of the incoming signal.

Several types of fm detectors have been developed and are in use, but in this section you will study three of the most common: (1) the phase-shift detector, (2) the ratio detector, and (3) the gated-beam detector.

SLOPE DETECTION

To be able to understand the principles of operation for fm detectors, you need to first study the simplest form of frequency-modulation detector, the SLOPE DETECTOR. The slope detector is essentially a tank circuit which is tuned to a frequency either slightly above or below the fm carrier frequency. View (A) of figure 3-9 is a plot of voltage versus frequency for a tank circuit. The resonant frequency of the tank is the frequency at point 4. Components are selected so that the resonant frequency is higher than the frequency of the fm carrier signal at point 2. The entire frequency deviation for the fm signal falls on the lower slope of the bandpass curve between points 1 and 3. As the fm signal is applied to the tank circuit in view (B), the output amplitude of the signal varies as its frequency swings closer to, or further from, the resonant frequency of the tank. Frequency variations will still be present in this waveform, but it will also develop amplitude variations, as shown in view (B). This is because of the response of the tank circuit as it varies with the input frequency. This signal is then applied to the diode detector in view (C) and the detected waveform is the output. This circuit has the major disadvantage that any amplitude variations in the rf waveform will pass through the tank circuit and be detected. This disadvantage can be eliminated by placing a limiter circuit before the tank input. (Limiter circuits were discussed in *NEETS*, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*.) This circuit is basically the same as an AM detector with the tank tuned to a higher or lower frequency than the received carrier.

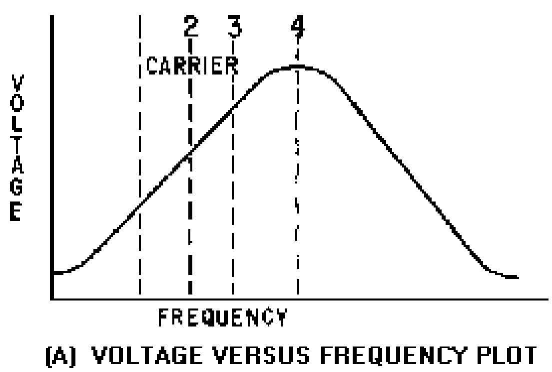

Figure 3-9A.—Slope detector. VOLTAGE VERSUS FREQUENCY PLOT.

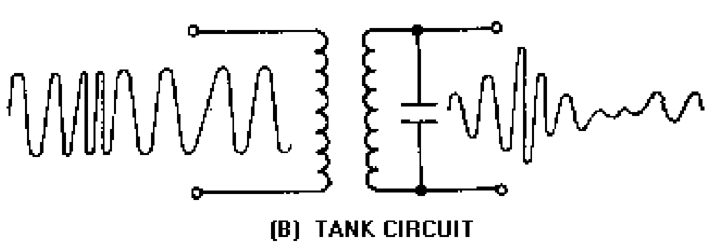

Figure 3-9B.—Slope detector. TANK CIRCUIT.

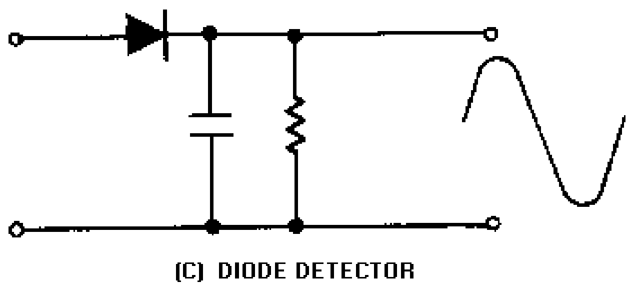

Figure 3-9C.—Slope detector. DIODE DETECTOR.

Q-21. What is the simplest form of fm detector?

Q-22. What is the function of an fm detector?

FOSTER-SEELEY DISCRIMINATOR

The FOSTER-SEELEY DISCRIMINATOR is also known as the PHASE-SHIFT DISCRIMINATOR. It uses a double-tuned rf transformer to convert frequency variations in the received fm signal to amplitude variations. These amplitude variations are then rectified and filtered to provide a dc output voltage. This voltage varies in both amplitude and polarity as the input signal varies in frequency. A typical discriminator response curve is shown in figure 3-10. The output voltage is 0 when the input frequency is equal to the carrier frequency (f_r). When the input frequency rises above the center frequency, the output increases in the positive direction. When the input frequency drops below the center frequency, the output increases in the negative direction.

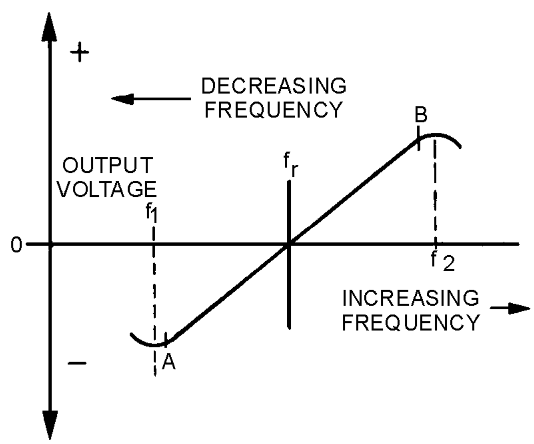

Figure 3-10.—Discriminator response curve.

The output of the Foster-Seeley discriminator is affected not only by the input frequency, but also to a certain extent by the input amplitude. Therefore, using limiter stages before the detector is necessary.

Circuit Operation of a Foster-Seeley Discriminator

View (A) of figure 3-11 shows a typical Foster-Seeley discriminator. The collector circuit of the preceding limiter/amplifier circuit (Q1) is shown. The limiter/amplifier circuit is a special amplifier circuit which limits the amplitude of the signal. This limiting keeps interfering noise low by removing excessive amplitude variations from signals. The collector circuit tank consists of C1 and L1. C2 and L2 form the secondary tank circuit. Both tank circuits are tuned to the center frequency of the incoming fm signal. Choke L3 is the dc return path for diode rectifiers CR1 and CR2. R1 and R2 are not always necessary but are usually used when the back (reverse bias) resistance of the two diodes is different. Resistors R3 and R4 are the load resistors and are bypassed by C3 and C4 to remove rf. C5 is the output coupling capacitor.

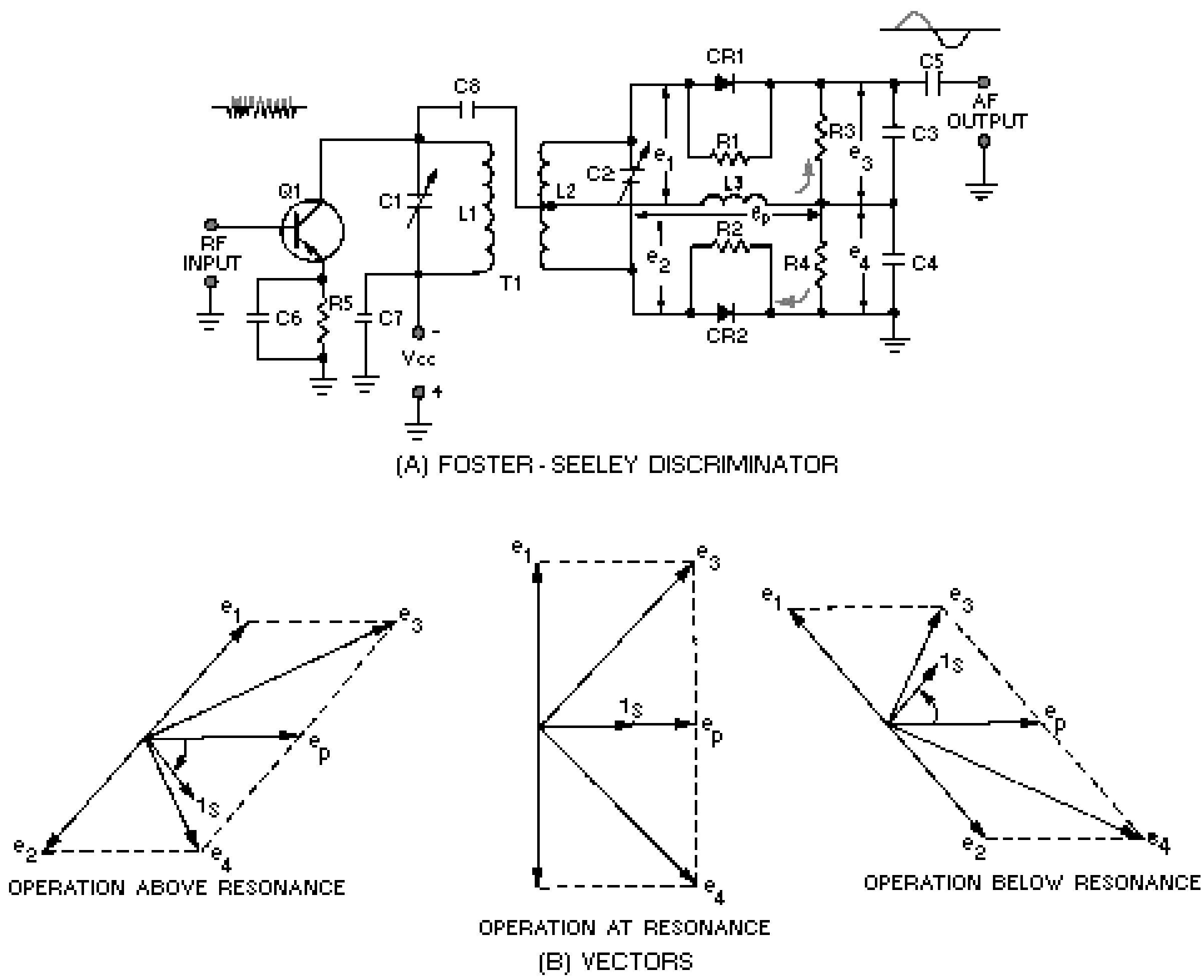

Figure 3-11.—Foster-Seeley discriminator. FOSTER-SEELEY DISCRIMINATOR.

CIRCUIT OPERATION AT RESONANCE.—The operation of the Foster-Seeley discriminator can best be explained using vector diagrams [figure 3-11, view (B)] that show phase relationships between the voltages and currents in the circuit. Let's look at the phase relationships when the *input frequency is equal to the center frequency* of the resonant tank circuit.

The input signal applied to the primary tank circuit is shown as vector e_p. Since coupling capacitor C8 has negligible reactance at the input frequency, rf choke L3 is effectively in parallel with the primary tank circuit. Also, because L3 is effectively in parallel with the primary tank circuit, input voltage e_p also appears across L3. With voltage e_p applied to the primary of T1, a voltage is induced in the secondary which causes current to flow in the secondary tank circuit. When the input frequency is equal to the center frequency, the tank is at resonance and acts resistive. Current and voltage are in phase in a resistance circuit, as shown by is and e_p. The current flowing in the tank causes voltage drops across each half of the balanced secondary winding of transformer T1. These voltage drops are of equal amplitude and opposite polarity with respect to the center tap of the winding. Because the winding is inductive, the voltage across it is 90 degrees out of phase with the current through it. Because of the center-tap arrangement, the voltages at each end of the secondary winding of T1 are 180 degrees out of phase and are shown as e_1 and e_2 on the vector diagram.

The voltage applied to the anode of CR1 is the vector sum of voltages e_p and e_1, shown as e_3 on the diagram. Likewise, the voltage applied to the anode of CR2 is the vector sum of voltages e_p and e_2, shown as e_4 on the diagram. At resonance e_3 and e_4 are equal, as shown by vectors of the same length. Equal anode voltages on diodes CR1 and CR2 produce equal currents and, with equal load resistors, equal and opposite voltages will be developed across R3 and R4. The output is taken across R3 and R4 and will be 0 at resonance since these voltages are equal and of appositive polarity.

The diodes conduct on opposite half cycles of the input waveform and produce a series of dc pulses at the rf rate. This rf ripple is filtered out by capacitors C3 and C4.

OPERATION ABOVE RESONANCE.—A phase shift occurs when an *input frequency higher than the center frequency* is applied to the discriminator circuit and the current and voltage phase relationships change. When a series-tuned circuit operates at a frequency above resonance, the inductive reactance of the coil increases and the capacitive reactance of the capacitor decreases. Above resonance the tank circuit acts like an inductor. Secondary current lags the primary tank voltage, e_p. Notice that secondary voltages e_1 and e_2 are still 180 degrees out of phase with the current (i_S) that produces them. The change to a lagging secondary current rotates the vectors in a clockwise direction. This causes el to become more in phase with e_p while e_2 is shifted further out of phase with e_p. The vector sum of e_p and e_2 is less than that of e_p and e_1. Above the center frequency, diode CR1 conducts more than diode CR2. Because of this heavier conduction, the voltage developed across R3 is greater than the voltage developed across R4; the output voltage is positive.

OPERATION BELOW RESONANCE.—When the *input frequency is lower than the center frequency*, the current and voltage phase relationships change. When the tuned circuit is operated at a frequency lower than resonance, the capacitive reactance increases and the inductive reactance decreases. Below resonance the tank acts like a capacitor and the secondary current leads primary tank voltage e_p. This change to a leading secondary current rotates the vectors in a *counterclockwise* direction. From the vector diagram you should see that e_2 is brought nearer in phase with e_p, while el is shifted further out of phase with e_p. The vector sum of e_p and e_2 is larger than that of e and e_1. Diode CR2 conducts more than diode CR1 below the center frequency. The voltage drop across R4 is larger than that across R3 and the output across both is negative.

Disadvantages

These voltage outputs can be plotted to show the response curve of the discriminator discussed earlier (figure 3-10). When weak AM signals (too small in amplitude to reach the circuit limiting level) pass through the limiter stages, they can appear in the output. These unwanted amplitude variations will cause primary voltage e_p [view (A) of figure 3-11] to fluctuate with the modulation and to induce a similar voltage in the secondary of T1. Since the diodes are connected as half-wave rectifiers, these small AM signals will be detected as they would be in a diode detector and will appear in the output. This unwanted AM interference is cancelled out in the ratio detector (to be studied next in this chapter) and is the main disadvantage of the Foster-Seeley circuit.

Q-23. What type of tank circuit is used in the Foster-Seeley discriminator?

Q-24. What is the purpose of CR1 and CR2 in the Foster-Seeley discriminator?

Q-25. What type of impedance does the tank circuit have above resonance?

RATIO DETECTOR

The RATIO DETECTOR uses a double-tuned transformer to convert the instantaneous frequency variations of the fm input signal to instantaneous amplitude variations. These amplitude variations are then rectified to provide a dc output voltage which varies in amplitude and polarity with the input signal frequency. This detector demodulates fm signals and suppresses amplitude noise without the need of limiter stages.

Circuit Operation

Figure 3-12 shows a typical ratio detector. The input tank capacitor (C1) and the primary of transformer T1 (L1) are tuned to the center frequency of the fm signal to be demodulated. The secondary winding of T1 (L2) and capacitor C2 also form a tank circuit tuned to the center frequency. Tertiary (third) winding L3 provides additional inductive coupling which reduces the loading effect of the secondary on the primary circuit. Diodes CR1 and CR2 rectify the signal from the secondary tank. Capacitor C5 and resistors R1 and R2 set the operating level of the detector. Capacitors C3 and C4 determine the amplitude and polarity of the output. Resistor R3 limits the peak diode current and furnishes a dc return path for the rectified signal. The output of the detector is taken from the common connection between C3 and C4. Resistor R_L is the load resistor. R5, C6, and C7 form a low-pass filter to the output.

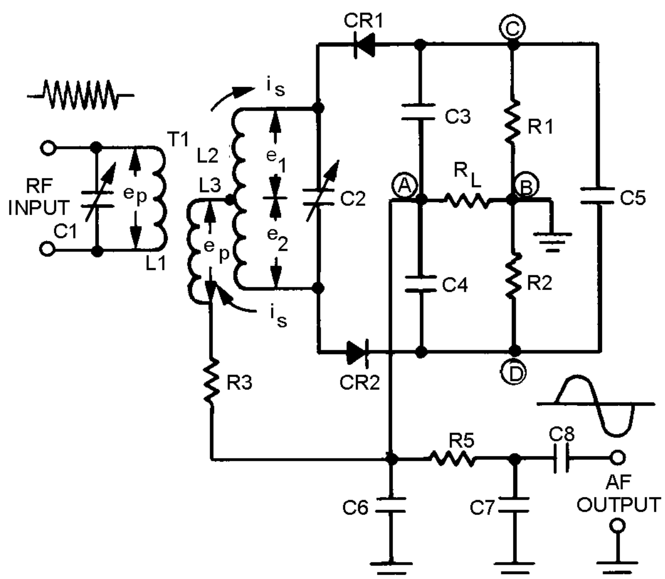

Figure 3-12.—Ratio detector.

This circuit operates on the same principles of phase shifting as did the Foster-Seeley discriminator. In that discussion, vector diagrams were used to illustrate the voltage amplitudes and polarities for conditions at resonance, above resonance, and below resonance. The same vector diagrams apply to the ratio detector but will not be discussed here. Instead, you will study the resulting current flows and polarities on simplified schematic diagrams of the detector circuit.

OPERATION AT RESONANCE.—When the input voltage e_p is applied to the primary in figure 3-12 it also appears across L3 because, by inductive coupling, it is effectively connected in parallel with the primary tank circuit. At the same time, a voltage is induced in the secondary winding and causes current to flow around the secondary tank circuit. At resonance the tank acts like a resistive circuit; that is, the tank current is in phase with the primary voltage e_p. The current flowing in the tank circuit causes voltages e_1 and e_2 to be developed in the secondary winding of T1. These voltages are of equal magnitude and of opposite polarity with respect to the center tap of the winding. Since the winding is inductive, the voltage drop across it is 90 degrees out of phase with the current through it.

Figure 3-13 is a simplified schematic diagram of a ratio detector at resonance. The voltage applied to the cathode of CR1 is the vector sum of e_1 and e_p. Likewise, the voltage applied to the anode of CR2 is the vector sum of e_2 and e_p. No phase shift occurs at resonance and both voltages are equal. Both diodes conduct equally. This equal current flow causes the same voltage drop across both R1 and R2. C3 and C4 will charge to equal voltages with opposite polarities. Let's assume that the voltages across C3 and C4 are equal in amplitude (5 volts) and of opposite polarity and the total charge across C5 is 10 volts. R1 and R2 will each have 5 volts dropped across them because they are of equal values. The output is taken between points **A** and **B**. To find the output voltage, you algebraically add the voltages between points **A** and **B** (loop **ACB** or **ADB**). Point **A** to point **D** is −5 volts. Point **D** to point **B** is + 5 volts. Their algebraic sum is 0 volts and the output voltage is 0 at resonance. If the voltages on branch **ACB** were figured, the same output would be found because the circuit branches are in parallel.

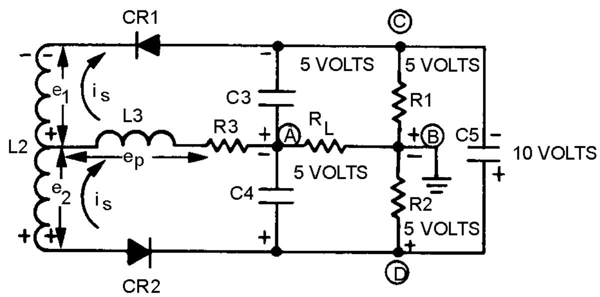

Figure 3-13.—Current flow and polarities at resonance.

When the input signal reverses polarity, the secondary voltage across L2 also reverses. The diodes will be reverse biased and no current will flow. Meanwhile, C5 retains most of its charge because of the long time constant offered in combination with R1 and R2. This slow discharge helps to maintain the output.

OPERATION ABOVE RESONANCE.—When a tuned circuit (figure 3-14) operates at a frequency higher than resonance, the tank is inductive. The secondary current i lags the primary voltage e_p. Secondary voltage e_1 is nearer in phase with primary voltage e, while e_2 is shifted further out of phase with e_p. The vector sum of e_1 and e_p is larger than that of e_2 and e_p. Therefore, the voltage applied to the cathode of CR1 is greater than the voltage applied to the anode of CR2 above resonance.

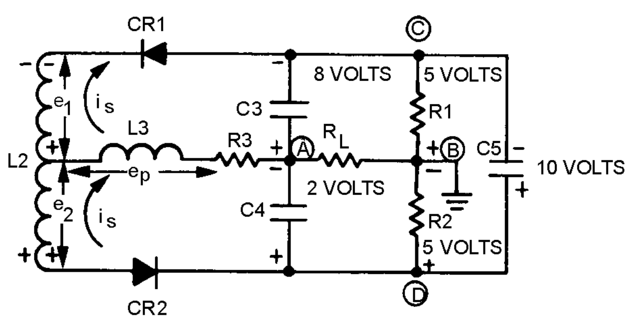

Figure 3-14.—Current flow and polarities above resonance.

Assume that the voltages developed above resonance are such that the higher voltage on the cathode of CR1 causes C3 to charge to 8 volts. The lower voltage on the anode of CR2 causes C4 to charge to 2 volts. Capacitor C5 remains charged to the sum of these two voltages, 10 volts. Again, by adding the voltages in loop **ACB** or **ADB** between points **A** and **B**, you can find the output voltage. Point **A** to point **D** equals -2 volts. Point **D** to point **B** equals +5 volts. Their algebraic sum, and the output, equals +3 volts when tuned above resonance. During the negative half cycle of the input signal, the diodes are reverse biased and C5 helps maintain a constant output.

OPERATION BELOW RESONANCE.—When a tuned circuit operates below resonance (figure 3-15), it is capacitive. Secondary current $_{is}$ leads the primary voltage e_p and secondary voltage e_2 is nearer in phase with primary voltage e_p. The vector sum of e_2 and e_p is larger than the sum of e_1 and e_p. The voltage applied to the anode of CR2 becomes greater than the voltage applied to the cathode of CR1 below resonance.

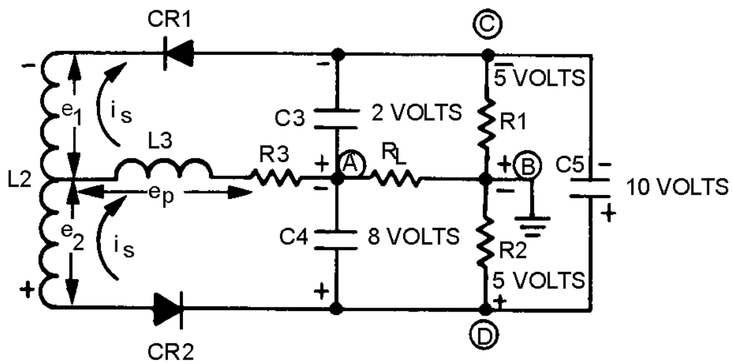

Figure 3-15.—Current flow and polarities below resonance.

Assume that the voltages developed below resonance are such that the higher voltage on the anode of CR2 causes C4 to charge to 8 volts. The lower voltage on the cathode of CR1 causes C3 to charge to 2 volts. Capacitor C5 remains charged to the sum of these two voltages, 10 volts. The output voltage equals –8 volts plus +5 volts, or –3 volts, when tuned below resonance. During the negative half cycle of the input signal, the diodes are reverse biased and C5 helps maintain a constant output.

Advantage of a Ratio Detector

The ratio detector is not affected by amplitude variations on the fm wave. The output of the detector adjusts itself automatically to the average amplitude of the input signal. C5 charges to the sum of the voltages across R1 and R2 and, because of its time constant, tends to filter out any noise impulses. Before C5 can charge or discharge to the higher or lower potential, the noise disappears. The difference in charge across C5 is so slight that it is not discernible in the output. Ratio detectors can operate with as little as 100 millivolts of input. This is much lower than that required for limiter saturation and less gain is required from preceding stages.

Q-26. What is the primary advantage of a ratio detector?

Q-27. What is the purpose of C5 in figure 3-12?

GATED-BEAM DETECTOR

An fm demodulator employing a completely different detection principle is the GATED-BEAM DETECTOR (sometimes referred to as the QUADRATURE DETECTOR). A simplified diagram of a gated-beam detector is shown in figure 3-16. It uses a gated-beam tube to limit, detect, and amplify the received fm signal. The output voltage is 0 when the input frequency is *equal to the center frequency*. When the input frequency rises *above the center frequency*, the output voltage goes positive. When the input frequency drops *below the center frequency*, the output voltage goes negative.

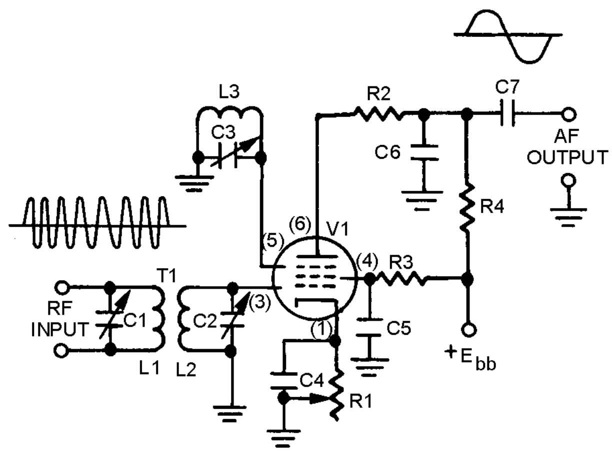

Figure 3-16.—Gated-beam detector.

Circuit Operation

The gated-beam detector employs a specially designed gated-beam tube. The elements of this tube are shown in figure 3-17. The focus electrode forms a shield around the tube cathode except for a narrow slot through which the electron beam flows. The beam of electrons flows toward the limiter grid which acts like a gate. When the gate is open, the electron beam flows through to the next grid. When closed, the gate completely stops the beam.

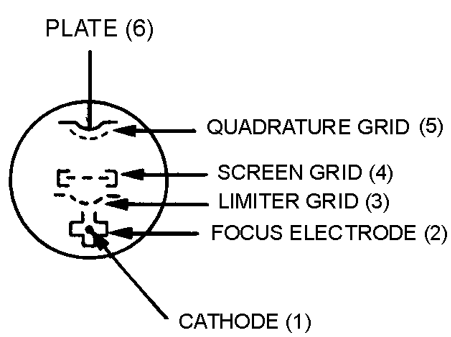

Figure 3-17.—Gated-beam tube physical layout.

After the electron beam passes the limiter grid, the screen grid refocuses the beam toward the quadrature grid. The quadrature grid acts much the same as the limiter grid; it either opens or closes the passage for electrons. These two grids act similar to an AND gate in digital devices; both gates must be open for the passage of electrons to the plate. Either grid can cut off plate current. AND gates were presented in *NEETS*, Module 13, *Introduction to Number Systems, Boolean Algebra, and Logic Circuits*.

Look again at the circuit in figure 3-16. With no signal applied to the limiter grid (3), the tube conducts. The electron beam moving near the quadrature grid (5) induces a current into the grid which develops a voltage across the high-Q tank circuit (L3 and C3). C3 charges until it becomes sufficiently negative to cut off the current flow. L3 tends to keep the current moving and, as its field collapses, discharges C3. When C3 discharges sufficiently, the quadrature grid becomes positive, grid current flows, and the cycle repeats itself. This tank circuit (L3 and C3) is tuned to the center frequency of the received fm signal so that it will oscillate at that frequency.

The waveforms for the circuit are shown in figure 3-18. View (A) is the fm input signal. The limiter-grid gate action creates a wave shape like view (B) because the tube is either cut off or saturated very quickly by the input wave. Note that this is a square wave and is the current waveform passing the limiter grid.

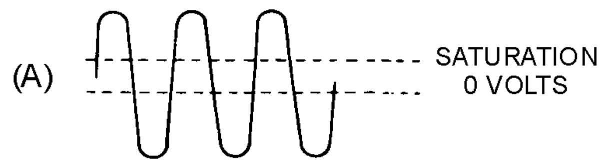

Figure 3-18A.—Gated-beam detector waveforms.

Figure 3-18B.—Gated-beam detector waveforms.

At the quadrature grid the voltage across C3 lags the current which produces it [view (C)]. The result is a series of pulses, shown in view (D), appearing on the quadrature grid at the center frequency, but lagging the limiter-grid voltage by 90 degrees. Because the quadrature grid has the same conduction and cutoff levels as the limiter grid, the resultant current waveform will be transformed into a square wave.

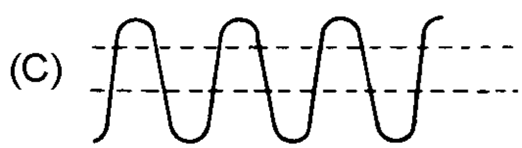

Figure 3-18C.—Gated-beam detector waveforms.

Figure 3-18D.—Gated-beam detector waveforms.

Both the limiter and quadrature grids must be positive at the same time to have plate current. You can see how much conduction time occurs for each cycle of the input by overlaying the current waveforms in views (B) and (D), as shown in view (E). The times when both grids are positive are shown by the shaded area of view (E). These plate current pulses are shown for operation at resonance in view (F).

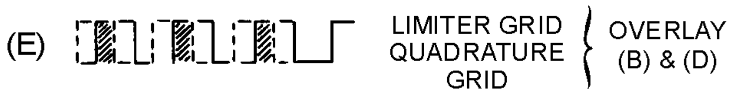

Figure 3-18E.—Gated-beam detector waveforms.

Figure 3-18F.—Gated-beam detector waveforms.

Now consider what happens with a deviation in frequency at the input. If the frequency increases, the frequency across the quadrature tank also increases. Above resonance, the tank appears capacitive to the induced current; voltage then lags the applied voltage by more than 90 degrees, as shown in view (G). Note in view (H) that the two grid signals have moved more out of phase and the average plate current level has decreased.

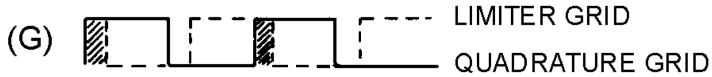

Figure 3-18G.—Gated-beam detector waveforms.

Figure 3-18H.—Gated-beam detector waveforms.

As the input frequency decreases, the opposite action takes place. The two grid signals move more in phase, as shown in view (I), and the average plate current increases, as shown in view (J).

Figure 3-18I.—Gated-beam detector waveforms.

Figure 3-18J.—Gated-beam detector waveforms.

View (K) shows the resultant plate-current pulses when an fm signal is applied to a gated-beam detector. Plate load resistor R4 and capacitor C6 form an integrating network which filters these pulses to form the sine-wave output.

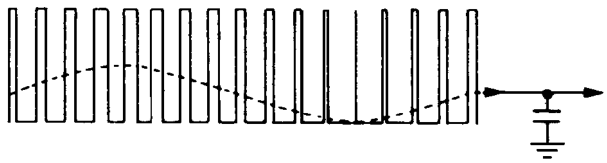

Figure 3-18K.—Gated-beam detector waveforms.

Advantages of the Gated-Beam Detector

The primary advantage of the gated-beam detector lies in its extreme simplicity. It employs only one tube, yet provides a very effective limiter with linear detection. It requires relatively few components and is very easily adjusted.

There are more than the three types of fm demodulators presented in this chapter. However, these are representative of the types with which you will be working. The principles involved in their operation are similar to the other types. You will now briefly study PHASE DEMODULATION which uses the same basic circuitry as fm demodulators.

Q-28. What circuit functions does the tube in a gated-beam detector serve?

Q-29. What condition must exist on both the limiter and quadrature grids for current to flow in a gated-beam detector?

Q-30. Name two advantages of the gated-beam detector.

PHASE DEMODULATION

In phase modulation (pm) the intelligence is contained in the *amount and rate of phase shift* in a carrier wave. You should recall from your study of pm that there is an incidental shift in frequency as the phase of the carrier is shifted. Because of this incidental frequency shift, fm demodulators, such as the Foster-Seeley discriminator and the ratio detector, can also be used to demodulate phase-shift signals.

Another circuit that may be used is the gated-beam (quadrature) detector. Remember that the fm phase detector output was determined by the phase of the signals present at the grids. A QUADRATURE DETECTOR FOR PHASE DEMODULATION works in the same manner.

A basic schematic is shown in figure 3-19. The quadrature-grid signal is excited by a reference from the transmitter. This may be a sample of the unmodulated master oscillator providing a phase reference for the detector.

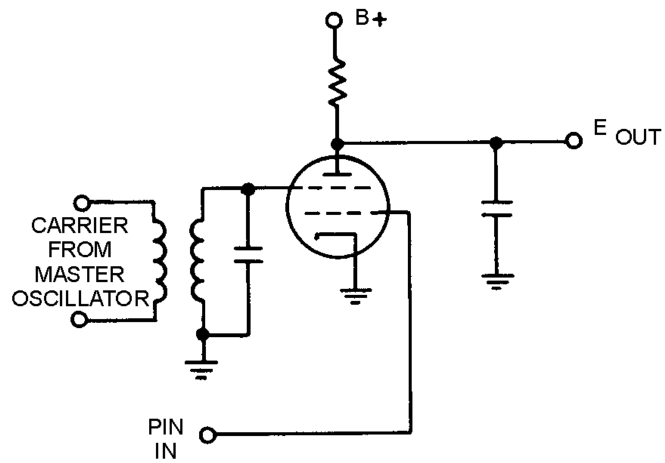

Figure 3-19.—Phase detector.

The modulated waveform is applied to the limiter grid. Gating action in the tube will occur as the phase shifts between the input waveform and the reference. The combined output current from the gated-beam tube will be a series of current pulses. These pulses will vary in width as shown in figure 3-20. The width of these pulses will vary in accordance with the phase difference between the carrier and the modulated wave.

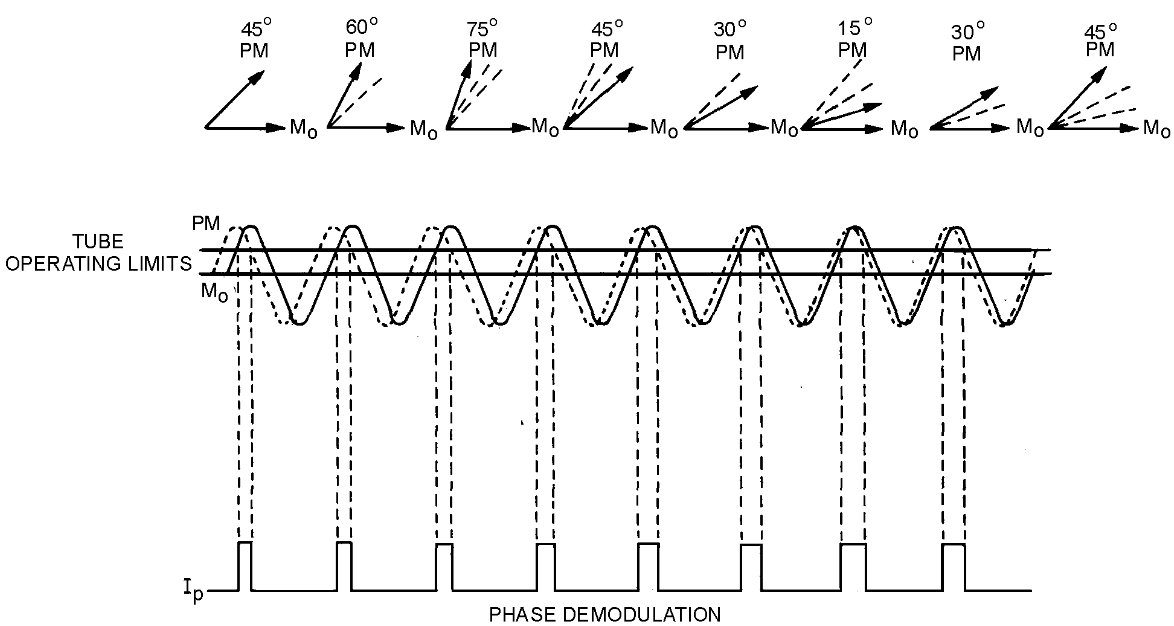

Figure 3-20.—Phase-detector waveforms.

Q-31. Where is the intelligence contained in a phase-modulated signal?

Q-32. Why can phase-modulated signals be detected by fm detectors?

Q-33. How is a quadrature detector changed when used for phase demodulation?

PULSE DEMODULATION

Pulse modulation is used in radar circuits as well as communications circuits, as discussed in chapter 2. A pulse-modulated signal in radar may be detected by a simple circuit that detects the presence of rf energy. Circuits that are capable of this were covered in this chapter in the cw detection discussion; therefore, the information will not be repeated here. A RADAR DETECTOR, in its simplest form, must be capable of producing an output when rf energy (reflected from a target) is present at its input.

In COMMUNICATIONS PULSE DETECTORS the modulated waveform must be restored to its original form. In this chapter you will study three basic methods of pulse demodulation: PEAK, LOW-PASS FILTER, and CONVERSION.

PEAK DETECTION

Peak detection uses the amplitude of a pulse-amplitude modulated (pam) signal or the duration of a pulse-duration modulated (pdm) signal to charge a holding capacitor and restore the original waveform. This demodulated waveform will contain some distortion because the output wave is not a pure sine wave. However, this distortion is not serious enough to prevent the use of peak detection.

Pulse-Amplitude Demodulation

Peak detection is used to detect pam. Figure 3-21 includes a simplified circuit [view (A)] for this demodulator and its waveforms [views (B) and (C)]. CR1 is the input diode which allows capacitor C1 to charge to the peak value of the pam input pulse. Pam input pulses are shown in view (B). CR1 is reverse biased between input pulses to isolate the detector circuit from the input. CR2 and CR3 are biased so that they are normally nonconducting. The discharge path for the capacitor is through the resistor (R1). These components are chosen so that their time constant is at least 10 times the interpulse period (time between pulses). This maintains the charge on C1 between pulses by allowing only a small discharge before the next pulse is applied. The capacitor is discharged just prior to each input pulse to allow the output voltage to follow the peak value of the input pulses. This discharge is through CR2 and CR3. These diodes are turned on by a negative pulse from a source that is time-synchronous with the timing-pulse train at the transmitter. Diode CR3 ensures that the output voltage is near 0 during this discharge period. View (C) shows the output wave shape from this circuit. The peaks of the output signal follow very closely the original modulating wave, as shown by the dotted line. With additional filtering this stepped waveform closely approximates its original shape.

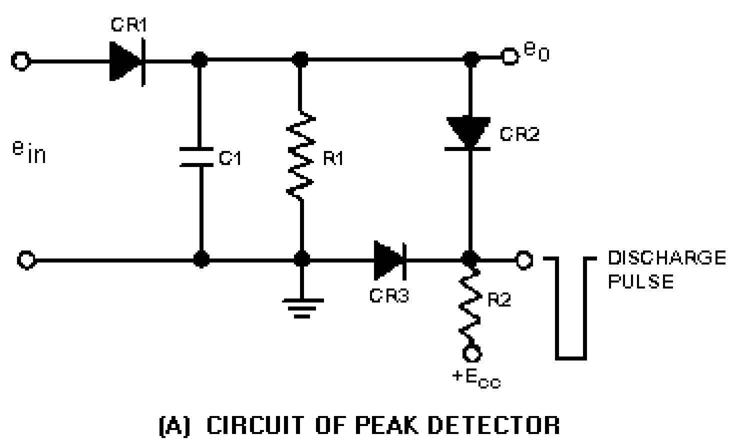

Figure 3-21A.—Peak detector. CIRCUIT OF PEAK DETECTOR.

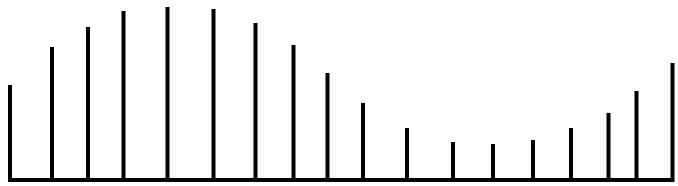

Figure 3-21B.—Peak detector. AMPLITUDE MODULATED PULSES.

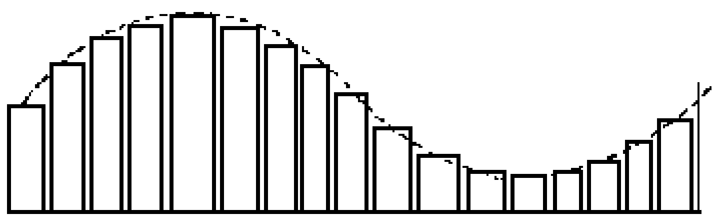

Figure 3-21C.—Peak detector. PEAK DETECTION.

Pulse-Duration Modulation

The peak detector circuit may also be used for pdm. To detect pdm, you must modify view (A) of figure 3-21 so that the time constant for charging C1 through CR1 is at least 10 times the maximum received pulse width. This may be done by adding a resistor in series with the cathode or anode circuit of CR1. The amplitude of the voltage to which C1 charges, before being discharged by the negative pulse, will be directly proportional to the input pulse width. A longer pulse width allows C1 to charge to a higher potential than a short pulse. This charge is held, because of the long time constant of R1 and C1, until the discharge pulse is applied to diodes CR2 and CR3 just prior to the next incoming pulse. These charges across C1 result in a wave shape similar to the output shown for pam detection in view (C) of figure 3-21.

Q-34. In its simplest form, what functions must a radar detector be capable of performing?

Q-35. What characteristic of a pulse does a peak detector sample?

Q-36. What is the time constant of the resistor and capacitor in a peak detector for pam?

Q-37. How can a peak detector for pam be modified to detect pdm?

LOW-PASS FILTER

Another method of demodulating pdm is by the use of a low-pass filter. If the voltage of a pulse waveform is averaged over both the pulse and no-pulse time, average voltage is the result. Since the amplitude of pdm pulses is constant, average voltage is directly proportional to pulse width. The pulse width varies with the modulation (intelligence) in pdm. Because the average value of the pulse train varies in accordance with the modulation, the intelligence may be extracted by passing the width-modulated pulses through a low-pass filter. The components of such a filter must be selected so that the filter passes only the desired modulation frequencies. As the varying-width pulses are applied to the low-pass filter, the average voltage across the filter will vary in the same way as the original modulating voltage. This varying voltage will closely approximate the original modulating voltage.

CONVERSION

Pulse-position modulation (ppm), pulse-frequency modulation (pfm), and pulse-code modulation (pcm) are most easily demodulated by first converting them to either pdm or pam. After conversion these pulses are demodulated using either peak detection or a low-pass filter. This conversion may be done in many ways, but your study will be limited to the simpler methods.

Pulse-Position Modulation

Ppm can be converted to pdm by using a flip-flop circuit. (Flip flops were discussed in *NEETS*, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*.) Figure 3-22 shows the waveforms for conversion of ppm to pdm. View (A) is the pulse-modulated pulse train and view (B) is a series of reset trigger pulses. The trigger pulses must be synchronized with the unmodulated position of the ppm pulses, but with a fixed time delay from these pulses. As the position-modulated pulse is applied to the flip-flop, the output is driven positive, as shown in view (C). After a period of time, the trigger pulse is again generated and drives the flip-flop output negative and the pulse ends. Because the ppm pulses are constantly varying in position with reference to the unmodulated pulses, the output of the flip-flop also varies in duration or width. This pdm signal can now be applied to one of the circuits that has already been discussed for demodulation.

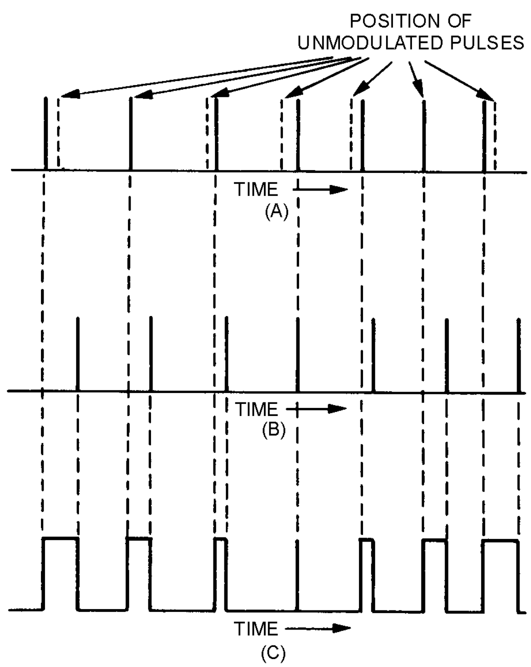

Figure 3-22.—Conversion of ppm to pdm.

Pulse-frequency modulation is a variation of ppm and may be converted by the same method.

Pulse-Code Modulation

Pulse-code modulation can easily be decoded, provided the pulse-code groups have been transmitted in reverse order; that is, if the pulse with the lowest value is transmitted first, the pulse with the highest value is transmitted last. A circuit that will provide a constant value of current without regard to its load is known as a current source. A current source is used to apply the pcm pulses to an RC circuit, such as that shown in figure 3-23, view (A). The current source must be capable of supplying a linear charge to C1 that will increase each time a pulse is applied if C1 is not allowed to discharge between pulses. In other words, if C1 charges to 16 volts during the period of one pulse, then each additional pulse increases the charge by 16 volts. Thus, the cumulative value increases by 16 volts for each received pulse. This does not provide a usable output unless a resistor is chosen that allows C1 to discharge to one-half its value between pulses. If only one pulse is received at T1, C1 charges to 16 volts and then begins to discharge. At T2 the charge has decayed to 8 volts and continues to decay unless another pulse is received. At T3 it has a 4-volt charge and at T4 it only has a 2-volt charge. At the sampling time, a 1-volt charge remains; this charge corresponds to the binary-weighted pulse train of 0001. Now we will apply a pcm signal which corresponds to the binary-coded equivalent of 7 volts (0111) in figure 3-23, view (A). View (B) is the pulse code that is received. Remember that the pulses are transmitted in reverse order. View (C) is the response curve of the circuit. At T1 the pulse corresponding to the least significant digit is applied and C1 charges to 16 volts. C1 discharges between pulses until it reaches 8 volts at T2. At T2 another pulse charges it to 24 volts. At T3, C1 has discharged through R1 to a value of 12 volts. The pulse at T3 increases the charge on C1 by 16 volts to a total charge of 28 volts. At T4, C1 has discharged to one-half its value and is at 14 volts. No pulse is present at T4 so C1 will not receive an additional charge. C1 continues to discharge until T5 when it has reached 7 volts and is sampled to provide a pam pulse which can be peak detected. This sampled output corresponds to the original sampling of the analog voltage in the modulation.

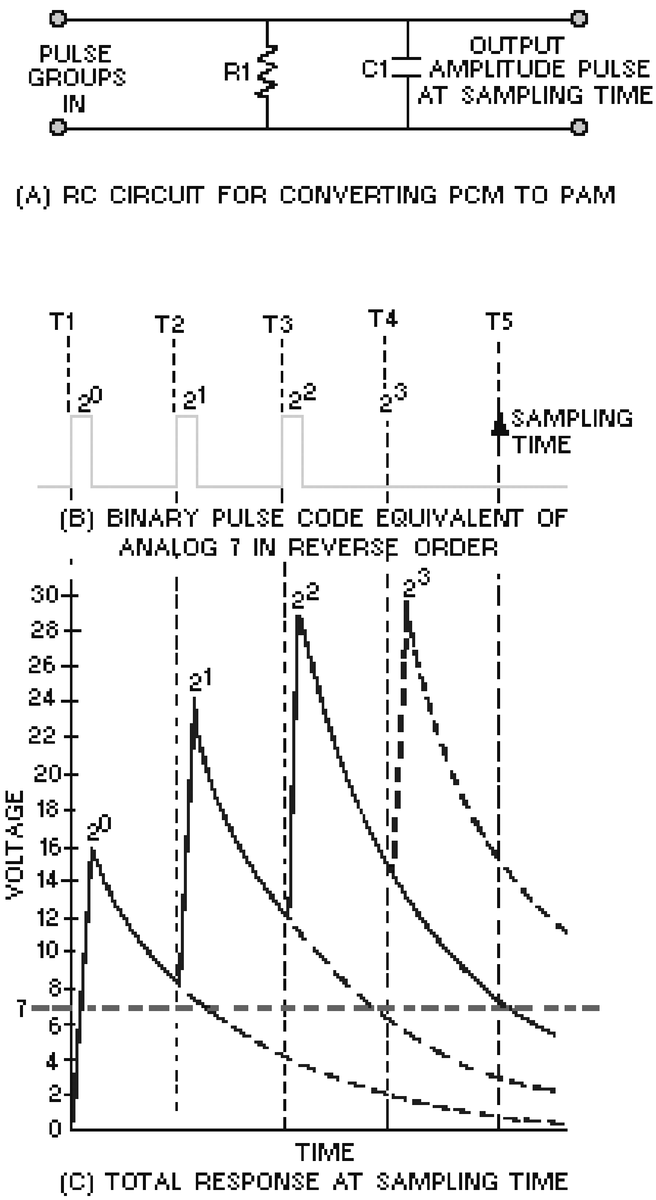

Figure 3-23.—Pcm conversion.

When the pcm demodulator recognizes the presence or absence of pulses in each position, it reproduces the correct standard amplitude represented by the pulse code group. For this reason, noise introduces no error if the largest peaks of noise are not mistaken for pulses. The pcm signal can be retransmitted as many times as desired without the introduction of additional noise effects so long as the signal-to-noise ratio is maintained at a level where noise pulses are not mistaken for a signal pulse. This is not the only method for demodulating pcm, but it is one of the simplest.

This completes your study of demodulation. You should remember that this module has been a basic introduction to the principles of modulation and demodulation. With the advent of solid-state electronics, integrated circuits have replaced discrete components. Although you cannot trace the signal flow through these circuits, the end result of the electronic action within the integrated circuit is the same as it would be with discrete components.

Q-38. How does a low-pass filter detect pdm?

Q-39. How is conversion used in pulse demodulation?

Q-40. What is the discharge rate for the capacitor in a pcm converter?

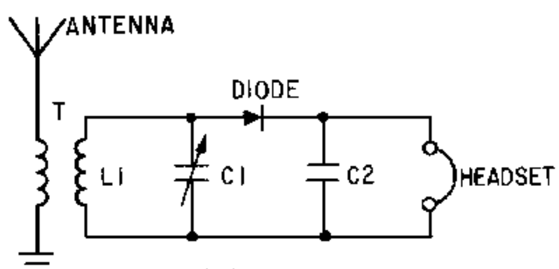
SUMMARY

Now that you have completed this chapter, a short review of what you have learned is in order. The following summary will refresh your memory of demodulation, its basic principles, and typical circuitry required to accomplish this task.

DEMODULATION, also called DETECTION, is the process of re-creating original modulating frequencies (intelligence) from radio frequencies.

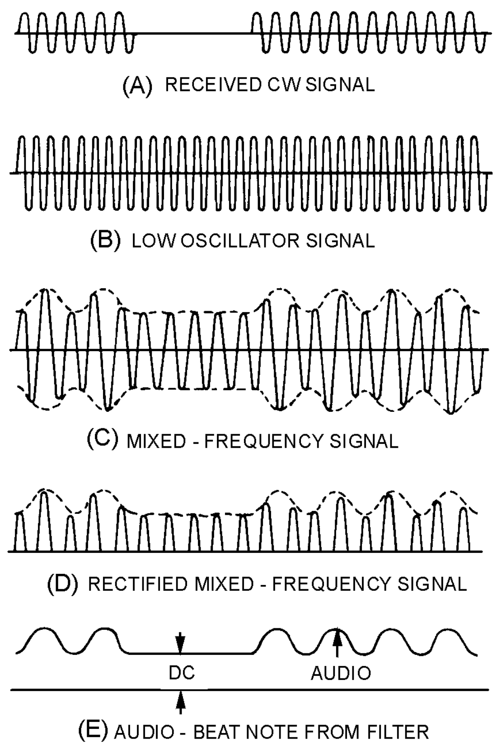
The **DEMODULATOR**, or DETECTOR, is the circuit in which the original modulating frequencies are restored.

A **CW DEMODULATOR** is a circuit that is capable of detecting the presence of rf energy.

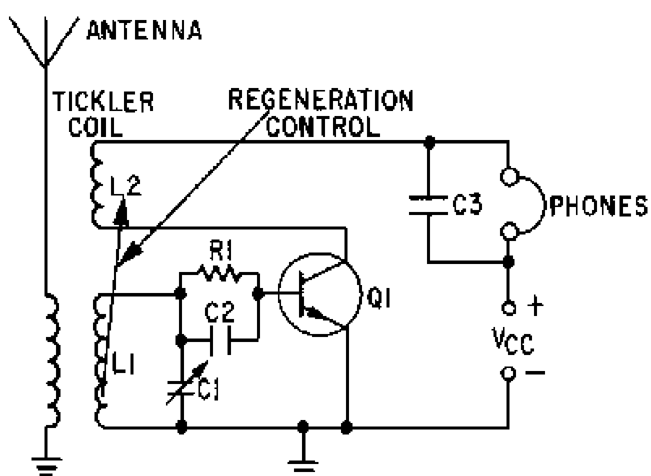


(A) CIRCUIT

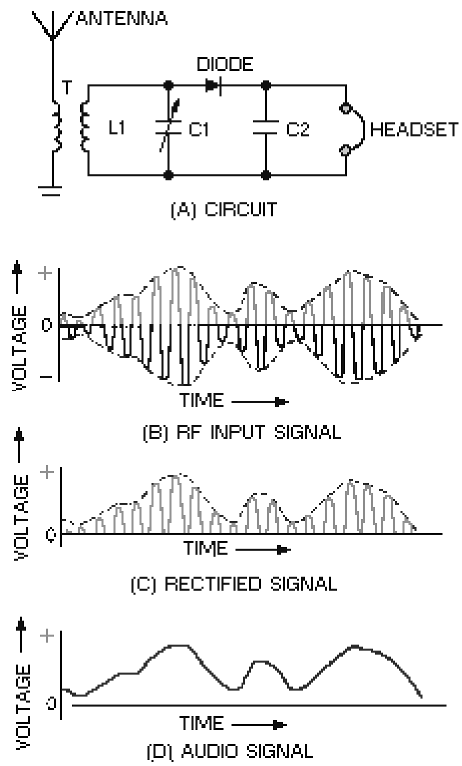
HETERODYNE DETECTION uses a locally generated frequency to beat with the cw carrier frequency to provide an audio output.



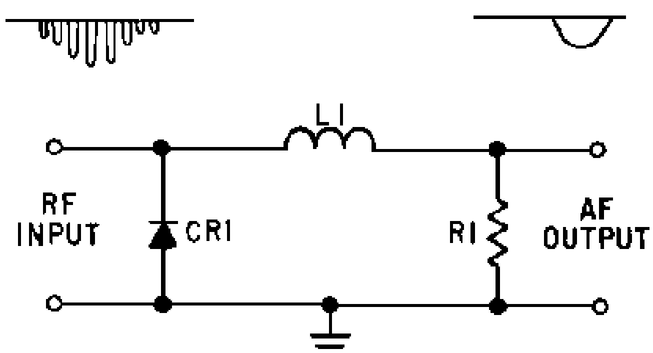
The **REGENERATIVE DETECTOR** produces its own oscillations, heterodynes them with an incoming signal, and detects them.



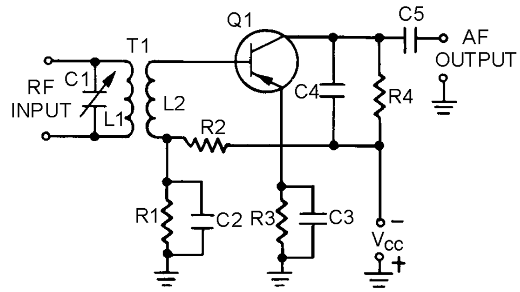
The **SERIES- (VOLTAGE-) DIODE DETECTOR** has a rectifier diode that is in series with the input voltage and the load impedance.



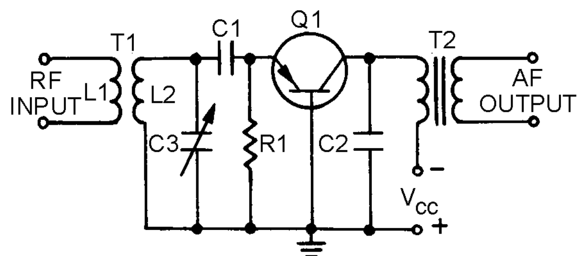
SHUNT- (CURRENT-) DIODE DETECTOR is characterized by a rectifier diode in parallel with the input and load impedance.



The **COMMON-EMITTER DETECTOR** is usually used in receivers to supply a detected and amplified output.

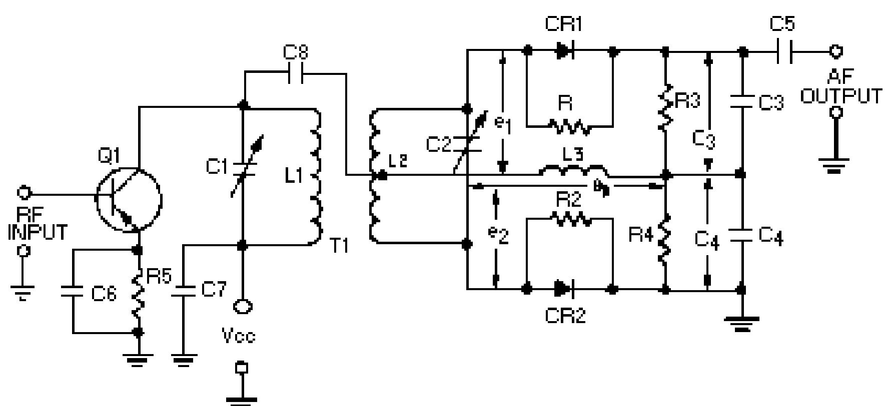


The **COMMON-BASE DETECTOR** is an amplifying detector that is used in portable receivers.

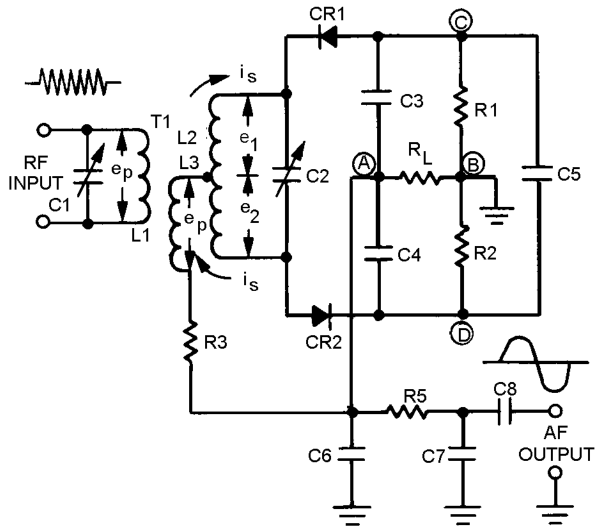


The **SLOPE DETECTOR** is the simplest form of frequency detector. It is essentially a tank circuit tuned slightly away from the desired fm carrier.

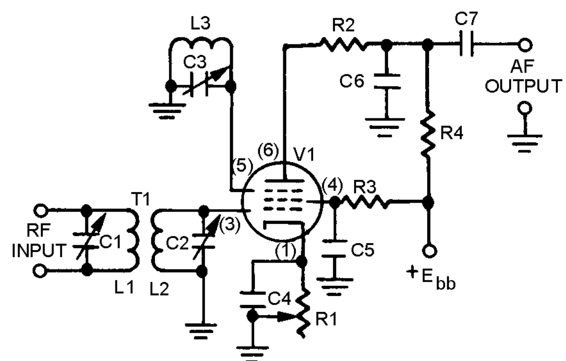
The **FOSTER-SEELEY DISCRIMINATOR** uses a double tuned rf transformer to convert frequency changes of the received fm signal into amplitude variations of the rf wave.



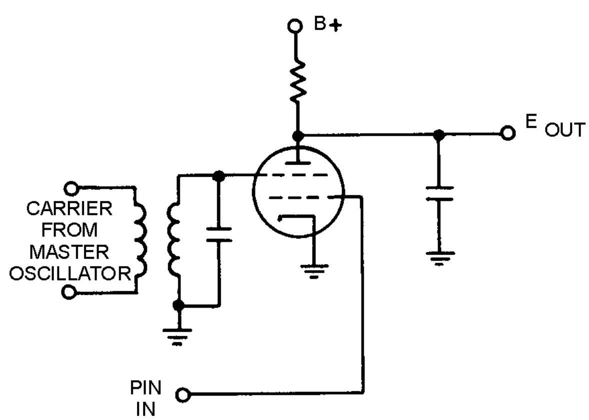
The **RATIO DETECTOR** uses a double-tuned transformer connected so that the instantaneous frequency variations of the fm input signal are converted into instantaneous amplitude variations.



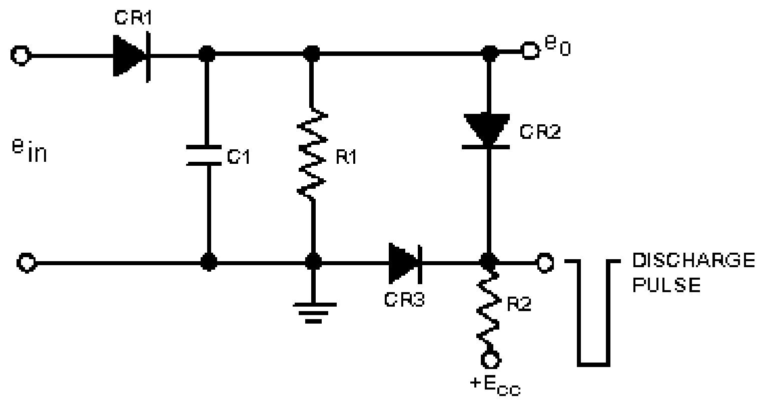
The **GATED-BEAM DETECTOR** uses a specially-designed tube to limit, detect, and amplify the received fm signal.



PHASE DEMODULATION may be accomplished using a frequency discriminator or a quadrature detector.



PEAK DETECTION uses the amplitude, or duration, of a pulse to charge a holding capacitor and restore the modulating waveform.



(A) CIRCUIT OF PEAK DETECTOR

A **LOW-PASS FILTER** is used to demodulate pdm by averaging the pulse amplitude over the entire period between pulses.

PULSE CONVERSION is used to convert ppm, pdm, or pcm to pdm or pam for demodulation.

ANSWERS TO QUESTIONS Q1. THROUGH Q40.

A-1. Re-creating original modulating frequencies (intelligence) from radio frequencies.

A-2. Circuit in which intelligence restoration is achieved.

A-3. A circuit that can detect the presence or absence of rf energy.

A-4. An antenna, tank circuit for tuning, rectifier for detection, filter to give constant output, and an indicator device.

A-5. Heterodyning.

A-6. By giving a different beat frequency for each signal.

A-7. Regenerative detector.

A-8. Oscillator, mixer, and detector.

A-9. (1) Sensitive to the type of modulation applied, (2) nonlinear, and (3) provide filtering.

A-10. The modulation envelope.

A-11. Rectifies the rf pulses in the received signal.

A-12. To filter the rf pulses and develop the modulating wave (intelligence) from the modulation envelope.

A-13. The current-diode detector is in parallel with the input and load.

A-14. When the input voltage variations are too small to give a usable output from a series detector.

A-15. Emitter-base junction.

A-16. R1.

A-17. By the collector current flow through R4.

A-18. Emitter-base junction.

A-19. A diode detector followed by a stage of audio amplification.

A-20. C1 and R1.

A-21. Slope detector.

A-22. Converting frequency variations of received fm signals to amplitude variations.

A-23. A double-tuned tank circuit.

A-24. Rectify the rf voltage from the discriminator.

A-25. Inductive.

A-26. Suppresses amplitude noise without limiter stages.

A-27. It helps to maintain a constant circuit voltage to prevent noise fluctuations from interfering with the output.

A-28. Limits, detects, and amplifies.

A-29. Both grids must be positively biased.

A-30. Extreme simplicity, few components, and ease of adjustment.

A-31. In the amount and rate of phase shift of the carrier wave.

A-32. Because of the incidental frequency shift that is caused while phase-shifting a carrier wave that is similar to fm modulation.

A-33. The quadrature grid signal is excited by a reference from the transmitter.

A-34. Detecting the presence of rf energy.

A-35. Pulse amplitude or pulse duration.

A-36. At least 10 times the interpulse period.

A-37. By making the time constant for charging the capacitor at least 10 times the maximum received pulse width.

A-38. By averaging the value of the pulses over the period of the pulse-repetition rate.

A-39. Ppm, pfm, and pcm are converted to either pdm or pam for demodulation.

A-40. It will discharge to one-half its value between pulses.

APPENDIX I

GLOSSARY

AMPLITUDE—Used to represent values of electrical current or voltage. The greater its height, the greater the value it represents.

AMPLITUDE MODULATION—Any method of varying the amplitude of an electromagnetic carrier frequency in accordance with the intelligence to be transmitted

ANGLE MODULATION—Modulation in which the angle of a sine-wave carrier is varied by a modulating wave.

AVERAGE POWER—The peak power value averaged over the pulse-repetition time.

BANDWIDTH—The section of the frequency spectrum that specific signals occupy.

BASE-INJECTION MODULATOR—Similar to control-grid modulator. Gain of a transistor is varied by changing the bias on its base.

BLOCKED-GRID KEYING—A method of keying in which the bias is varied to turn plate current on and off.

BUFFER—A voltage amplifier used between the oscillator and power amplifier.

CARBON MICROPHONE—Microphone in which sound waves vary the resistance of a pile of carbon granules. May be single-button or double-button.

CARRIER FREQUENCY—The assigned transmitter frequency.

CARRIER—Radio-frequency sine wave.

CATHODE KEYING—A system in which the cathode circuit is interrupted so that neither grid current nor plate current can flow.

CATHODE MODULATOR—Voltage on the cathode is varied to produce the modulation envelope.

CHANNEL—Carrier frequency assignment usually with a fixed bandwidth.

COLLECTOR-INJECTION MODULATOR—Transistor equivalent of plate modulator. Modulating voltage is applied to collector circuit.

COMMON-BASE DETECTOR—An amplifying detector where detection occurs in emitter-base junction and amplification occurs at the output of the collector junction.

COMMON-EMITTER DETECTOR—Often used in receivers to supply detected and amplified output. The emitter-base junction acts as the detector.

COMPLEX WAVE—A wave composed of two or more parts.

CONTINUOUS-WAVE KEYING—The "on-off" keying of a carrier.

CONTROL-GRID MODULATOR—Uses a variation of grid bias to vary the instantaneous plate voltage and current. The modulating signal is applied to the control grid.

CONVERSION—The process of changing ppm or pcm to pdm or pam to make them easier to demodulate.

CRYSTAL MICROPHONE—Uses the piezo-electric effect of crystalline materials to generate a voltage from sound waves.

CUSPS—Sharp phase reversals.

CW DEMODULATOR—A circuit that detects the presence of rf oscillations and converts them into a useful form.

CYCLE—360 degree rotation of a vector generating a sine wave.

DEMODULATION—The removal of intelligence from a transmission medium.

DEMODULATION or DETECTION—The process of re-creating original modulating-frequency intelligence from the rf carrier.

DEMODULATOR or DETECTOR—A circuit in which demodulation or restoration of the original intelligence is achieved.

DIODE DETECTOR—A simple type of crystal receiver.

DUTY CYCLE—The ratio of working time to total time for intermittently operated devices.

DYNAMIC MICROPHONE—A device in which sound waves move a coil of fine wire that is mounted on the back of a diaphragm and located in the magnetic field of a permanent magnet.

EMITTER-INJECTION MODULATOR—The transistor equivalent of the cathode modulator. The gain is varied by changing the voltage on the emitter.

FIDELITY—The ability to faithfully re-produce the input in the output.

FINAL POWER AMPLIFIER (fpa)—The final stage of amplification in a transmitter.

FIXED SPARK GAP—A device used to discharge the pulse-forming network. A trigger pulse ionizes the air between two contacts to initiate the discharge.

FOSTER-SEELEY DISCRIMINATOR—A circuit that uses a double-tuned rf transformer to convert frequency variations in the received fm signal to amplitude variations. Also known as a phase-shift discriminator.

FREQUENCY DEVIATION—The amount the frequency departs from the carrier frequency.

FREQUENCY MODULATION (fm)—Angle modulation in which the modulating signal causes the carrier frequency to vary. The *amplitude* of the modulating signal determines how far the frequency changes and the *frequency* of the modulating signal determines how fast the frequency changes.

FREQUENCY MULTIPLIERS—Special rf power amplifiers that multiply the input frequency.

FREQUENCY—The rate at which the vector that generates a sine wave rotates.

FREQUENCY-SHIFT KEYING (fsk)—Frequency modulation somewhat similar to continuous-wave (cw) keying in AM transmitters. The carrier is shifted between two differing frequencies by opening and closing a key.

GATED-BEAM DETECTOR—An fm demodulator that uses a special gated-beam tube to limit, detect, and amplify the received fm signal. Also known as a quadrature detector.

HARMONIC FREQUENCIES—Integral multiples of a fundamental frequency

HETERODYNE DETECTION—The use of an af voltage to distinguish between available signals. The incoming cw signal is mixed with locally generated oscillations to give an af output.

HETERODYNING—Mixing two frequencies across a nonlinear impedance.

HIGH-LEVEL MODULATION—Modulation produced in the plate circuit of the last radio stage of the system.

INSTANTANEOUS AMPLITUDE—The amplitude at any given point along a sine wave at a specific instant in time.

INTERMEDIATE POWER AMPLIFIER (ipa)—The amplifier between the oscillator and final power amplifier.

KEY CLICKS—Interference in the form of "clicks" or "thumps" caused by the sudden application or removal of power.

KEY-CLICK FILTERS—Filters used in keying systems to prevent key-click interference.

KEYING RELAYS—Relays used in high- power transmitters where the ordinary hand key cannot accommodate the plate current without excessive arcing.

LINEAR IMPEDANCE—An impedance in which a change in current through a device changes in direct proportion to the voltage applied to the device.

LOW-LEVEL MODULATION—Modulation produced in an earlier stage than the final.

LOW-PASS FILTER—A method of demodulating pdm by averaging the voltage over pulse and no-pulse time.

LOWER SIDEBAND—All difference frequencies below that of the carrier.

MACHINE KEYING—A method of cw keying using punched tape or other mechanical means to key a transmitter.

MAGNETIC MICROPHONE—A microphone in which the sound waves vibrate a moving armature. The armature consists of a coil wound on the armature and located between the pole pieces of a permanent magnet. The armature is mechanically linked to the diaphragm.

MARK—An interval during which a signal is present. Also the presence of an rf signal in cw keying. The key-closed condition (presence of data) in communications systems.

MASTER OSCILLATOR POWER AMPLIFIER (MOPA)—A transmitter in which the oscillator is isolated from the antenna by a power amplifier.

MICROPHONE—An energy converter that changes sound energy into electrical energy.

MODULATED WAVE—A complex wave consisting of a carrier and a modulating wave that is transmitted through space.

MODULATING WAVE—An information wave representing intelligence.

MODULATION FACTOR (M)—An indication of relative magnitudes of the rf carrier and the audio-modulating signal.

MODULATION INDEX—The ratio of frequency deviation to the frequency of the modulating signal.

MODULATION—The ability to impress intelligence upon a transmission medium, such as radio waves.

MODULATOR—The last audio stage in which intelligence is applied to the rf stage to modulate the carrier.

MULTIPLICATION FACTOR—The number of times an input frequency is multiplied.

MULTIVIBRATOR MODULATOR—An astable multivibrator used to provide frequency modulation by inserting the modulating af voltage in series with the base-return of the multivibrator transistors.

NEGATIVE ALTERNATION—That part of a sine wave that is below the reference level.

NONLINEAR DEVICE—A device in which the output does not rise and fall directly with the input.

NONLINEAR IMPEDANCE—An impedance in which the resulting current through the device is not proportional to the applied voltage.

OVERMODULATION—A condition that exists when the peaks of the modulating signal are limited.

PEAK AMPLITUDE—The maximum value above or below the reference line.

PEAK DETECTION—Detection that uses the amplitude of pam or the duration of pdm to charge a holding capacitor and restore the original waveform.

PEAK POWER—The maximum value of the transmitted pulse.

PERCENT OF MODULATION—The degree of modulation defined in terms of the maximum permissible amount of modulation.

PERIOD—The duration of a waveform.

PHASE MODULATION (pm)—Angle modulation in which the phase of the carrier is controlled by the modulating waveform. The *amplitude* of the modulating wave determines the amount of phase shift and the *frequency* of the modulation determines how often the phase shifts.

PHASE or PHASE ANGLE—The angle that exists between the starting point of a vector and its position at that instant. An indication of how much of a cycle has been completed at any given instant in time.

PHASE-SHIFT DISCRIMINATOR—See Foster-Seeley discriminator.

PHASE-SHIFT KEYING—Similar to ON-OFF cw keying in AM systems and frequency-shift keying in fm systems. Each time a *mark* is received, the phase is reversed. No phase reversal takes place when a space is received.

PLATE KEYING—A keying system in which the plate supply is interrupted.

PLATE MODULATOR—An electron-tube modulator in which the modulating voltage is applied to the plate circuit of the tube.

POSITIVE ALTERNATION—That part of a sine wave that is above the reference line.

PULSE DURATION (pd)—The period of time during which a pulse is present.

PULSE MODULATION—A form of modulation in which one of the characteristics of a pulse train is varied.

PULSE WIDTH (pw)—The period of time during which a pulse occurs.

PULSE—A surge of plate current that occurs when a tube is momentarily saturated.

PULSE-AMPLITUDE MODULATION (pam)—Pulse modulation in which the *amplitude* of the pulses is varied by the modulating signal.

PULSE-CODE MODULATION (pcm)—A modulation system in which the standard values of a quantized wave are indicated by a series of coded pulses.

PULSE-DURATION MODULATION (pdm)—Pulse modulation in which the *time duration* of the pulses is changed by the modulating signal.

PULSE-FORMING NETWORK (pfn)—A circuit used for storing energy. Essentially a short section of artificial transmission line.

PULSE-FREQUENCY MODULATION (pfm)—Pulse modulation in which the modulating voltage varies the *repetition rate* of a pulse train.

PULSE-POSITION MODULATION (ppm)—Pulse modulation in which the *position* of the pulses is varied by the modulating voltage.

PULSE-REPETITION FREQUENCY—The rate, in pulses per second, at which the pulses occur.

PULSE-REPETITION TIME (prt)—The total time for one complete pulse cycle of operation (*rest time* plus *pulse width*).

PULSE-TIME MODULATION (ptm)—Pulse modulation that varies one of the *time characteristics* of a pulse train (*pwm, pdm, ppm,* and *pfm*).

PULSE-WIDTH MODULATION (pwm)—Pulse modulation in which the *duration* of the pulses is varied by the modulating voltage.

PULSING—Allowing oscillations to occur for a specific period of time only during selected intervals.

QUANTIZED WAVE—A wave created by arbitrarily dividing the entire range of amplitude (or frequency, or phase) values of an analog wave into a series of standard values. Each sample takes the standard value nearest its actual value when modulated.

QUANTIZING NOISE—A distortion introduced by quantizing the signal.

RADAR DETECTOR—A detector which, in its simplest form, only needs to be capable of producing an output when rf energy (reflected from a target) is present at its input.

RATIO DETECTOR—A detector that uses a double-tuned transformer to convert the instantaneous frequency variations of the fm input signal to instantaneous amplitude variations.

RATIO OF TRANSMITTED POWERS—The power ratio (*fsk* verses *AM*) that expresses the overall improvement of fsk transmission when compared to AM under rapid-fading and high-noise conditions.

REACTANCE TUBE—A tube connected in parallel with the tank circuit of an oscillator. Provides a signal that will either lag or lead the signal produced by the tank.

REACTANCE-TUBE MODULATOR—An fm modulator that uses a reactance tube in parallel with the oscillator tank circuit.

REGENERATIVE DETECTOR—A detector circuit that produces its own oscillations, heterodynes them with an incoming signal, and detects them.

REST FREQUENCY—The carrier frequency during the constant-amplitude portions of a phase modulation signal.

REST TIME (rt)—The time when there is no pulse or nonpulse.

ROTARY GAP—Similar to a mechanically driven switch. Used to discharge a pulse-forming network.

SENSITIVITY OF A MICROPHONE—Efficiency of a microphone. Describes micro- phone power delivered to a matched-impedance load as compared to the sound level being converted. Usually expressed in terms of the electrical power level.

SERIES-DIODE DETECTOR—The semiconductor diode in series with the input voltage and the load impedance. Sometimes called a voltage-diode detector.

SHUNT—Means the same as parallel or to place in parallel with other components.

SHUNT-DIODE DETECTOR—A diode detector in which the diode is in parallel with the input voltage and the load impedance. Also known as a current detector because it operates with smaller input levels.

SIGNAL DISTORTION—Any unwanted change to the signal.

SIGNIFICANT SIDEBANDS—Those sidebands with significantly large amplitude.

SINE WAVE—The basic synchronous alternating waveform for all complex waveforms.

SLOPE DETECTOR—A tank circuit tuned to a frequency, either slightly above or below an fm carrier frequency, that is used to detect intelligence.

SPACE—Absence of an rf signal in cw keying. Key-open condition or lack of data in communications systems. Also a period of no signal.

SPARK-GAP MODULATOR—Modulator consists of a circuit for storing energy, a circuit for rapidly discharging the storage circuit (spark gap), a pulse transformer, and a power source.

SPECTRUM ANALYSIS—The display of electromagnetic energy arranged according to wavelength or frequency.

SPLATTER—Unwanted sideband frequencies that are generated from overmodulation.

THYRATRON MODULATOR—An electronic switch that requires a low potential to turn it on.

TRANSMISSION MEDIUM—A means of transferring intelligence from point to point. Can be described as light, smoke, sound, wirelines, or radio-frequency waves.

UPPER SIDEBAND—All of the sum frequencies above the carrier.

VARACTOR—A diode, or pn junction, that is designed to have a certain amount of capacitance between junctions.

VARACTOR FM MODULATOR—An fm modulator which uses avoltage-variable capacitordiode (varactor).

VOLTAGE-DIODE DETECTOR—Series detector in which the crystal is in series with the input voltage and the load impedance.

VECTOR—Mathematical method of showing both magnitude and direction.

WAVELENGTH—The physical dimension of a sine wave.

MODULE 12 INDEX

ASSIGNMENT 1

Textbook assignment: Chapter 1, “Amplitude Modulation,” pages 1-1 through 1-75.

1-1. The action of impressing intelligence upon a transmission medium is referred to as

1. modulating
2. demodulating
3. heterodyning
4. wave generating

1-2. You can communicate with others using which of the following transmissions mediums?

1. Light
2. Wire lines
3. Radio waves
4. Each of the above

1-3. When you use a vector to indicate force in a diagram, what do (a) length and (b) arrowhead position indicate?

1. (a) Magnitude (b) direction
2. (a) Magnitude (b) frequency
3. (a) Phase (b) frequency
4. (a) Phase (b) direction

1-4. Vectors are used to show which of the following characteristics of a sine wave?

1. Fidelity
2. Amplitude
3. Resonance
4. Distortion

1-5. A rotating coil in the uniform magnetic field between two magnets produces a sine wave. It is called a sine wave because the voltage depends on which of the following factors?

1. The number of turns in the coil
2. The speed at which the coil is rotating
3. The angular position of the coil in the magnetic field
4. Each of the above

1-6. The trigonometric relationship for the sine of an angle in a right triangle is figured using which of the following ratios?

1. Opposite side ÷ hypotenuse
2. Adjacent side ÷ hypotenuse
3. Hypotenuse ÷ opposite side
4. Hypotenuse ÷ adjacent side

1-7. The part of a sine wave that is above the voltage reference line is referred to as the

1. peak amplitude
2. positive alternation
3. negative alternation
4. instantaneous amplitude

1-8. The degree to which a cycle has been completed at any given instant is referred to as the

1. phase
2. period
3. frequency
4. amplitude

1-9. The frequency of the sine wave is determined by which of the following sine-wave factors?

1. The maximum voltage
2. The rate at which the vector rotates
3. The number of degrees of vector rotation
4. Each of the above

1-10. Which of the following mathematical relationships do you use to figure the period of a sine wave?

1. $\frac{1}{\text{phase}}$
2. $\frac{1}{\text{duration}}$
3. $\frac{1}{\text{frequency}}$
4. $\frac{1}{\text{amplitude}}$

1-11. Which of the following Greek letters is the symbol for wavelength?

1. θ
2. ϑ
3. λ
4. ω

1-12. Which of the following waveform characteristics determines the wavelength of a sine wave?

1. Phase
2. Period
3. Amplitude
4. Phase Angle

1-13. An electromagnetic wavefront moves through free space at approximately what speed in meters per second?

1. 3,000,000
2. 30,000,000
3. 300,000,000
4. 3,000,000,000

1-14. What is the wavelength of a 1.5 MHz frequency?

1. 100 meters
2. 200 meters
3. 300 meters
4. 400 meters

1-15. As the frequency of a signal is increased, what change can be noted about its wavelength?

1. It decreases
2. It increases
3. It remains the same

1-16. The ability of a circuit to faithfully reproduce the input signal in the output is known by what term?

1. Fidelity
2. Fluctuation
3. Directivity
4. Discrimination

1-17. In rf communications, modulation impresses information on which of the following types of waves?

1. Carrier wave
2. Complex wave
3. Modulated wave
4. Modulating wave

1-18. Which of the following types of modulation is a form of amplitude modulation?

1. Angle
2. Phase
3. Frequency
4. Continuous-wave

1-19. With a sine-wave input, how will the output compare to the input in (a) a linear circuit and (b) a nonlinear circuit?

1. (a) Proportional
   (b) proportional
2. (a) Proportional
   (b) not proportional
3. (a) Not proportional
   (b) not proportional
4. (a) Not proportional
   (b) proportional

1-20. What effect, if any, does a nonlinear device have on a sine wave?

1. It amplifies without distortion
2. It attenuates without distortion
3. It generates harmonic frequencies
4. None

1-21. For the heterodyning action to occur in a circuit, (a) what number of frequencies must be present and (b) to what type of circuit must they be applied?

1. (a) Two (b) linear
2. (a) Two (b) nonlinear
3. (a) Three (b) nonlinear
4. (a) Three (b) linear

1-22. Spectrum analysis is used to view which of the following characteristics of an rf signal?

1. Phase
2. Bandwidth
3. Modulating wave
4. Modulation envelope

1-23. The method of rf communication that uses either the presence or absence of a carrier in a prearranged code is what type of modulation?

1. Pulse modulation
2. Amplitude modulation
3. Continuous-wave modulation
4. Pulse-time modulation

1-24. What is the purpose of the key in a cw transmitter?

1. It generates the rf oscillations
2. It heterodynes the rf oscillations
3. It controls the rf output
4. It amplifies the rf signal

1-25. To ensure frequency stability in a cw transmitter, you should NOT key what circuit?

1. The mixer
2. The detector
3. The oscillator
4. The rf amplifier

1-26. When keying a high-power transmitter, what component should you use to reduce the shock hazard?

1. A coil
2. A relay
3. A resistor
4. A capacitor

1-27. Interference detected by a receiver is often caused by the application and removal of power in nearby transmitters. This interference can be prevented by using what type of circuit in such transmitters?

1. Power filter
2. On-off filter
3. Key-click filter
4. Rf detector filter

1-28. Transmitter machine keying was developed for which of the following purposes?

1. To increase the speed of communications
2. To make communications more intelligible
3. To reduce interference
4. Each of the above

1-29. Which of the following advantages is a benefit of cw communications?

1. Wide bandwidth
2. Fast transmission
3. Long-range operation
4. Each of the above

1-30. To prevent a transmitter from being loaded unnecessarily, where should you connect the antenna?

1. At the oscillator input
2. At the oscillator output
3. At the power-amplifier input
4. At the power-amplifier output

1-31. Amplifier tubes are added to the output of a transmitter for which of the following reasons?

1. To increase power
2. To increase frequency
3. To increase stability
4. To increase selectivity

1-32. Which of the following combinations of frequency multiplier stages will produce a total multiplication factor of 72?

1. 36, 36
2. 4, 3, 3, 2
3. 4, 4, 3, 2
4. 18, 18, 18, 18

1-33. To change sound energy into electrical energy, which of the following devices should you use?

1. A speaker
2. A microphone
3. An amplifier
4. An oscillator

1-34. Which of the following is the schematic symbol for a microphone?

1. 
3. 
2. 
4. 
1-35. What component in a carbon microphone converts a dc voltage into a varying current?

1. Button
2. Diaphragm
3. Transformer
4. Carbon granules

1-36. The action of the double-button carbon microphone is similar to which of the following electronic circuits?

1. A limiter
2. An oscillator
3. A voltage doulber
4. A push-pull amlifier

1-37. A carbon microphone has which of the following advantages over other types of microphones?

1. Ruggedness
2. Sensitivity
3. Low output voltage
4. Frequency response

1-38. The voltage produced by mechanical stress placed on certain crystals is a result of which of the following effects?

1. Hall
2. Acoustic
3. Electrostatic
4. Piezoelectric

1-39. If you require a microphone that is lightweight, has high sensitivity, is rugged, requires no external voltage, can withstand temperature, vibration, and moisture extremes, and has a uniform frequency response of 40 to 15,000 hertz, which of the following types of microphones should you select?

1. Carbon
2. Crystal
3. Dynamic
4. Electrostatic

1-40. What component in a magnetic microphone causes the lines of flux to alternate?

1. The coil
2. The magnet
3. The diaphragm
4. The armature

1-41. What are the two major sections of an AM transmitter?

1. Audio frequency unit and radio frequency unit
2. Audio frequency unit and master oscillator
3. Audio frequency unit and final power amplifier
4. Audio frequency unit and intermediate power amplifier

1-42. The intermediate power amplifier serves what function in a transmitter?

1. It generates the carrier
2. It modulates the carrier
3. It increases the frequency of the signal
4. It increases the power level of the signal

1-43. The final audio stage in an AM transmitter is the

1. mixer
2. modulator
3. multipler
4. multiplexer

1-44. The vertical axis on a frequency-spectrum graph represents which of the following waveform characteristics?

1. Phase
2. Duration
3. Frequency
4. Amplitude

1-45. When a 500-hertz signal modulates a 1-megahertz carrier, the 1-megahertz carrier and what two other frequencies are transmitted?

1. 500 and 999,500 hertz
2. 500 and 1,000,500 hertz
3. 999,500 and 1,500,000 hertz
4. 999,500 and 1,000,500 hertz

1-46. If 750 hertz modulates a 100-kilohertz carrier, what would the upper-sideband frequency be?

1. 99,250 hertz
2. 100,000 hertz
3. 100,500 hertz
4. 100,750 hertz

1-47. In an AM wave, where is the audio intelligence located?

1. In the carrier frequency
2. In the spacing between the sideband frequencies
3. In the spacing between the carrier and sideband frequencies
4. In the sideband frequencies

1-48. What determines the bandwidth of an AM wave?

1. The carrier frequency
2. The number of sideband frequencies
3. The lowest modulating frequency
4. The highest modulating frequency

1-49. If an 860-kilohertz AM signal is modulated by frequencies of 5 and 10 kilohertz, what is the bandwidth?

1. 5 kilohertz
2. 10 kilohertz
3. 15 kilohertz
4. 20 kilohertz

1-50. If a 1-megahertz signal is modulated by frequencies of 50 and 75 kilohertz, what is the resulting maximum frequency range?

1. 925,000 to 1,000,000 hertz
2. 925,000 to 1,075,000 hertz
3. 975,000 to 1,025,000 hertz
4. 1,000,000 to 1,075,000 hertz

1-51. If an rf carrier is 100 percent AM-modulated, what will be the rf output when the modulating signal is (a) at its negative peak and (b) at its positive peak?

1. (a) 0
   (b) 2 times the amplitude of the unmodulated carrier
2. (a) 0
   (b) 1/2 the amplitude of the unmodulated carrier
3. (a) 1/2 the amplitude of the unmodulated carrier
   (b) 1/2 the amplitude of the unmodulated carrier
4. (a) 1/2 the amplitude of the unmodulated carrier
   (b) 2 times the amplitude of the unmodulated carrier

1-52. In an AM signal that is 100 percent modulated, what maximum voltage value is present in each sideband?

1. 1/4 the carrier voltage
2. 1/2 the carrier voltage
3. 3/4 the carrier voltage
4. Same as the carrier voltage

1-53. Overmodulation of an AM signal will have which, if any, of the following effects on the bandwidth?

1. It will increase
2. It will decrease
3. It will remain the same

1-54. In a carrier wave with a peak amplitude of 400 volts and a peak modulating voltage of 100 volts, what is the modulation factor?

1. 0.15
2. 0.25
3. 0.45
4. 0.55

1-55. The percent of modulation for a modulated carrier wave is figured using which of the following formulas?

1. $\frac{E_m}{E_c}$
2. $\frac{E_c}{E_m}$
3. $\frac{E_m}{E_c} \times 100$
4. $\frac{E_c}{E_m} \times 100$

1-56. Modulation produced in the plate circuit of the last radio stage of a system is known by what term?

1. Low-level modulation
2. High-level modulation
3. Final-amplifier modulation
4. Radio frequency modulation

1-57. Which, if any, of the following advantages is a primary benefit of plate modulation?

1. It operates at low efficiency
2. It operates at low power levels
3. It operates with high efficiency
4. None of the above

1-58. A final rf power amplifier biased for plate modulation operates in what class of operation?

1. A
2. B
3. AB
4. C

1-59. Heterodyning action in a plate modulator takes place in what circuit?

1. Grid
2. Plate
3. Screen
4. Cathode

1-60. A plate modulator produces a modulated rf output by controlling which of the following voltages?

1. Plate voltage
2. Cathode voltage
3. Grid-bias voltage
4. Grid-input voltage

1-61. To achieve 100-percent modulation in a plate modulator, what maximum voltage must the modulator tube be capable of providing to the final power amplifier (fpa)?

1. Twice the fpa plate voltage
2. The same as the fpa plate voltage
3. Three times the fpa plate voltage
4. Half the fpa plate voltage

1-62. In a plate modulator, with no modulation, how will the plate current of the final rf amplifier appear on a scope?

1. A series of pulses at the carrier frequency
2. A series of pulses at twice the carrier frequency
3. A series of pulses at 1/4 the carrier frequency
4. A series of pulses at 1/2 the carrier frequency

1-63. In the collector-injection modulator, af and rf are heterodyned by injecting the rf into (a) what circuit and the af into (b) what circuit?

1. (a) Base (b) collector
2. (a) Base (b) emitter
3. (a) Emitter (b) collector
4. (a) Emitter (b) base

1-64. Plate- and collector-injection modulators are the most commonly used modulators for which of the following reasons?

1. The rf amplifier stages can be operated class C for linearity
2. The rf amplifier stages can be operated class C for maximum efficiency
3. They require small amounts of audio power
4. They require large amounts of audio power

1-65. A control-grid modulator would be used in which of the following situations?

1. In extremely high-power, wideband equipment where high-level modulation is difficult to achieve
2. In cases where the use of a minimum of audio power is desired
3. In portable and mobile equipment to reduce size and power requirements
4. Each of the above

1-66. Which of the following inputs is/are applied to the grid of a control-grid modulator?

1. Rf
2. Af
3. Dc bias
4. Each of the above

1-67. Excessive modulating signal levels have which, if any, of the following effects on a control-grid modulator?

1. They increase output. amplitude
2. They decrease output amplitude
3. They create distortion
4. None

1-68. Compared to a plate modulator, the control-grid modulator has which of the following advantages?

1. It is more efficient
2. It has less distortion
3. It requires less power from the modulator
4. It requires less power from the amplifier

1-69. The control-grid modulator is similar to which of the following modulator circuits?

1. Plate
2. Cathode
3. Base-injection
4. Emitter-injection

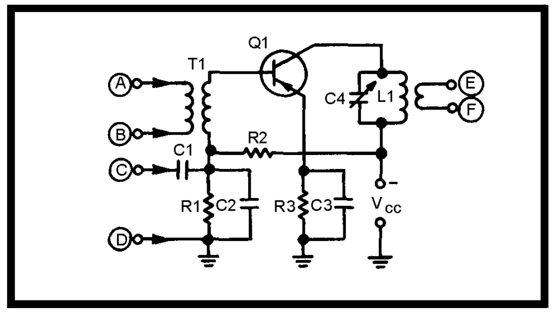


Figure 1A.—Modulator circuit.

IN ANSWERING QUESTIONS 1-70 THROUGH 1-72, REFER TO FIGURE 1A.

1-70. What components in the circuit establish the bias for Q1?

1. R1 and R2
2. R2 and R3
3. R1 and R3

1-71. The rf voltage in the circuit is applied at (a) what points and the af voltage is applied at (b) what points?

1. (a) A and B (b) C and D
2. (a) C and D (b) A and B
3. (a) C and D (b) E and F
4. (a) E and F (b) C and D

1-72. What components develop the rf modulation envelope?

1. C1 and R1
2. C2 and R1
3. C3 and R3
4. C4 and L1

1-73. A cathode modulator is used in which of the following situations?

1. When rf power is unlimited and distortion can be tolerated
2. When rf power is limited and distortion cannot be tolerated
3. When af power is unlimited and distortion can be tolerated
4. When af power is limited and distortion cannot be tolerated

1-74. In a cathode modulator, the modulating voltage is in series with which of the following voltages?

1. The grid voltage only
2. The plate voltage only
3. Both the grid and plate voltages
4. The cathode voltage only

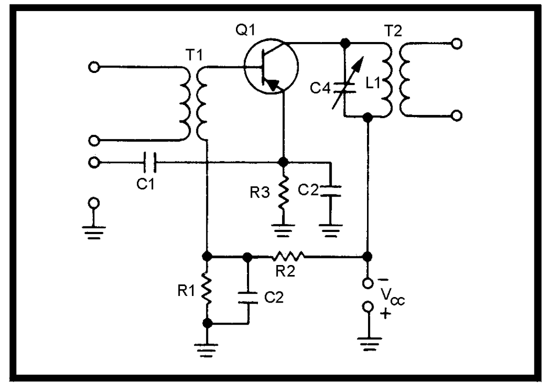

Figure 1B.—Emitter-injection modulator.

IN ANSWERING QUESTION 1-75, REFER TO FIGURE 1B.

1-75. In the circuit, what components develop the modulation envelope?

1. Q1
2. C2 and R1
3. C3 and R3
4. C4 and L1

ASSIGNMENT 2

Textbook assignment: Chapter 2, "Angle and Pulse Modulation," pages 2-1 through 2-64.

2-1. Frequency-shift keying resembles what type of AM modulation?

1. CW modulation
2. Analog AM modulation
3. Plate modulation
4. Collector-injection modulation

2-2. Frequency-shift keying is generated using which of the following methods?

1. By shifting the frequency of an oscillator at an af rate
2. By shifting the frequency of an oscillator at an rf rate
3. By keying an af oscillator at an rf rate
4. By keying an af oscillator at an af rate

2-3. In a frequency-shift keyed signal, where is the intelligence contained?

1. In the duration of the rf energy
2. In the frequency of the rf energy
3. In the amplitude of the rf energy
4. In the spacing between bursts of rf energy

2-4. If an fsk transmitter has a MARK frequency of 49.575 kilohertz and a SPACE frequency of 50.425 kilohertz, what is the assigned channel frequency?

1. 49 kilohertz
2. 49.575 kilohertz
3. 50 kilohertz
4. 50.425 kilohertz

2-5. Fsk is NOT affected by noise interference for which of the following reasons?

1. Noise is outside the bandwidth of an fsk signal
2. Fsk does not rely on the amplitude of the transmitted signal to carry intelligence
3. The wide bandwidth of an fsk signal prevents noise interference
4. Each of the above

2-6. In an fsk transmitter, what stage is keyed?

1. The oscillator
2. The power supply
3. The power amplifier
4. The buffer amplifier

2-7. When the amount of oscillator frequency shift in an fsk transmitter is determined, which of the following factors must be considered?

1. The number of buffer amplifiers
2. The transmitter power output
3. The frequency multiplication factor for the transmitter amplifiers
4. The oscillator rest frequency

2-8. In an fsk transmitter with a doubler and a tripler stage, the desired frequency shift is 1,200 hertz. To what maximum amount is the oscillator frequency shift limited?

1. 60 hertz
2. 100 hertz
3. 120 hertz
4. 200 hertz

2-9. Fsk has which of the following advantages over cw?

1. Fsk has a more stable oscillator
2. Fsk is easier to generate
3. Fsk rejects unwanted weak signals
4. Fsk does not have noise in its output

2-10. The "ratio of transmitted powers" provides what information?

1. Transmitter power out in a cw system
2. Transmitter power out in an fsk system
3. Improvement shown using cw instead of fsk transmission
4. Improvement shown using fsk instead of cw transmission methods

2-11. In an fm signal, (a) the RATE of shift is proportional to what characteristic of the modulating signal, and (b) the AMOUNT of shift is proportional to what characteristic?

1. (a) Amplitude (b) amplitude
2. (a) Amplitude (b) frequency
3. (a) Frequency (b) frequency
4. (a) Frequency (b) amplitude

THIS SPACE LEFT BLANK INTENTIONALLY.

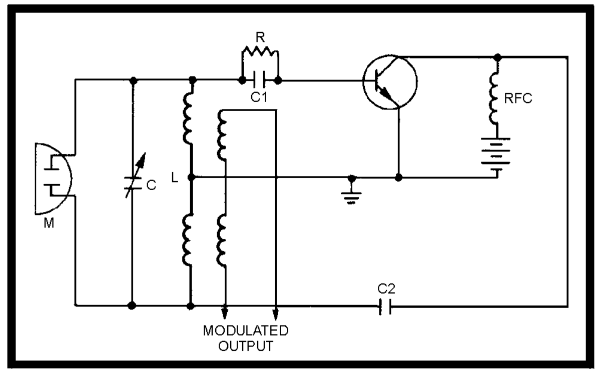

Figure 2A.—Oscillator circuit.

IN ANSWERING QUESTIONS 2-12 THROUGH 2-14, REFER TO FIGURE 2A.

2-12. When a sound wave strikes the condenser microphone (M), it has which, if any, of the following effects on the oscillator circuit?

1. It changes output phase
2. It changes output voltage
3. It changes output frequency
4. It has no effect

2-13. What is the purpose of capacitor C in the circuit?

1. It helps set the carrier frequency of the oscillator
2. It prevents amplitude variations in the oscillator output
3. It sets the maximum frequency deviation of the oscillator
4. It varies the output frequency in accordance with the modulating voltage

2-14. A 1,000-hertz tone of a certain loudness causes the frequency-modulated carrier for the circuit to vary ±1,000 hertz at a rate of 1,000 times per second. If the AMPLITUDE of the modulating tone is doubled, what will be the maximum carrier variation?

1. ±1,000 hertz at 1,000 times per second
2. ±1,000 hertz at 2,000 times per second
3. ±2,000 hertz at 1,000 times per second
4. ±2,000 hertz at 2,000 times per second

2-15. The maximum deviation for a 1.5 MHz carrier is set at ±50 kHz. If the carrier varies between 1.5125 MHz and 1.4875 MHz (±12.5 kHz), what is the percentage of modulation?

1. 25 %
2. 50 %
3. 75 %
4. 100 %

2-16. An fm transmitter has a 50-watt carrier with no modulation. What maximum amount of output power will it have when it is 50-percent modulated?

1. 25 watts
2. 50 watts
3. 75 watts
4. 100 watts

2-17. Frequencies that are located between adjacent channels to prevent interference are referred to as

1. sidebands
2. bandwidths
3. guard bands
4. blank channels

2-18. Modulation index may be figured by using which of the following formulas?

1. $2f/f_m$
2. $f_m/2f$
3. $f_m/\Delta f$
4. $\Delta f/f_m$

2-19. A 50-megahertz fm carrier varies between 49.925 megahertz and 50.075 megahertz 10,000 times per second. What is its modulation index?

1. 5
2. 10
3. 15
4. 20

MODULATION INDEX	SIGNIFICANT SIDEBANDS
.01	2
.4	2
.5	4
1.0	6
2.0	8
3.0	12
4.0	14
5.0	16
6.0	18
7.0	22
8.0	24
9.0	26
10.0	28
11.0	32
12.0	32
13.0	36
14.0	38
15.0	38

Figure 2B.—Modulation index table.

IN ANSWERING QUESTIONS 2-20 AND 2-21, REFER TO FIGURE 2B.

2-20. An fm-modulated carrier varies between 925 kilohertz and 1,075 kilohertz 15,000 times per second. What is the bandwidth, in kilohertz, of the transmitted signal? (HINT: You will need to figure MI to be able to find the sidebands.)

1. 120
2. 240
3. 340
4. 420

2-21. The spectrum of a 500 kilohertz fm-modulated carrier has a 60-kilohertz bandwidth and contains 12 significant sidebands. How much, in kilohertz, is the carrier deviated?

1. ±5
2. ±7.5
3. ±10
4. ±15

2-22. In a reactance-tube modulator, the reactance tube shunts what part of the oscillator circuitry?

1. The amplifier
2. The tank circuit
3. The biasing network
4. The feedback network

2-23. With no modulating signal applied, a reactance tube has which, if any, of the following effects on the output of an oscillator?

1. It will decrease amplitude
2. It will increase amplitude
3. It will change resonant frequency
4. It will have no effect

2-24. The reactance-tube frequency modulates the oscillator by which of the following actions?

1. By shunting the tank circuit with a variable resistance
2. By shunting the tank circuit with a variable reactance
3. By shunting the tank circuit with a variable capacitance
4. By causing a resultant current flow in the tank circuit which either leads or lags resonant current

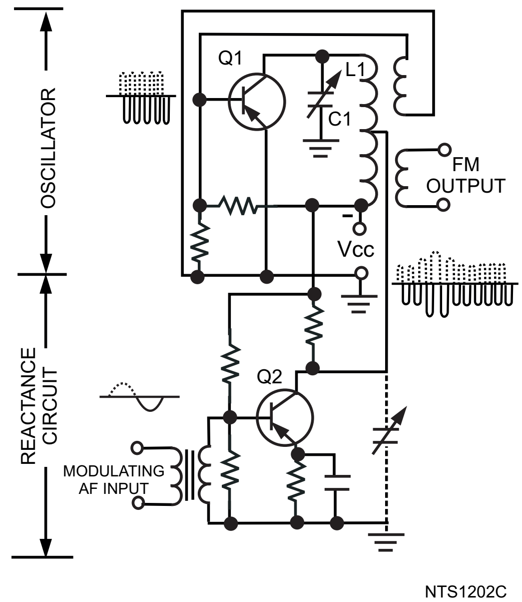

Figure 2C.—Semiconductor reactance modulator.

IN ANSWERING QUESTIONS 2-25 AND 2-26, REFER TO FIGURE 2C.

2-25. The semiconductor reactance modulator in the circuit is in parallel with a portion of the oscillator tank circuit coil. Modulation results because of interaction with which of the following transistor characteristics?

1. Collector-to-emitter resistance
2. Collector-to-emitter capacitance
3. Base-to-emitter resistance
4. Base-to-emitter capacitance

2-26. With a positive-going modulating signal applied to the base of Q2, (a) what will circuit capacitance do and (b) what will the output frequency do?

1. (a) Decrease (b) decrease
2. (a) Decrease (b) increase
3. (a) Increase (b) increase
4. (a) Increase (a) decrease

2-27. What type of circuit is used to remove the AM component in the output of a semiconductor reactance modulator?

1. A mixer
2. A filter
3. A limiter
4. A buffer amplifier

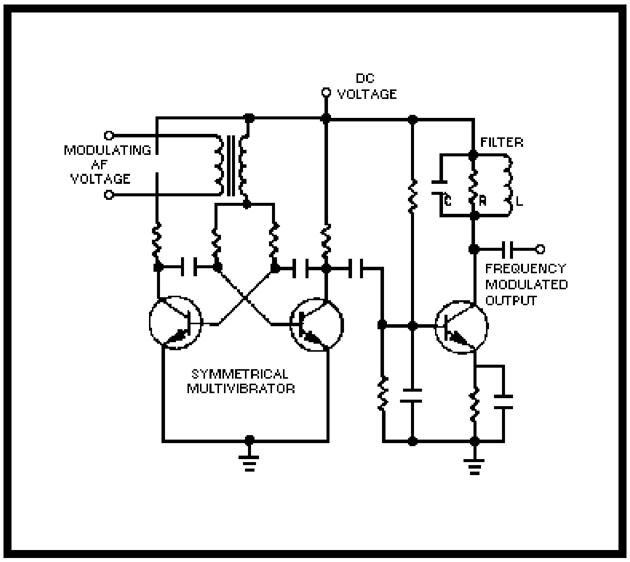

Figure 2D.—Multivibrator modulator.

IN ANSWERING QUESTIONS 2-28 AND 2-29, REFER TO FIGURE 2D.

2-28. The multivibrator modulator produces fm modulation by which of the following actions?

1. By modulating the collector voltages
2. By modulating the base-return voltages
3. By modulating the value of the base value of the base capacitors
4. By modulating the value of the base resistors

2-29. What is the purpose of the filter on the output of the multivibrator modulator?

1. To establish the fundamental operating frequency
2. To eliminate unwanted frequency variations
3. To eliminate unwanted odd harmonics
4. To eliminate unwanted even harmonics

2-30. A multivibrator frequency modulator is limited to frequencies below what maximum frequency?

1. 1 megahertz
2. 2 megahertz
3. 5 megahertz
4. 10 megahertz

2-31. To ensure the frequency stability of an fm transmitter, which, if any, of the following actions could be taken?

1. Modulate a crystal-controlled oscillator at the desired frequency
2. Modulate a low-frequency oscillator, and use frequency multipliers to achieve the operating frequency
3. Modulate a low-frequency oscillator, and heterodyne it with a higher-frequency oscillator to achieve the desired frequency
4. None of the above

2-32. A varactor is a variable device that acts as which of the following components?

1. Resistor
2. Inductor
3. Capacitor
4. Transistor

2-33. As the positive potential is increased on the cathode of a varactor, (a) what happens to reverse bias and (b) how is dielectric width affected?

1. (a) Increases (b) increases
2. (a) Increases (b) decreases
3. (a) Decreases (b) decreases
4. (a) Decreases (b) increases

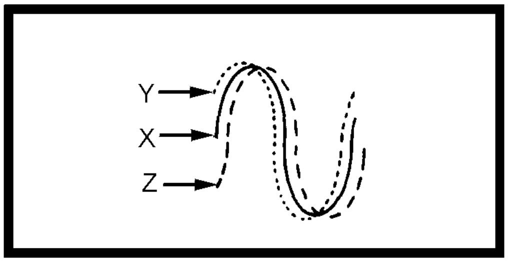

Figure 2E.—Phase relationships.

IN ANSWERING QUESTION 2-34, REFER TO FIGURE 2E.

2-34. In the figure, (a) waveform X has what phase relationship to waveform Y, and (b) waveform Y has what relationship to waveform Z?

1. (a) Lags (b) leads
2. (a) Lags (b) lags
3. (a) Leads (b) lags
4. (a) Leads (b) leads

2-35. A 10 kilohertz, 10-volt square wave is applied as the phase-modulating signal to a transmitter with a carrier frequency of 60 megahertz. What is the output frequency during the constant-amplitude portions of the modulating signal?

1. 10 kilohertz
2. 59,990 kilohertz
3. 60,000 kilohertz
4. 60,010 kilohertz

2-36. In a phase modulator, the frequency during the constant-amplitude portion of the modulating wave is the

1. peak frequency
2. rest frequency
3. deviation frequency
4. modulating frequency

2-37. In phase modulation, (a) the AMPLITUDE of the modulating signal determines what characteristic of the phase shift, and (b) the FREQUENCY of the modulating signal determines what characteristic of the phase shift?

1. (a) Rate (b) rate
2. (a) Rate (b) amount
3. (a) Amount (b) amount
4. (a) Amount (b) rate

2-38. The frequency spectrums of a phase-modulated signal resemble the spectrum of which, if any, of the following types of modulation?

1. Amplitude modulated
2. Frequency modulated
3. Continuous-wave modulated
4. None of the above

2-39. Compared to fm, increasing the modulating frequency in phase modulation has what effect, if any, on the bandwidth of the phase-modulated signal?

1. It increases
2. It decreases
3. None

2-40. A simple phase modulator consists of a capacitor in series with a variable resistance. What total amount of carrier shift will occur when X_C is 10 times the resistance?

1. 0 degrees
2. 45 degrees
3. 60 degrees
4. 90 degrees

2-41. The primary advantage of phase modulation over frequency modulation is that phase modulation has better carrier

1. power stability
2. amplitude stability
3. frequency stability
4. directional stability

2-42. Phase-shift keying is most useful under which of the following code element conditions?

1. When mark elements are longer than space elements
2. When mark elements are shorter than space elements
3. When mark and space elements are the same length
4. When mark and space elements are longer than synchronizing elements

2-43. When a carrier is phase-shift keying modulated, (a) a data bit ONE will normally cause the carrier to shift its phase what total number of degrees, and (b) a data bit ZERO will cause the carrier to shift its phase what total number of degrees?

1. (a) 60 (b) 0
2. (a) 0 (b) 180
3. (a) 180 (b) 180
4. (a) 180 (b) 0

2-44. Which of the following circuits is used to generate a phase-shift keyed signal?

1. Logic circuit
2. Phasor circuit
3. Phasitron circuit
4. Longitudinal circuit

2-45. When a carrier is modulated by a square wave, what maximum number of sideband pairs will be generated?

1. 1
2. 9
3. 3
4. An infinite number

2-46. As the square wave modulating voltage is increased to the same amplitude as that of the carrier, what will be the effect on (a) the carrier amplitude and (b) amplitude of the sidebands?

1. (a) Remains constant
   (b) Increases
2. (a) Decreases
   (b) Increases
3. (a) Increases
   (b) Remains constant
4. (a) Increases
   (b) Decreases

2-47. In a square-wave modulated signal, total sideband power is what percentage of the total power?

1. 0 percent
2. 25 percent
3. 33 percent
4. 50 percent

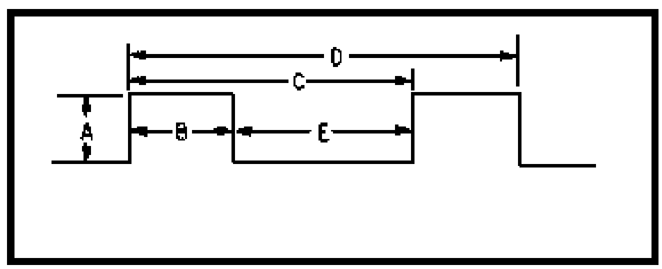

Figure 2F.—Waveform.

IN ANSWERING QUESTIONS 2-48 THROUGH 2-51, REFER TO FIGURE 2F. SELECT THE FIGURE LETTER THAT CORRESPONDS WITH THE WAVEFORM LISTED IN THE QUESTIONS. LETTERS MAY BE USED ONCE, MORE THAN ONCE, OR NOT AT ALL.

2-48. Pulse width.

1. A
2. B
3. C
4. D

2-49. Rest time.

1. B
2. C
3. D
4. E

2-50. Pulse duration.

1. A
2. B
3. D
4. E

2-51. Pulse-repetition time.

1. B
2. C
3. D
4. E

2-52. Which of the following ratios is used to determine pulse-repetition frequency (prf)?

1. $\text{Prf} = \frac{1}{\text{prt}}$
2. $\text{Prf} = \frac{1}{\text{pw}}$
3. $\text{Prf} = \frac{1}{\text{pd}}$
4. $\text{Prf} = \frac{1}{\text{rt}}$

2-53. Average power in a pulse-modulation system is defined as the

1. power during rest time
2. power during each pulse
3. power during each pulse averaged over rest time
4. power during each pulse averaged over one operating cycle

2-54. In pulse modulation, what term is used to indicate the ratio of time the system is actually producing rf?

1. Rest cycle
2. Duty cycle
3. Average cycle
4. Transmit cycle

2-55. In a pulse-modulation system, which of the following formulas is used to figure the percentage of transmitting time?

1. $\frac{\text{pw}}{\text{prt}} \times 100$
2. $\frac{\text{prt}}{\text{pw}} \times 100$
3. $\frac{\text{pw}}{\text{rt}} \times 100$
4. $\frac{\text{rt}}{\text{pw}} \div 100$

2-56. When pulse modulation is used for range finding in a radar application, which of the following types of pulse information is used?

1. Reflected pulse return interval
2. Reflected pulse duration
3. Reflected pulse amplitude
4. Reflected pulse frequency

2-57. In a spark-gap modulator, what is the function of the pulse-forming network?

1. To store energy
2. To increase the level of stored energy
3. To act as a power bleeder
4. To rapidly discharge stored energy

2-58. The damping diode in a thyratron modulator serves which of the following purposes?

1. It discharges the pulse-forming network
2. It limits the input signal
3. It prevents the breakdown of the thyratron by reverse-voltage transients
4. It rectifies the input signal

2-59. Compared to a spark-gap modulator, the thyratron modulator exhibits which of the following advantages?

1. Improved timing
2. Higher output pulses
3. Higher trigger voltage
4. Operates over a narrower range of anode voltages and pulse-repetition rates

2-60. To transmit intelligence using pulse modulation, which of the following pulse characteristics may be varied?

1. Pulse duration
2. Pulse amplitude
3. Pulse-repetition time
4. Each of the above

2-61. To accurately reproduce a modulating signal in a pulse-modulated system, what minimum number of samples must be taken per cycle?

1. One
2. Two
3. Three
4. Four

2-62. What is the simplest form of pulse modulation?

1. Pulse-code modulation
2. Pulse-duration modulation
3. Pulse-frequency modulation
4. Pulse-amplitude modulation

2-63. The same pulse characteristic is varied in which of the following types of pulse modulations?

1. Pam and pdm
2. Pdm and pwm
3. Pwm and ppm
4. Ppm and pam

THIS SPACE LEFT BLANK INTENTIONALLY.

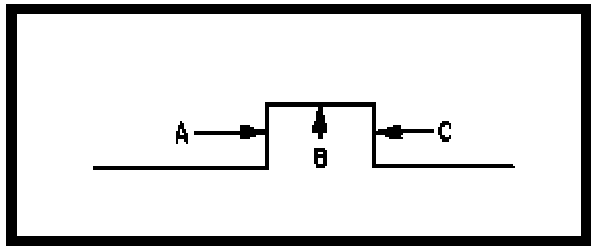

Figure 2G.—Waveform.

IN ANSWERING QUESTION 2-64, REFER TO FIGURE 2G.

2-64. Which of the points shown in the waveform may be varied in pulse-duration modulation?

1. A only
2. B only
3. C only
4. A and/or C

2-65. Which, if any, of the following is the primary disadvantage of pulse-position modulation?

1. It depends on transmitter-receiver synchronization
2. It is susceptible to noise interference
3. Transmitter power varies
4. None of the above

2-66. A pfm transmitter transmits 10,000 pulses per second without a modulating signal applied. How, if at all, will a modulating signal affect the transmitted pulse rate?

1. It will decrease the transmitted pulse rate
2. It will increase the transmitted pulse rate
3. Both 1 and 2 above
4. It will not affect the transmitted pulse rate

2-67. The process of arbitrarily dividing a wave into a series of standard values is referred to as

1. arbitration
2. quantization
3. interposition
4. approximation

2-68. A pcm system is capable of transmitting 32 standard levels that ate sampled 2.5 times per cycle of a 3-kilohertz modulating signal. What maximum number of bits per second are transmitted?

1. 18,750
2. 37,500
3. 75,000
4. 240,000

2-69. Which of the following is a characteristic of a pcm system that makes it advantageous for use in multiple-relay link systems?

1. Average power is constant
2. Average power decreases with each relay
3. Noise is not cumulative at relay stations
4. Quantization noise decreases with each relay

ASSIGNMENT 3

Textbook assignment: Chapter 3, "Demodulation," pages 3-1 through 3-35.

3-1. The process of recreating the original modulating frequencies (intelligence) from an rf carrier is known by which of the following terms?

1. Detection
2. Demodulation
3. Both 1 and 2 above
4. Distribution

3-2. When a demodulator fails to accurately recover intelligence from a modulated carrier, which of the following types of distortion result?

1. Phase
2. Frequency
3. Amplitude
4. Each of the above

3-3. In a demodulator circuit, which of the following components is required for demodulation to occur?

1. A linear device
2. A nonlinear device
3. A variable resistor

3-4. In cw demodulation, the first requirement of the circuit is the ability to detect

1. the presence or absence of the carrier
2. amplitude variations in the carrier
3. frequency variations in the carrier
4. phase variations in the carrier

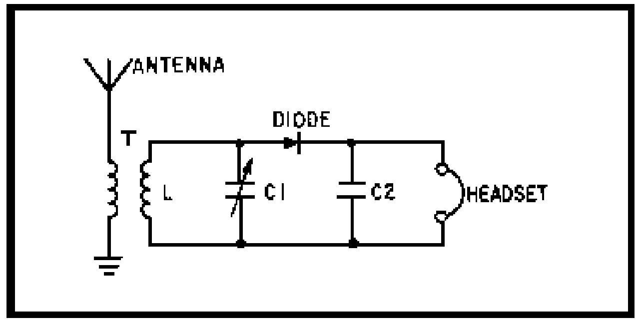

Figure 3A.—Cw demodulation.

IN ANSWERING QUESTION 3-5, REFER TO FIGURE 3A.

3-5. In the figure, L and C1 form a frequency-selective network that serves what purpose?

1. It removes the carrier
2. It rectifies the oscillations
3. It tunes the circuit to the desired rf carrier
4. It provides filtering to maintain a constant dc output

3-6. To aid in distinguishing between two or more cw signals that are close to the same frequency, which of the following detectors is used?

1. Diode
2. Crystal
3. Heterodyne
4. Transistor

3-7. Assume that two signals are received, one at 500 kHz and the other at 501 kHz. What frequency, in kHz, should be mixed with them to distinguish the 501 kHz signal by producing a 1 kHz output?

1. 499
2. 500
3. 501
4. 502

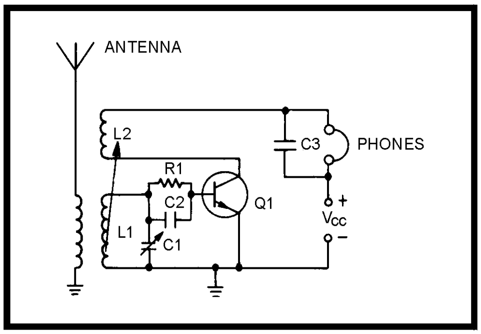

Figure 3B.—Detector.

IN ANSWERING QUESTIONS 3-8 THROUGH 3-11, REFER TO FIGURE 3B.

3-8. The detector circuit in the figure uses the heterodyning principle to detect the incoming signal. What type of detector is it?

1. Hartley
2. Colpitts
3. Armstrong
4. Regenerative

3-9. What component controls the operating frequency of the detector?

1. C1
2. C2
3. L2
4. R1

3-10. What component provides the feedback necessary for oscillations to occur?

1. R1
2. C2
3. C3
4. L2

3-11. Which of the following circuit functions does Q1 perform?

1. Mixer
2. Detector
3. Oscillator
4. Each of the above

3-12. A circuit that is nonlinear, provides filtering, and is sensitive to the type of modulation applied to it fulfills the requirements of which, if any, of the following circuits?

1. Mixer
2. Modulator
3. Demodulator
4. None of the above

3-13. A detector uses which of the following signals to approximate the original waveform?

1. The sum frequency
2. The carrier frequency
3. The modulation envelope

THIS SPACE LEFT BLANK INTENTIONALLY.

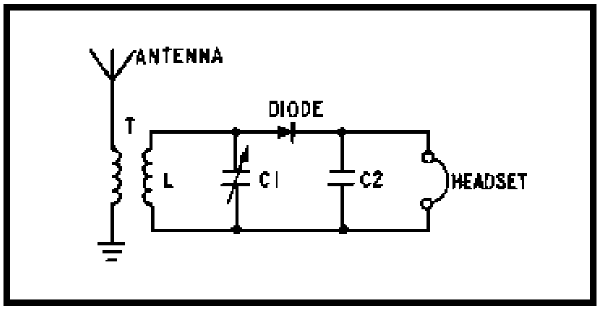

Figure 3C.—Detector.

IN ANSWERING QUESTIONS 3-14 THROUGH 3-16, REFER TO FIGURE 3C.

3-14. What type of detector is shown in the figure?

1. Series-diode
2. Parallel-diode
3. Inductive-diode
4. Capacitive-diode

3-15. What is the purpose of C1 and L?

1. To smooth the incoming rf
2. To select the desired af signal
3. To select the desired rf signal
4. To smooth the detected af signal

3-16. What is the purpose of C2?

1. To smooth the incoming rf signal
2. To select the desired af signal
3. To select the desired rf signal
4. To smooth the detected af signal

3-17. A shunt diode circuit is used as a detector in which of the following instances?

1. When a large input signal is supplied
2. When a large output current is required
3. When the input signal variations overdrive the audio amplifier stages
4. When the input signal variations are too small to produce a full output from audio amplifier stages

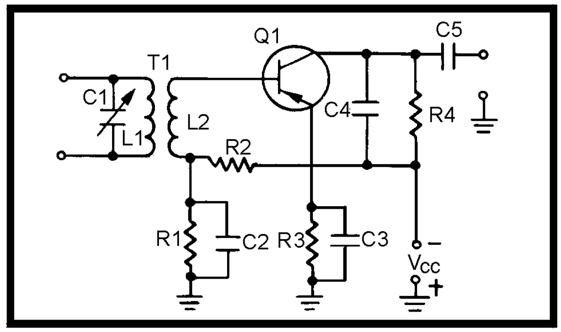

Figure 3D.—Detector.

IN ANSWERING QUESTIONS 3-18 THROUGH 3-21, REFER TO FIGURE 3D.

3-18. What type of detector is shown in the figure?

1. Ratio
2. Common-base
3. Regenerative
4. Common-emitter

3-19. What circuit component acts as the load for the detected audio?

1. R1
2. R2
3. R3
4. R4

3-20. What is the purpose of C4?

1. Tp bypass af
2. To bypass rf
3. To remove power supply voltage variations
4. To determine the operating frequency of the circuit

3-21. This detector circuit is used under which of the following circuit conditions?

1. When higher frequencies are used
2. When the best possible frequency selection is required
3. When weak signals need to be detected
4. When strong signals need to be detected

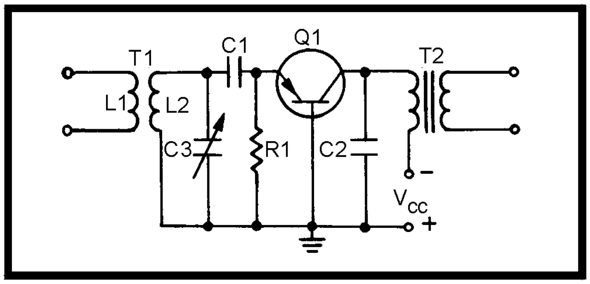

Figure 3E.—Circuit.

IN ANSWERING QUESTIONS 3-22 THROUGH 3-24, REFER TO FIGURE 3E.

3-22. What type of Circuits is/are shown in the figure?

1. A detector
2. An amplifier
3. Both 1 and 2 above
4. An oscillator

3-23. What is the purpose of T2?

1. To filter rf
2. To filter af
3. To couple the af output
4. To couple the rf output

3-24. What is the function of C1 and R1?

1. To act as an integrator
2. To act as a frequency-selective network
3. To act as a filter network
4. To act as a differentiator

THIS SPACE LEFT BLANK INTENTIONALLY.

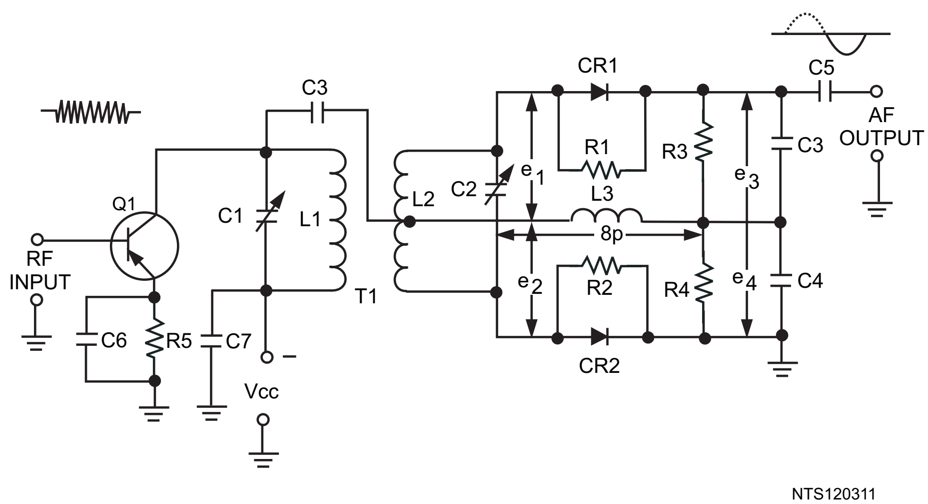

Figure 3F.—Foster-Seeley discriminator.

IN ANSWERING QUESTIONS 3-25 THROUGH 3-30, REFER TO FIGURE 3F.

3-25. In the figure, what is the purpose of Q1?

1. To act as a limiter only
2. To act as an amplifier only
3. To act as a limiter and an amplifier
4. To act as an oscillator

3-26. To what frequency are C1/L1 and C2/L2 tuned?

1. The af input
2. The center frequency of fm signal
3. The lowest fm deviation frequency
4. The highest fm deviation frequency

3-27. What is the function of L3?

1. To couple af to the output
2. To couple rf from the tank circuits to CR1 and CR2
3. To prevent af from being coupled to the power supply
4. To provide the dc return path for CR1 and CR2

3-28. At resonance, what is the amplitude of e_3 compared to e_4?

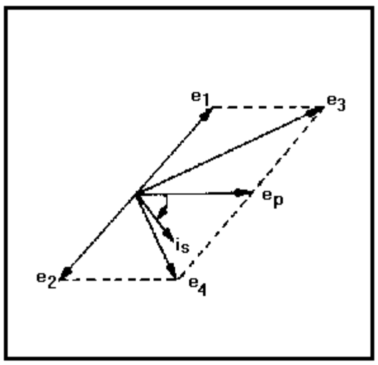
1. e_3 is less than e_4
2. e_3 is equal to e_4
3. e_3 is greater than e_4

3-29. When the circuit is operating ABOVE resonance, (a) does inductive reactance increase or decrease, and (b) does capacitive reactance increase or decrease?

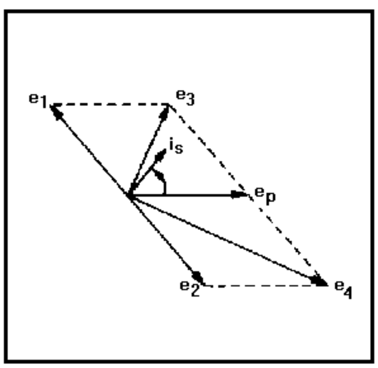
1. (a) Increases (b) increases
2. (a) Increases (b) decreases
3. (a) Decreases (b) decreases
4. (a) Decreases (b) increases

3-30. Circuit operation BELOW resonance is represented by which of the following vector diagrams?

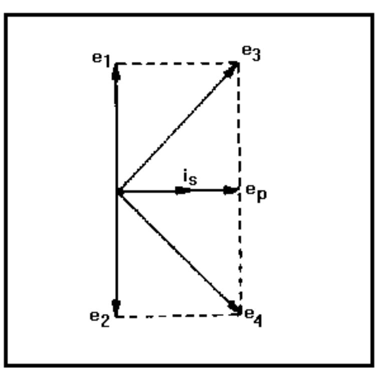
1.



2.



3.



THIS SPACE LEFT BLANK INTENTIONALLY.

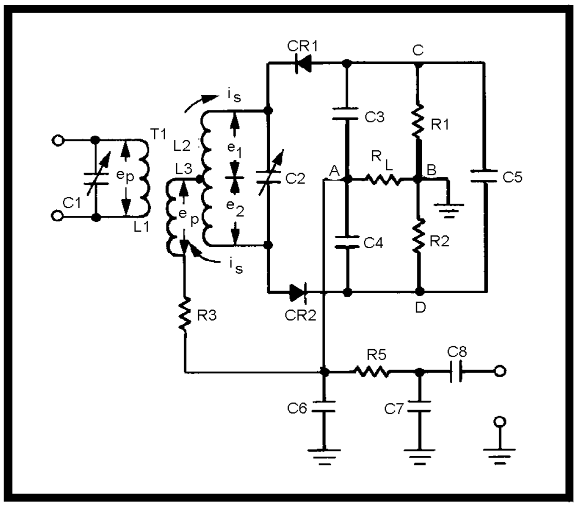


Figure 3G.—Ratio detector.

IN ANSWERING QUESTIONS 3-31 THROUGH 3-40, REFER TO FIGURE 3G.

3-31. To what frequency(ies) are (a) L1 and C1 and (b) L2 and C2 tuned?

1. (a) Center frequency
   (b) lower frequency limit
2. (a) Center frequency
   (b) center frequency
3. (a) Lower frequency limit
   (b) center frequency
4. (a) Lower frequency limit
   (b) lower frequency limit

3-32. What circuit filtering function do R5, C6, and C7 provide?

1. Low-pass
2. High-pass
3. Band-pass
4. Band-reject

3-33. At resonance, what type of circuit does the tank circuit appear to be?

1. Reactive
2. Resistive
3. Inductive
4. Capacitive

3-34. At resonance, what is the phase relationship between tank current and primary voltage?

1. Tank current leads primary voltage by 90 degrees
2. Tank current lags primary voltage by 90 degrees
3. Tank current and primary voltage are in phase
4. Tank current and primary voltage are out of phase

3-35. At resonance, what relative amount of conduction takes place through CR1 compared to that for CR2?

1. CR1 conducts more than CR2
2. CR1 conducts less than CR2
3. CR1 and CR2 conduct the same amount

3-36. At resonance, (a) will the charges on C3 and C4 be equal or unequal, and (b) will their polarities be the same or opposite?

1. (a) Equal (b) same
2. (a) Equal (b) opposite
3. (a) Unequal (b) opposite
4. (a) Unequal (b) same

3-37. ABOVE resonance, both voltages e_1 and e_2 have specific phase shift relationships to voltage e in that they either shift nearer to or farther from the phase of e_p. What are the phase relationships between (a) e_1 and e_p and (b) e_2 and e_p?

1. (a) e_1 is nearer to e_p
   (b) e_2 is nearer to e_p
2. (a) e_1 is nearer to e_p
   (b) e_2 is farther from e_p
3. (a) e_1 is farther from e_p
   (b) e_2 is nearer to e_p
4. (a) e_1 is farther from e_p
   (b) e_2 is farther from e_p

3-38. If C3 is charged to 6 volts and C4 is charged to 4 volts, what is the output voltage?

1. 1 volt
2. 2 volts
3. 3 volts
4. 4 volts

3-39. When operating BELOW resonance, what is the relationship of the vector sum of e_1 and e_p to the vector sum of e_2 and e_p?

1. The sum of e_1 and e_p is larger than the sum of e_2 and e_p
2. The sum of e_1 and e_p is smaller than the sum of e_2 and e_p
3. The slam of e_1 and e_p is equal to the sum of e_2 an e_p

3-40. What components help to reduce the effects of amplitude variations at the input of the circuit?

1. R1, R2, and C5
2. R5, C6, and C7
3. R1, R2, C3, and C4
4. L1, L2, L3, and C2

3-41. What is the minimum input voltage, in millivolts, required for a ratio detector?

1. 100
2. 200
3. 300
4. 400

3-42. Which of the following circuit functions is performed by the gated-beam detector?

1. Limiter
2. Detector
3. Amplifier
4. Each of the above

THIS SPACE LEFT BLANK INTENTIONALLY.

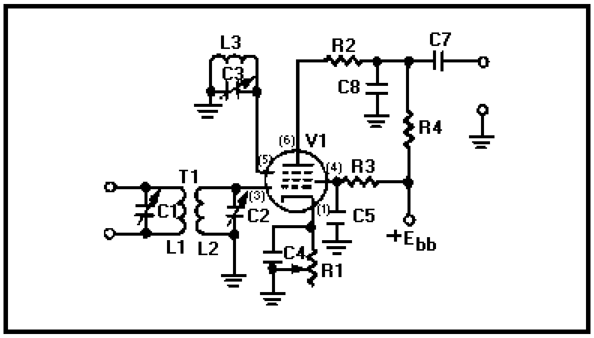

Figure 3H.—Gated-beam detector.

IN ANSWERING QUESTIONS 3-43 THROUGH 3-47, REFER TO FIGURE 3H.

3-43. What components in the circuit are used to set the reference frequency for a gated-beam detector?

1. C1 and L1
2. C2 and L2
3. C3 and L3
4. C4 and R1

3-44. What tube pins connect to elements that perform in a manner similar to an AND gate in a digital device?

1. Pins 1 and 3
2. Pins 3 and 4
3. Pins 3 and 5
4. Pins 4 and 5

3-45. What type of tank circuit is the quadrature tank (L3 and C3)?

1. Low-Q
2. High-Q
3. Nonresonant
4. Series-resonant

3-46. For plate current to flow, what must be the polarities of (a) the quadrature grid and (b) the limiter grid?

1. (a) Negative (b) negative
2. (a) Negative (b) positive
3. (a) Positive (b) positive
4. (a) Positive (b) negative

3-47. ABOVE the center frequency of the received fm signal, (a) will the tank appear capacitive or inductive, and (b) will the average plate current increase or decrease?

1. (a) Inductive (b) increase
2. (a) Inductive (b) decrease
3. (a) Capacitive (b) decrease
4. (a) Capacitive (b) increase

3-48. To demodulate a phase-modulated signal, which, if any, of the following types of demodulators may be used?

1. Peak
2. Quadrature
3. Series-diode
4. None of the above

3-49. Which of the following circuits can be used as a communications pulse demodulator?

1. Conversion
2. Peak detector
3. Low-pass filter
4. Each of the above

THIS SPACE LEFT BLANK INTENTIONALLY.

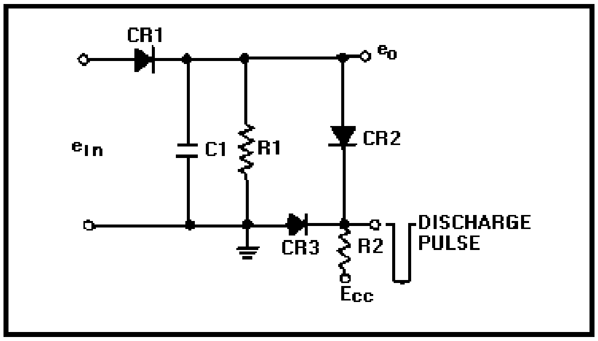

Figure 3I.—Detector.

IN ANSWERING QUESTIONS 3-50 THROUGH 3-52, REFER TO FIGURE 3I.

3-50. To detect pulse-amplitude modulation, what value must the RC time constant of R1 and C1 in the circuit be?

1. Five times the pulse width
2. Ten times the pulse width
3. Five times the interpulse period
4. Ten times the interpulse period

3-51. Which, if any, of the following functions is the purpose of CR2?

1. To quickly discharge C1 between received pulses
2. To rectify input pulses
3. To clamp the output to a positive level
4. None of the above

3-52. What change must be made to the circuit to detect pulse-duration modulation?

1. Remove R1
2. Increase the value of R1
3. Decrease the value of R1
4. Add a resistor in series with CR1

3-53. When a pulse-duration modulated signal is determined by using a low-pass filter, what characteristic of the signal is used?

1. Width
2. Amplitude
3. Frequency
4. Pulse position

3-54. To detect pulse-duration modulation, the low-pass filter components must be selected so that they pass only the

1. carrier frequency
2. intermediate frequency
3. pulse-repetition frequency
4. desired modulating frequency

3-55. What type(s) of modulation is/are normally detected by first converting it/them to another type of modulation?

1. Ppm only
2. Pfm only
3. Pcm only
4. Ppm, pfm, and pcm

3-56. What type of circuit can be used to convert from ppm to pdm for demodulation?

1. An amplifier
2. A flip-flop
3. An oscillator
4. A transformer

THIS SPACE LEFT BLANK INTENTIONALLY.

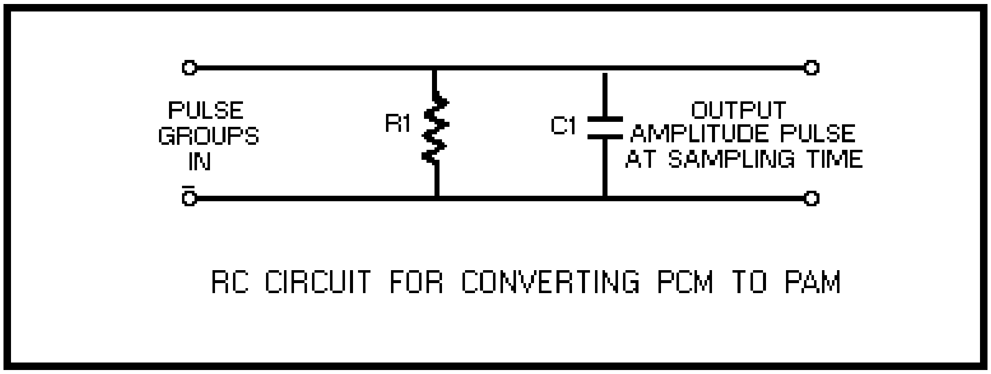

Figure 3J.—Pcm conversion.

IN ANSWERING QUESTIONS 3-57 THROUGH 3-59, REFER TO FIGURE 3J.

3-57. To convert from pcm to pam, what type of circuit is used to apply the pcm to the input of the circuit shown?

1. A constant-current source
2. A constant-voltage source
3. A limiter-amplifier source
4. An oscillator-amplifier source

3-58. If C1 is allowed to charge 16 volts during the period of one pulse, each additional pulse increases the charge by 16 volts. With the binary-coded equivalent of an analog 12 applied to the input, what will be the output of the circuit at sampling time?

1. 10 volts
2. 12 volts
3. 14 volts
4. 16 volts

3-59. Between pulses, R1 must allow C1 to discharge to what voltage?

1. 0 volts
2. One fourth of the charge on C1
3. One half of the charge on C1
4. Three fourths of the charge on C1

PREFACE

About this course:

This is a self-study course. By studying this course, you can improve your professional/military knowledge, as well as prepare for the Navywide advancement-in-rate examination. It contains subject matter about day-to-day occupational knowledge and skill requirements and includes text, tables, and illustrations to help you understand the information. An additional important feature of this course is its reference to useful information in other publications. The well-prepared Sailor will take the time to look up the additional information.

Training series information:

This is Module 13 of a series.

History of the course:

Sep 1998: *Original edition released. Prepared by FTCS(SS) Steven F. Reith.*
Jan 2004: *Administrative update. Reviewed by ETC(SW/AW) Scott Collie. Graphics updated No change in technical content.*

ASSIGNMENT QUESTIONS follow Index.

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

CHAPTER 1

NUMBER SYSTEMS

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions are based on the objectives. By successfully completing the NRTC, you indicate that you have met the objectives and have learned the information. The learning objectives are listed below.

Upon completion of this chapter, you should be able to do the following:

1. Recognize different types of number systems as they relate to computers.

2. Identify and define unit, number, base/radix, positional notation, and most and least significant digits as they relate to decimal, binary, octal, and hexadecimal number systems.

3. Add and subtract in binary, octal, and hexadecimal number systems.

4. Convert values from decimal, binary, octal, hexadecimal, and binary-coded decimal number systems to each other and back to the other systems.

5. Add in binary-coded decimal.

INTRODUCTION

How many days' leave do you have on the books? How much money do you have to last until payday? It doesn't matter what the question is—if the answer is in dollars or days or cows, it will be represented by numbers.

Just try to imagine going through one day without using numbers. Some things can be easily described without using numbers, but others prove to be difficult. Look at the following examples:

I am stationed on the aircraft carrier *Nimitz*.

He owns a green Chevrolet.

The use of numbers wasn't necessary in the preceding statements, but the following examples depend on the use of numbers:

I have $25 to last until payday.

I want to take 14 days' leave.

You can see by these statements that numbers play an important part in our lives.

BACKGROUND AND HISTORY

Man’s earliest number or counting system was probably developed to help determine how many possessions a person had. As daily activities became more complex, numbers became more important in trade, time, distance, and all other phases of human life.

As you have seen already, numbers are extremely important in your military and personal life. You realize that you need more than your fingers and toes to keep track of the numbers in your daily routine.

Ever since people discovered that it was necessary to count objects, they have been looking for easier ways to count them. The abacus, developed by the Chinese, is one of the earliest known calculators. It is still in use in some parts of the world.

Blaise Pascal (French) invented the first adding machine in 1642. Twenty years later, an Englishman, Sir Samuel Moreland, developed a more compact device that could multiply, add, and subtract. About 1672, Gottfried Wilhelm von Leibniz (German) perfected a machine that could perform all the basic operations (add, subtract, multiply, divide), as well as extract the square root. Modern electronic digital computers still use von Liebniz's principles.

MODERN USE

Computers are now employed wherever repeated calculations or the processing of huge amounts of data is needed. The greatest applications are found in the military, scientific, and commercial fields. They have applications that range from mail sorting, through engineering design, to the identification and destruction of enemy targets. The advantages of digital computers include speed, accuracy, and man-power savings. Often computers are able to take over routine jobs and release personnel for more important work—work that cannot be handled by a computer.

People and computers do not normally speak the same language. Methods of translating information into forms that are understandable and usable to both are necessary. Humans generally speak in words and numbers expressed in the decimal number system, while computers only understand coded electronic pulses that represent digital information.

In this chapter you will learn about number systems in general and about binary, octal, and hexadecimal (which we will refer to as hex) number systems specifically. Methods for converting numbers in the binary, octal, and hex systems to equivalent numbers in the decimal system (and vice versa) will also be described. You will see that these number systems can be easily converted to the electronic signals necessary for digital equipment.

TYPES OF NUMBER SYSTEMS

Until now, you have probably used only one number system, the decimal system. You may also be familiar with the Roman numeral system, even though you seldom use it.

THE DECIMAL NUMBER SYSTEM

In this module you will be studying modern number systems. You should realize that these systems have certain things in common. These common terms will be defined using the decimal system as our base. Each term will be related to each number system as that number system is introduced.

Each of the number systems you will study is built around the following components: the UNIT, NUMBER, and BASE (RADIX).

Unit and Number

The terms *unit* and *number* when used with the decimal system are almost self-explanatory. By definition the unit is a single object; that is, an apple, a dollar, a day. A number is a symbol representing a unit or a quantity. The figures 0, 1, 2, and 3 through 9 are the symbols used in the decimal system. These symbols are called Arabic numerals or figures. Other symbols may be used for different number systems. For example, the symbols used with the Roman numeral system are letters — V is the symbol for 5, X for 10, M for 1,000, and so forth. We will use Arabic numerals and letters in the number system discussions in this chapter.

Base (Radix)

The base, or radix, of a number system tells you the number of symbols used in that system. The base of any system is always expressed in decimal numbers. The base, or radix, of the decimal system is 10. This means there are 10 symbols — 0, 1, 2, 3, 4, 5, 6, 7, 8, and 9 — used in the system. A number system using three symbols — 0, 1, and 2 — would be base 3; four symbols would be base 4; and so forth. Remember to count the zero or the symbol used for zero when determining the number of symbols used in a number system.

The base of a number system is indicated by a subscript (decimal number) following the value of the number. The following are examples of numerical values in different bases with the subscript to indicate the base:

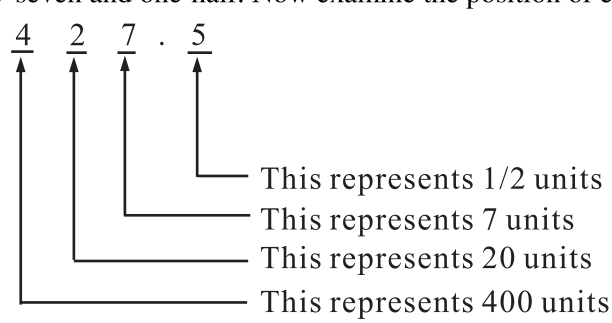
$$7592_{10} \qquad 214_5 \quad 123_4 \quad 656_7$$

You should notice the highest value symbol used in a number system is always one less than the base of the system. In base 10 the largest value symbol possible is 9; in base 5 it is 4; in base 3 it is 2.

Positional Notation and Zero

You must observe two principles when counting or writing quantities or numerical values. They are the POSITIONAL NOTATION and the ZERO principles.

Positional notation is a system where the value of a number is defined not only by the symbol but by the symbol's position. Let's examine the decimal (base 10) value of 427.5. You know from experience that this value is four hundred twenty-seven and one-half. Now examine the position of each number:



NTS130101

If 427.5 is the quantity you wish to express, then each number must be in the position shown. If you exchange the positions of the 2 and the 7, then you change the value.

Each position in the positional notation system represents a power of the base, or radix. A POWER is the number of times a base is multiplied by itself. The power is written above and to the right of the base and is called an EXPONENT. Examine the following base 10 line graph:

Radix Point

$10^3 \quad 10^2 \quad 10^1 \quad 10^0 \quad . \quad 10^{-1} \quad 10^{-2} \quad 10^{-3}$

10^3	= 10 x 100, or 1000
10^2	= 10 x 10, or 100
10^1	= 10 x 1, or 10
10^0	= (any number raised to the power of 0 equals 1)
10^{-1}	= 1 + 10, or .1
10^{-2}	= 1 + 100. or .01
10^{-3}	= 1 + 1000, or .001

NTS130102

Now let's look at the value of the base 10 number 427.5 with the positional notation line graph:

Radix Point

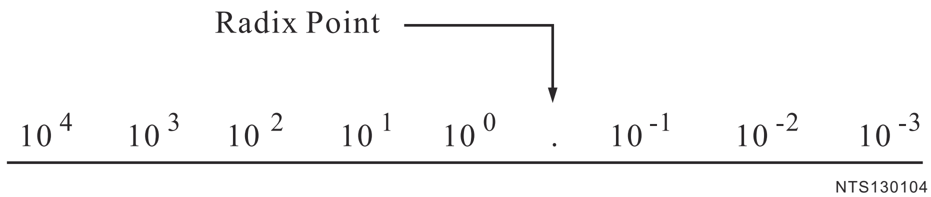
10^2	10^1	10^0	.	10^{-1}
4	2	7	.	5

10^2	= 4 x 100, or 400
10^1	= 2 x 10, or 20
10^0	= 7 x 1, or 7
10^{-1}	= 5 x .1, or .5

NTS130103

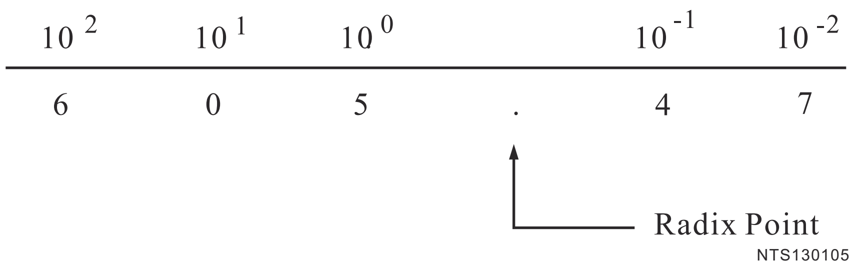
You can see that the power of the base is multiplied by the number in that position to determine the value for that position.

The following graph illustrates the progression of powers of 10:



All numbers to the left of the decimal point are whole numbers, and all numbers to the right of the decimal point are fractional numbers. A whole number is a symbol that represents one, or more, complete objects, such as one apple or $5. A fractional number is a symbol that represents a portion of an object, such as half of an apple (.5 apples) or a quarter of a dollar ($0.25). A mixed number represents one, or more, complete objects, and some portion of an object, such as one and a half apples (1.5 apples). When you use any base other than the decimal system, the division between whole numbers and fractional numbers is referred to as the RADIX POINT. The decimal point is actually the radix point of the decimal system, but the term radix point is normally not used with the base 10 number system.

Just as important as positional notation is the use of the zero. The placement of the zero in a number can have quite an effect on the value being represented. Sometimes a position in a number does not have a value between 1 and 9. Consider how this would affect your next paycheck. If you were expecting a check for $605.47, you wouldn't want it to be $65.47. Leaving out the zero in this case means a difference of $540.00. In the number 605.47, the zero indicates that there are no tens. If you place this value on a bar graph, you will see that there are no multiples of 10^1.



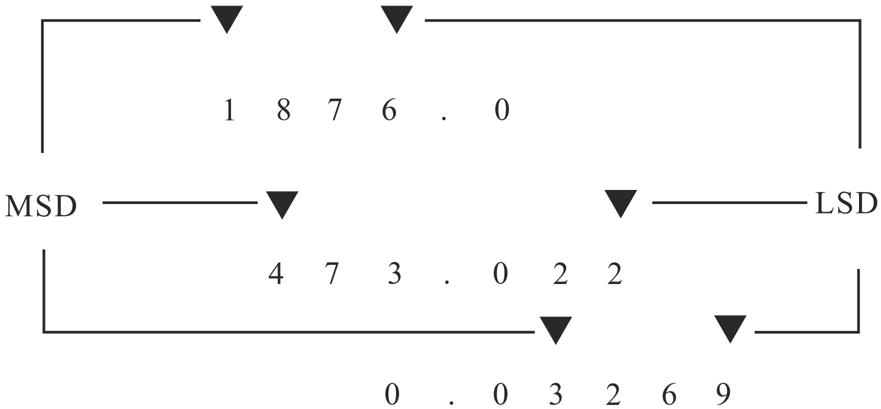
Most Significant Digit and Least Significant Digit (MSD and LSD)

Other important factors of number systems that you should recognize are the MOST SIGNIFICANT DIGIT (MSD) and the LEAST SIGNIFICANT DIGIT (LSD).

The MSD in a number is the digit that has the *greatest* effect on that number.

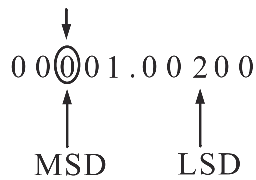
The LSD in a number is the digit that has the *least* effect on that number.

Look at the following examples:



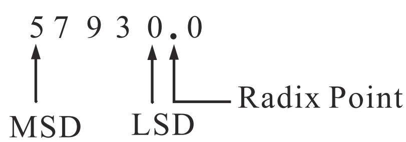
NTS130106

You can easily see that a change in the MSD will increase or decrease the value of the number the greatest amount. Changes in the LSD will have the smallest effect on the value. The nonzero digit of a number that is the farthest LEFT is the MSD, and the nonzero digit farthest RIGHT is the LSD, as in the following example:



NTS130107

In a whole number the LSD will always be the digit immediately to the left of the radix point.



NTS130108

Q1. What term describes a single object?

Q2. A symbol that represents one or more objects is called a _________.

Q3. The symbols 0, 1, 2, and 3 through 9 are what type of numerals?

Q4. What does the base, or radix, of a number system tell you about the system?

Q5. How would you write one hundred seventy-three base 10?

Q6. What power of 10 is equal to 1,000? 100? 10? 1?

Q7. The decimal point of the base 10 number system is also known as the _________.

Q8. What is the MSD and LSD of the following numbers

(a) 420.

(b) 1045.06

(c) 0.0024

(d) 247.0001

Carry and Borrow Principles

Soon after you learned how to count, you were taught how to add and subtract. At that time, you learned some concepts that you use almost everyday. Those concepts will be reviewed using the decimal system. They will also be applied to the other number systems you will study.

ADDITION—Addition is a form of counting in which one quantity is added to another. The following definitions identify the basic terms of addition:

AUGEND—The quantity to which an addend is added

ADDEND—A number to be added to a preceding number

SUM —The result of an addition (the sum of 5 and 7 is 12)

CARRY —A carry is produced when the sum of two or more digits in a vertical column equals or exceeds the base of the number system in use

How do we handle the carry; that is, the two-digit number generated when a carry is produced? The lower order digit becomes the sum of the column being added; the higher order digit (the carry) is added to the next higher order column. For example, let's add 15 and 7 in the decimal system:

1	Carry
15	Augend
+7	Addend
22	Sum

NTS130109

Starting with the first column, we find the sum of 5 and 7 is 12. The 2 becomes the sum of the lower order column and the 1 (the carry) is added to the upper order column. The sum of the upper order column is 2. The sum of 15 and 7 is, therefore, 22.

The rules for addition are basically the same regardless of the number system being used. Each number system, because it has a different number of digits, will have a unique digit addition table. These addition tables will be described during the discussion of the adding process for each number system.

A decimal addition table is shown in table 1-1. The numbers in row X and column Y may represent either the addend or the augend. If the numbers in X represent the augend, then the numbers in Y must represent the addend and vice versa. The sum of X + Y is located at the point in array Z where the selected X row and Y column intersect.

Table 1-1. —Decimal Addition Table

+	0	1	2	3	4	5	6	7	8	9
0	0	1	2	3	4	5	6	7	8	9
1	1	2	3	4	5	6	7	8	9	10
2	2	3	4	5	6	7	8	9	10	11
3	3	4	5	6	7	8	9	10	11	12
4	4	5	6	7	8	9	10	11	12	13
5	5	6	7	8	9	10	11	12	13	14
6	6	7	8	9	10	11	12	13	14	15
7	7	8	9	10	11	12	13	14	15	16
8	8	9	10	11	12	13	14	15	16	17
9	9	10	11	12	13	14	15	16	17	18

X

Z

Y

To add 5 and 7 using the table, first locate one number in the X row and the other in the Y column. The point in field Z where the row and column intersect is the sum. In this case the sum is 12.

SUBTRACTION.—The following definitions identify the basic terms you will need to know to understand subtraction operations:

- SUBTRACT—To take away, as a part from the whole or one number from another
- MINUEND—The number from which another number is to be subtracted
- SUBTRAHEND—The quantity to be subtracted
- REMAINDER, or DIFFERENCE—That which is left after subtraction
- BORROW—To transfer a digit (equal to the base number) from the next higher order column for the purpose of subtraction.

Use the rules of subtraction and subtract 8 from 25. The form of this problem is probably familiar to you:

$$\begin{array}{rrl} & {}^{1}\,{}^{15} & \text{Carry} \\ \longrightarrow & \cancel{2}\cancel{5} & \text{Minuend} \\ \longrightarrow & \underline{-8} & \text{Subtrahend} \\ & 17 & \text{Difference} \end{array}$$

NTS130110

It requires the use of the *borrow*; that is, you cannot subtract 8 from 5 and have a positive difference. You must borrow a 1, which is really one group of 10. Then, one group of 10 plus five groups of 1 equal 15, and 15 minus 8 leaves a difference of 7. The 2 was reduced by 1 by the borrow; and since nothing is to be subtracted from it, it is brought down to the difference.

Since the process of subtraction is the opposite of addition, the addition table 1-1 may be used to illustrate subtraction facts for any number system we may discuss.

In addition,

$$X + Y = Z$$

In subtraction, the reverse is true; that is,

$$Z - Y = X$$

OR

$$Z - X = Y$$

Thus, in subtraction the minuend is always found in array Z and the subtrahend in either row X or column Y. If the subtrahend is in row X, then the remainder will be in column Y. Conversely, if the subtrahend is in column Y, then the difference will be in row X. For example, to subtract 8 from 15, find 8 in either the X row or Y column. Find where this row or column intersects with a value of 15 for Z; then move to the remaining row or column to find the difference.

THE BINARY NUMBER SYSTEM

The simplest possible number system is the BINARY, or base 2, system. You will be able to use the information just covered about the decimal system to easily relate the same terms to the binary system.

Unit and Number

The base, or radix—you should remember from our decimal section—is the number of symbols used in the number system. Since this is the base 2 system, only two symbols, 0 and 1, are used. The base is indicated by a subscript, as shown in the following example:

$$1_2$$

When you are working with the decimal system, you normally don't use the subscript. Now that you will be working with number systems other than the decimal system, it is important that you use the subscript so that you are sure of the system being referred to. Consider the following two numbers:

$$11 \qquad 11$$

With no subscript you would assume both values were the same. If you add subscripts to indicate their base system, as shown below, then their values are quite different:

$$11_{10} \qquad 11_2$$

The base ten number 11_{10} is eleven, but the base two number 11_2 is only equal to three in base ten. There will be occasions when more than one number system will be discussed at the same time, so you MUST use the proper Subscript.

Positional Notation

As in the decimal number system, the principle of positional notation applies to the binary number system. You should recall that the decimal system uses powers of 10 to determine the value of a position. The binary system uses powers of 2 to determine the value of a position. A bar graph showing the positions and the powers of the base is shown below:

$2^4 \; 2^3 \; 2^2 \; 2^1 \; 2^0 \,.\; 2^{-1} \; 2^{-2} \; 2^{-3}$
2^4 is equal to 2 x 2 x 2 x 2, or 16_{10}
2^3 is equal to 2 x 2 x 2, or 8_{10}
2^2 is equal to 2 x 2, or 4_{10}
2^1 is equal to 2 x 1, or 2_{10}
2^0 is equal to 1_{10}
2^{-1} is equal to 1/2, or $.5_{10}$
2^{-2} is equal to 1/4, or $.25_{10}$
2^{-3} is equal to 1/8, or $.125_{10}$

NTS130111

All numbers or values to the left of the radix point are whole numbers, and all numbers to the right of the radix point are fractional numbers.

Let's look at the binary number 101.1 on a bar graph:

$$\begin{array}{cccccc} 2^2 & 2^1 & 2^0 & . & 2^{-2} \\ \hline 1 & 0 & 1 & . & 1 \end{array}$$

NTS130112

Working from the radix point to the right and left, you can determine the decimal equivalent:

$$\begin{aligned} 1 \text{ x } 2^{-1} &= .5_{10} \\ 1 \text{ x } 2^{0} &= 1.0_{10} \\ 1 \text{ x } 2^{1} &= 0.0_{10} \\ 1 \text{ x } 2^{2} &= 4.0_{10} \\ \hline & 5.5_{10} \end{aligned}$$

NTS130113

Table 1-2 provides a comparison of decimal and binary numbers. Notice that each time the total number of binary symbol positions increase, the binary number indicates the next higher power of 2. By this example, you can also see that more symbol positions are needed in the binary system to represent the equivalent value in the decimal system.

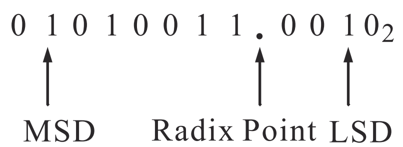
Table 1-2. —Decimal and Binary Comparison

	DECIMAL	BINARY	
10^0	0	0	2^0
	1	1	
	2	10	2^1
	3	11	
	4	100	2^2
	5	101	
	6	110	
	7	111	
	8	1000	2^3
	9	1001	
10^1	10	1010	
	11	1011	
	12	1100	
	13	1101	
	14	1110	
	15	1111	
	16	10000	2^4
	17	10001	
	18	10010	
	19	10011	
	20	10100	

NTS1301T2

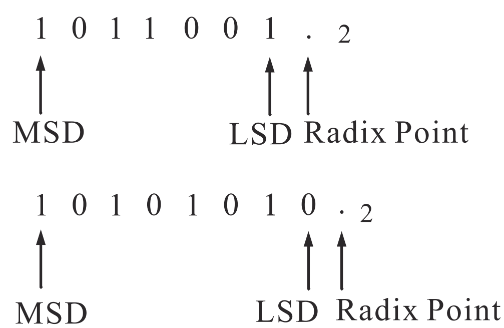
MSD and LSD

When you're determining the MSD and LSD for binary numbers, use the same guidelines you used with the decimal system. As you read from left to right, the first nonzero digit you encounter is the MSD, and the last nonzero digit is the LSD.



NTS130114

If the number is a whole number, then the first digit to the left of the radix point is the LSD.



NTS130115

Here, as in the decimal system, the MSD is the digit that will have the most effect on the number; the LSD is the digit that will have the least effect on the number.

The two numerals of the binary system (1 and 0) can easily be represented by many electrical or electronic devices. For example, 1_2 may be indicated when a device is active (on), and 0_2 may be indicated when a device is nonactive (off).

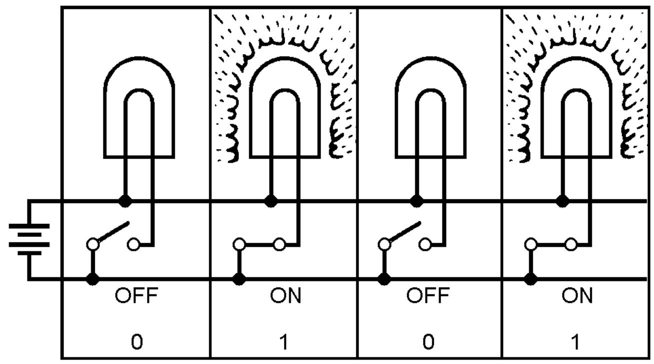


Figure 1-1. —Binary Example

Look at the preceding figure. It illustrates a very simple binary counting device. Notice that 1_2 is indicated by a lighted lamp and 0_2 is indicated by an unlighted lamp. The reverse will work equally well. The unlighted state of the lamp can be used to represent a binary 1 condition, and the lighted state can represent the binary 0 condition. Both methods are used in digital computer applications. Many other devices are used to represent binary conditions. They include switches, relays, diodes, transistors, and integrated circuits (ICs).

Addition of Binary Numbers

Addition of binary numbers is basically the same as addition of decimal numbers. Each system has an augend, an addend, a sum, and carries. The following example will refresh your memory:

1	Carry
15	Augend
+7	Addend
22	Sum

NTS130116

Since only two symbols, 0 and 1, are used with the binary system, only four combinations of addition are possible.

0 + 0

1 + 0

0 + 1

1 + 1

The sum of each of the first three combinations is obvious:

$$0 + 0 = 0_2$$

$$0 + 1 = 1_2$$

$$1 + 0 = 1_2$$

The fourth combination presents a different situation. The sum of 1 and 1 in any other number system is 2, but the numeral 2 does not exist in the binary system. Therefore, the sum of 1_2 and 1_2 is 10_2 (spoken as one zero base two), which is equal to 2_{10}.

$$\begin{array}{rl} {}^{1} & \text{Carry} \\ 1_2 & \text{Augend} \\ + \underline{1_2} & \text{Addend} \\ 10_2 & \text{Sum} \end{array}$$

NTS130117

Study the following examples using the four combinations mentioned above:

$$\begin{array}{rl} 101_2 & \text{Augend} \\ + \underline{010_2} & \text{Addend} \\ 111_2 & \text{Sum} \end{array}$$

NTS130118

$$\begin{array}{rl} {}^{1} & \text{Carry} \\ 101_2 & \text{Augend} \\ + \underline{101_2} & \text{Addend} \\ 1010_2 & \text{Sum} \end{array}$$

NTS130119

When a carry is produced, it is noted in the column of the next higher value or in the column immediately to the left of the one that produced the carry.

Example: Add 1011_2 and 1101_2.

Solution: Write out the problem as shown:

$$\begin{array}{rl} 1011_2 & \text{Augend} \\ + \underline{1101_2} & \text{Addend} \end{array}$$

NTS130120

As we noted previously, the sum of 1 and 1 is 2, which cannot be expressed as a single digit in the binary system. Therefore, the sum of 1 and 1 produces a carry:

$$\begin{array}{rl} {}^{1} & \text{Carry} \\ 1011_2 & \text{Augend} \\ + \underline{1101_2} & \text{Addend} \\ 0_2 & \text{Sum} \end{array}$$

NTS130121

The following steps, with the carry indicated, show the completion of the addition:

Previous Carry Used

$$\begin{array}{rl} 1\cancel{1} & \text{Carry} \\ 1011_2 & \text{Augend} \\ +\ \underline{1101_2} & \text{Addend} \\ 00_2 & \end{array}$$

NTS130122

When the carry is added, it is marked through to prevent adding it twice.

Previous Carry Used

$$\begin{array}{rl} 1\cancel{1}\cancel{1} & \text{Carry} \\ 1011_2 & \text{Augend} \\ +\ \underline{1101_2} & \text{Addend} \\ 000_2 & \end{array}$$

NTS130123

Previous Carry Used

$$\begin{array}{rl} 1\cancel{1}\cancel{1}\cancel{1} & \text{Carry} \\ 1011_2 & \text{Augend} \\ +\ \underline{1101_2} & \text{Addend} \\ 11000_2 & \end{array}$$

NTS130124

In the final step the remaining carry is brought down to the sum.

In the following example you will see that more than one carry may be produced by a single column. This is something that does not occur in the decimal system.

Example: Add 1_2, 1_2, 1_2, and 1_2

$$\begin{array}{rl} 1_2 & \text{Augend} \\ 1_2 & \text{1st Addend} \\ 1_2 & \text{2nd Addend} \\ +\ \underline{1_2} & \text{3rd Addend} \end{array}$$

The sum of the augend and the first addend is 0 with a carry. The sum of the second and third addends is also 0 with a carry. At this point the solution resembles the following example:

$$\begin{array}{rl} 1 & \text{Carry} \\ 1 & \text{Carry} \\ 1_2 & \text{Augend} \\ 1_2 & \text{1st Addend} \\ 1_2 & \text{2nd Addend} \\ +\ \underline{1_2} & \text{3rd Addend} \\ 0_2 & \end{array}$$

The sum of the carries is 0 with a carry, so the sum of the problem is as follows:

1	Carry
11	Carry
1_2	Augend
1_2	1st Addend
1_2	2nd Addend
$+\ 1_2$	3rd Addend
100_2	

The same situation occurs in the following example:

Add 100_2, 101_2, and 111_2

100_2	Augend
101_2	Addend
$+\ 111_2$	Addend

1	Carry
100_2	Augend
101_2	Addend
$+\ 111_2$	Addend
0_2	Sum

11	Carry
100_2	Augend
101_2	Addend
$+\ 111_2$	Addend
00_2	Sum

As in the previous example, the sum of the four 1s is 0 with two carries, and the sum of the two carries is 0 with one carry. The final solution will look like this:

1	Carry
1111	Carry
100_2	Augend
101_2	Addend
$+\ 111_2$	Addend
10000_2	Sum

In the addition of binary numbers, you should remember the following binary addition rules:

$$\text{Rule 1: } 0_2 + 0_2 = 0_2$$

$$\text{Rule 2: } 1_2 + 0_2 = 1_2$$

$$\text{Rule 3: } 0_2 + 1_2 = 1_2$$

$$\text{Rule 4: } 1_2 + 1_2 = 10_2$$

Now practice what you've learned by solving the following problems:

Q9.

Add:

$$\begin{array}{r} 10101_2 \\ +\ 1010_2 \\ \hline \end{array}$$

Q10.

Add:

$$\begin{array}{r} 10011_2 \\ +\ 1010_2 \\ \hline \end{array}$$

Q11.

Add:

$$\begin{array}{r} 11101_2 \\ +\ 100_2 \\ \hline \end{array}$$

Q12.

Add:

$$\begin{array}{r} 10110_2 \\ +\ 11001_2 \\ \hline \end{array}$$

Q13.

Add:

$$\begin{array}{r} 111_2 \\ +\ 1_2 \\ \hline \end{array}$$

Q14.

Add:

$$
\begin{array}{r}
1010010_2 \\
1110111_2 \\
+\quad 10101_2 \\
\hline
\end{array}
$$

Subtraction of Binary Numbers

Now that you are familiar with the addition of binary numbers, subtraction will be easy. The following are the four rules that you must observe when subtracting:

Rule 1: $0_2 - 0_2 = 0_2$

Rule 2: $1_2 - 0_2 = 1_2$

Rule 3: $1_2 - 1_2 = 0_2$

Rule 4: $0_2 - 1_2 = 1_2$ with a borrow

The following example ($10110_2 - 1100_2$) demonstrates the four rules of binary subtraction:

$$
\begin{array}{rl}
10110_2 & \text{Minuend} \\
-\ 1100_2 & \text{Subtrahend} \\
\hline
?010_2 & \text{Difference}
\end{array}
$$

Rule 1: $0_2 - 0_2 = 0_2$

Rule 2: $1_2 - 0_2 = 1_2$

Rule 3: $1_2 - 1_2 = 0_2$

Rule 4: (Explained below)

Rule 4 presents a different situation because you cannot subtract 1 from 0. Since you cannot subtract 1 from 0 and have a positive difference, you must borrow the 1 from the next higher order column of the minuend. The borrow may be indicated as shown below:

$$
\begin{array}{rl}
10 & \text{Borrow} \\
0 & \text{After borrow} \\
\cancel{1}0110_2 & \text{Minuend} \\
-\ 1100_2 & \text{Subtrahend} \\
\hline
1010_2 & \text{Difference}
\end{array}
$$

Rule 4: $(0_2 - 1_2)$

Now observe the following method of borrowing across more than one column in the example, $1000_2 - 1_2$:

$$
\begin{array}{rl}
1\ 1 & \text{Borrow} \\
0\ \cancel{10}\cancel{10}\cancel{10} & \text{After borrow (base 2)} \\
\cancel{1}000_2 & \text{Minuend} \\
-\ \qquad 1_2 & \text{Subtrahend} \\
\hline
0111_2 & \text{Difference}
\end{array}
$$

Let’s practice some subtraction by solving the following problems:

Q15. *Subtract:*

$$
\begin{array}{r}
11001_2 \\
-\ \ 1001_2 \\
\hline
\end{array}
$$

Q16. *Subtract:*

$$
\begin{array}{r}
10101_2 \\
-\ \ 1010_2 \\
\hline
\end{array}
$$

Q17. *Subtract:*

$$
\begin{array}{r}
11111_2 \\
-\ \ \ 10_2 \\
\hline
\end{array}
$$

Q18. Subtract:

$$\begin{array}{r} 111_2 \\ -\ \ 100_2 \\ \hline \end{array}$$

Q19. Subtract:

$$\begin{array}{r} 10001_2 \\ -\ \ 11_2 \\ \hline \end{array}$$

Q20. Subtract:

$$\begin{array}{r} 100000_2 \\ -\ \ 1_2 \\ \hline \end{array}$$

Complementary Subtraction

If you do any work with computers, you will soon find out that most digital systems cannot subtract—they can only add. You are going to need a method of adding that gives the results of subtraction. Does that sound confusing? Really, it is quite simple. A COMPLEMENT is used for our subtractions. A complement is something used to complete something else.

In most number systems you will find two types of complements. The first is the amount necessary to complete a number up to the highest number in the number system. In the decimal system, this would be the difference between a given number and all 9s. This is called the nines complement or the radix-1 or R's-1 complement. As an example, the nines complement of 254 is 999 minus 254, or 745.

The second type of complement is the difference between a number and the next higher power of the number base. As an example, the next higher power of 10 above 999 is 1,000. The difference between 1,000 and 254 is 746. This is called the tens complement in the decimal number system. It is also called the radix or R's complement. We will use complements to subtract. Let's look at the *magic* of this process. There are three important points we should mention before we start: (1) Never complement the minuend in a problem, (2) always disregard any carry beyond the number of positions of the largest of the original numbers, and (3) add the R's complement of the original subtrahend to the original minuend. This will have the same effect as subtracting the original number. Let's look at a base ten example in which we subtract 38 from 59:

R's
Complement

$$\begin{array}{r} 59 \\ -\ 38 \\ \hline 21 \end{array} \rightarrow \boxed{\begin{array}{r} 100 \\ -\ 38 \\ \hline 62 \end{array}} \rightarrow \begin{array}{r} 59 \\ +62 \\ \hline 121 \end{array}$$

Add the R's complement of 38

Disregard any carry

Now let's look at the number system that most computers use, the binary system. Just as the decimal system, had the nines (R's-1) and tens (R's) complement, the binary system has two types of complement methods. These two types are the ones (R's-1) complement and the twos (R's) complement. The binary system R's-1 complement is the difference between the binary number and all 1s. The R's complement is the difference between the binary number and the next higher power of 2.

Let's look at a quick and easy way to form the R's-1 complement. To do this, change each 1 in the original number to 0 and each 0 in the original number to 1 as has been done in the example below.

1011011_2

100100_2 R's-1 complement

There are two methods of achieving the R's complement. In the first method we perform the R's-1 complement and then add 1. This is much easier than subtracting the original number from the next higher power of 2. If you had subtracted, you would have had to borrow.

Saying it another way, to reach the R's complement of any binary number, change all 1s to 0s and all 0s to 1s, and then add 1.

As an example let's determine the R's complement of 10101101_2:

Step 1 -- R's - 1 complement	01010010_2
Step 2 -- Add 1:	$+\ \ 1_2$
	01010011_2

The second method of obtaining the R's complement will be demonstrated on the binary number 0010110100_2.

Step 1—Start with the LSD, working to the MSD, writing the digits as they are up to and including the first one.

first one

0010110100_2

100_2

Step 2—Now R's-1 complement the remaining digits:

$$\underbrace{1101001}_{\text{R's-1 complement of remaining digits}}\overset{\substack{\text{first one}\\ \downarrow}}{1}00_2$$

Now let's R's complement the same number using both methods:

Method 1

$$\begin{array}{rl}
1001100_2 & \\
0110011_2 & \text{R's-1 complement} \\
+ \quad\quad 1_2 & \text{Add 1} \\
\hline
0110100_2 & \text{R's complement answer}
\end{array}$$

Method 2

$$\begin{array}{ll}
1001100_2 & \\
\underbrace{0110}_{\text{R's-1 complement of remaining digits}}\underbrace{100}_{\text{Unchanged digits}}{}_2 & \text{R's-1 complement}
\end{array}$$

Now let's do some subtracting by using the R's complement method. We will go through the subtraction of 3_{10} from 9_{10} ($0011_2$from 1001_2):

$$\begin{array}{r}
9_{10} \\
-\ 3_{10} \\
\hline
\end{array}
\qquad
\begin{array}{rl}
1001_2 & \text{Minuend} \\
-\ 0011_2 & \text{Subtrahend} \\
\hline
\end{array}$$

Step 1—Leave the minuend alone:

1001_2 remains 1001_2

Step 2—Using either method, R's complement the subtrahend:

1101_2 R's complement of subtrahend

Step 3—Add the R's complement found in step 2 to the minuend of the original problem:

$$
\begin{array}{rl}
1001_2 & \text{Original minuend} \\
+\ 1101_2 & \text{R's complement of subtrahend} \\
\hline
10110_2 & \text{Difference of original problem}
\end{array}
$$

Step 4—Remember to discard any carry beyond the size of the original number. Our original problem had four digits, so we discard the carry that expanded the difference to five digits. This carry we disregard is significant to the computer. It indicates that the difference is positive. Because we have a carry, we can read the difference directly without any further computations. Let's check our answer:

$$
\begin{array}{rcr}
1001_2 & = & 9_{10} \\
-\ 0011_2 & = & -3_{10} \\
\hline
1\ 0110_2 & = & 6_{10}
\end{array}
$$

$\uparrow$

Discard

If we do *not* have a carry, it indicates the difference is a negative number. In that case, the difference must be R's complemented to produce the correct answer.

Let's look at an example that will explain this for you.

Subtract 9_{10} from 5_{10} (1001_2 from 0101_2):

$$
\begin{array}{rrl}
5_{10} & 0101_2 & \text{Minuend} \\
\underline{-9}_{10} & \underline{-\ 1001}_2 & \text{Subtrahend} \\
-4_{10} & &
\end{array}
$$

Step 1—Leave the minuend alone:

0101_2 remains 0101_2

Step 2—R's complement the subtrahend:

0111_2 R's complement of subtrahend

Step 3—Add the R's complement found in step 2 to the minuend of the original problem:

$$
\begin{array}{rl}
0101_2 & \text{Original minuend} \\
+\ 0111_2 & \text{Twos complement} \\
\hline
1100_2 & \text{Difference of original problem}
\end{array}
$$

Step 4—We do *not* have a carry; and this tells us, and any computer, that our difference (answer) is negative. With no carry, we must R's complement the difference in step 3. We will then have arrived at the answer (difference) to our original problem. Let's do this R's complement step and then check our answer:

0100_2 R's complement of difference in step 3

Remember, we had no carry in step 3. That showed us our answer was going to be negative. Make sure you indicate the difference is negative. Let's check the answer to our problem:

$$
\begin{array}{r}
0101_2 = 5_{10} \\
\underline{-\ 1001}_2 = \underline{-9}_{10} \\
-\ 0100_2 = -4_{10}
\end{array}
$$

Try solving a few subtraction problems by using the complement method:

Q21. Subtract:

$$
\begin{array}{r}
325_{10} \\
\underline{-\ 104}_{10}
\end{array}
$$

Q22. Subtract:

$$
\begin{array}{r}
10010111_2 \\
\underline{-\ 00110100}_2
\end{array}
$$

Q23. Subtract:

$$
\begin{array}{r}
1011_2 \\
\underline{-\ 1100}_2
\end{array}
$$

OCTAL NUMBER SYSTEM

The octal, or base 8, number system is a common system used with computers. Because of its relationship with the binary system, it is useful in programming some types of computers.

Look closely at the comparison of binary and octal number systems in table 1-3. You can see that one octal digit is the equivalent value of three binary digits. The following examples of the conversion of octal 225_8 to binary and back again further illustrate this comparison:

Octal to binary

2	2	5_8
010	010	101_2

Binary to Octal

010	010	101_2
2	2	5_8

Table 1-3. —Binary and Octal Comparison

	BINARY	OCTAL	
2^0	0	0	8^0
	1	1	
2^1	10	2	
	11	3	
2^2	100	4	
	101	5	
	110	6	
	111	7	
2^3	1000	10	8^1
	1001	11	
	1010	12	
	1011	13	
	1100	14	
	1101	15	
	1110	16	
	1111	17	
2^4	10000	20	
	10001	21	
	10010	22	
	10011	23	
	10100	24	
	10101	25	
	10110	26	
	10111	27	
	11000	30	

NTS1301T3

Unit and Number

The terms that you learned in the decimal and binary sections are also used with the octal system.

The unit remains a single object, and the number is still a symbol used to represent one or more units.

Base (Radix)

As with the other systems, the radix, or base, is the number of symbols used in the system. The octal system uses eight symbols — 0 through 7. The base, or radix, is indicated by the subscript 8.

Positional Notation

The octal number system is a positional notation number system. Just as the decimal system uses powers of 10 and the binary system uses powers of 2, the octal system uses power of 8 to determine the value of a number's position. The following bar graph shows the positions and the power of the base:

$$8^3 \; 8^2 \; 8^1 \; 8^0 \bullet 8^{-1} \; 8^{-2} \; 8^{-3}$$

Remember, that the power, or exponent, indicates the number of times the base is multiplied by itself. The value of this multiplication is expressed in base 10 as shown below:

$$8^3 = 8 \text{ x } 8 \text{ x } 8, \text{ or } 512_{10}$$

$$8^2 = 8 \text{ x } 8, \text{ or } 64_{10}$$

$$8^1 = 8_{10}$$

$$8^0 = 1_{10}$$

$$8^{-1} = \frac{1}{8}, \text{ or } .125_{10}$$

$$8^{-2} = \frac{1}{8 \text{ x } 8}, \text{ or } \frac{1}{64}, \text{ or } .015625_{10}$$

$$8^{-3} = \frac{1}{8 \text{ x } 8 \text{ x } 8}, \text{ or } \frac{1}{512}, \text{ or } .0019531_{10}$$

All numbers to the left of the radix point are whole numbers, and those to the right are fractional numbers.

MSD and LSD

When determining the most and least significant digits in an octal number, use the same rules that you used with the other number systems. The digit farthest to the left of the radix point is the MSD, and the one farthest right of the radix point is the LSD.

Example:

$$\begin{array}{cccccccc} 4 & 7 & 3 & 2 & \bullet & 2 & 6 & 1_8 \\ \uparrow & & & & \uparrow & & & \uparrow \\ \text{MSD} & & & & \text{Radix Point} & & & \text{LSD} \end{array}$$

If the number is a whole number, the MSD is the nonzero digit farthest to the left of the radix point and the LSD is the digit immediately to the left of the radix point. Conversely, if the number is a fraction only, the nonzero digit closest to the radix point is the MSD and the LSD is the nonzero digit farthest to the right of the radix point.

Addition of Octal Numbers

The addition of octal numbers is not difficult provided you remember that anytime the sum of two digits exceeds 7, a carry is produced. Compare the two examples shown below:

$$\begin{array}{r} 4_8 \\ +2_8 \\ \hline 6_8 \end{array} \qquad \begin{array}{r} 4_8 \\ +4_8 \\ \hline 10_8 \end{array}$$

The octal addition table in table 1-4 will be of benefit to you until you are accustomed to adding octal numbers. To use the table, simply follow the directions used in this example:

Add: 6_8 and 5_8

Table 1-4. —Octal Addition Table

+	0	1	2	3	4	5	6	7
0	0	1	2	3	4	5	6	7
1	1	2	3	4	5	6	7	10
2	2	3	4	5	6	7	10	11
3	3	4	5	6	7	10	11	12
4	4	5	6	7	10	11	12	13
5	5	6	7	10	11	12	13	14
6	6	7	10	11	12	13	14	15
7	7	10	11	12	13	14	15	16

X

Z

Y

Locate the 6 in the X column of the figure. Next locate the 5 in the Y column. The point in area Z where these two columns intersect is the sum. Therefore,

$$\begin{array}{r} 6_8 \\ +5_8 \\ \hline 13_8 \end{array}$$ (spoken, "one three, base eight")

If you use the concepts of addition you have already learned, you are ready to add octal numbers.

Work through the solutions to the following problems:

$$\begin{array}{rl} 11 & \text{Carry} \\ 456_8 & \text{Augend} \\ +\ 123_8 & \text{Addend} \\ \hline 601_8 & \text{Sum} \end{array}$$

$$\begin{array}{rl} 11111 & \text{Carry} \\ 77714_8 & \text{Augend} \\ +\quad 76_8 & \text{Addend} \\ \hline 100012_8 & \text{Sum} \end{array}$$

As was mentioned earlier in this section, each time the sum of a column of numbers exceeds 7, a carry is produced. More than one carry may be produced if there are three or more numbers to be added, as in this example:

$$\begin{array}{rl} 7_8 & \text{Augend} \\ 7_8 & \text{Addend} \\ \underline{+\ \ 7_8} & \text{Addend} \end{array}$$

The sum of the augend and the first addend is 6_8 with a carry. The sum of 6_8 and the second addend is 5_8 with a carry. You should write down the 5_8 and add the two carries and bring them down to the sum, as shown below:

$$\begin{array}{rl} 1 & \text{Carry} \\ 1 & \text{Carry} \\ 7_8 & \text{Augend} \\ \underline{+\ \ 7_8} & \text{First addend} \\ 6_8 & \text{Subsum} \\ \underline{+\ \ 7_8} & \text{Second addend} \\ 25_8 & \text{Sum} \end{array}$$

$$\begin{array}{rl} 1 & \text{Carry} \\ 1 & \text{Carry} \\ 7_8 & \text{Augend} \\ 7_8 & \text{Addend} \\ \underline{+\ \ 7_8} & \text{Addend} \\ 25_8 & \text{Sum} \end{array}$$

Now let's try some practice problems:

Q24. Add:

$$\begin{array}{r} 3_8 \\ \underline{+\ \ 5_8} \end{array}$$

Q25. Add:

$$\begin{array}{r} 22_8 \\ \underline{+\ \ 36_8} \end{array}$$

Q26. Add:

$$\begin{array}{r} 621_8 \\ +\ \underline{174_8} \end{array}$$

Q27. Add:

$$\begin{array}{r} 13255_8 \\ +\ \underline{7031_8} \end{array}$$

Q28. Add

$$\begin{array}{r} 24_8 \\ 42_8 \\ \underline{+\ \ 63_8} \end{array}$$

Q29. Add:

$$\begin{array}{r} 3_8 \\ 5_8 \\ 2_8 \\ 6_8 \\ \underline{+\ \ 4_8} \end{array}$$

Subtraction of Octal Numbers

The subtraction of octal numbers follows the same rules as the subtraction of numbers in any other number system. The only variation is in the quantity of the borrow. In the decimal system, you had to borrow a group of 10_{10}. In the binary system, you borrowed a group of 2_{10}. In the octal system you will borrow a group of 8_{10}.

Consider the subtraction of 1 from 10 in decimal, binary, and octal number systems:

DECIMAL	BINARY	OCTAL
$\begin{array}{r} 10_{10} \\ \underline{-\ \ 1_{10}} \\ 9_{10} \end{array}$	$\begin{array}{r} 10_{2} \\ \underline{-\ \ 1_{2}} \\ 1_{2} \end{array}$	$\begin{array}{r} 10_{8} \\ \underline{-\ \ 1_{8}} \\ 7_{8} \end{array}$

In each example, you cannot subtract 1 from 0 and have a positive difference. You must use a borrow from the next column of numbers. Let's examine the above problems and show the borrow as a *decimal* quantity for clarity:

$$\begin{array}{rcrcrl} {}^{10} & & {}^{2} & & {}^{8} & \text{Borrow} \\ \cancel{1}0_{10} & & \cancel{1}0_{2} & & \cancel{1}0_{8} & \\ -\ 1_{10} & & -\ 1_{2} & & -\ 1_{8} & \\ \hline 9_{10} & & 1_{2} & & 7_{8} & \end{array}$$

When you use the borrow, the column you borrow from is reduced by 1, and the amount of the borrow is added to the column of the minuend being subtracted. The following examples show this procedure:

$$\begin{array}{rl} {}^{10} & \text{Borrow (Base 10)} \\ {}^{2}\ \ & \text{After borrow} \\ \cancel{3}4_{10} & \text{Minuend} \\ -\ 9_{10} & \text{Subtrahend} \\ \hline 25_{10} & \text{Difference} \end{array}$$

$$\begin{array}{rl} {}^{10} & \text{Borrow (Base 8)} \\ {}^{3}\ \ & \text{After borrow} \\ \cancel{4}6_{8} & \text{Minuend} \\ -\ 7_{8} & \text{Subtrahend} \\ \hline 37_{8} & \text{Difference} \end{array}$$

In the octal example 7_8 cannot be subtracted from 6_8, so you must borrow from the 4. Reduce the 4 by 1 and add 10_8 (the borrow) to the 6_8 in the minuend. By subtracting 7_8 from 16_8, you get a difference of 7_8. Write this number in the difference line and bring down the 3. You may need to refer to table 1-4, the octal addition table, until you are familiar with octal numbers. To use the table for subtraction, follow these directions. Locate the subtrahend in column Y. Now find where this line intersects with the minuend in area Z. The remainder, or difference, will be in row X directly above this point.

Do the following problems to practice your octal subtraction:

Q30. Subtract:

$$\begin{array}{r} 765_8 \\ -\ 444_8 \\ \hline \end{array}$$

Q31. Subtract:

$$\begin{array}{r} 44_8 \\ -\ 6_8 \\ \hline \end{array}$$

Q32. Subtract:

$$\begin{array}{r} 532_8 \\ -\ \underline{174}_8 \end{array}$$

Q33. Subtract:

$$\begin{array}{r} 1023_8 \\ -\ \underline{424}_8 \end{array}$$

Q34. Subtract:

$$\begin{array}{r} 423_8 \\ -\ \underline{326}_8 \end{array}$$

Q35. Subtract:

$$\begin{array}{r} 7776_8 \\ -\ \underline{7}_8 \end{array}$$

Check your answers by adding the subtrahend and difference for each problem.

HEXADECIMAL (HEX) NUMBER SYSTEM

The hex number system is a more complex system in use with computers. The name is derived from the fact the system uses 16 symbols. It is beneficial in computer programming because of its relationship to the binary system. Since 16 in the decimal system is the fourth power of 2 (or 2^4); one hex digit has a value equal to four binary digits. Table 1-5 shows the relationship between the two systems.

Table 1-5. —Binary and Hexadecimal Comparison

	BINARY	OCTAL	
2^0	0	0	16^0
	1	1	
2^1	10	2	
	11	3	
2^2	100	4	
	101	5

	11001	19	
	11010	1A	
	11011	1B	
	11100	1C	

NTS1301T5

Unit and Number

As in each of the previous number systems, a unit stands for a single object.

A number in the hex system is the symbol used to represent a unit or quantity. The Arabic numerals 0 through 9 are used along with the first six letters of the alphabet. You have probably used letters in math problems to represent unknown quantities, but in the hex system A, B, C, D, E, and F, each have a definite value as shown below:

$$A_{16} = 10_{10}$$

$$B_{16} = 11_{10}$$

$$C_{16} = 12_{10}$$

$$D_{16} = 13_{10}$$

$$E_{16} = 14_{10}$$

$$F_{16} = 15_{10}$$

Base (Radix)

The base, or radix, of this system is 16, which represents the number of symbols used in the system. A quantity expressed in hex will be annotated by the subscript 16, as shown below:

$$A3EF_{16}$$

Positional Notation

Like the binary, octal, and decimal systems, the hex system is a positional notation system. Powers of 16 are used for the positional values of a number. The following bar graph shows the positions:

$$16^3\ 16^2\ 16^1\ 16^0 \bullet\ 16^{-1}\ 16^{-2}\ 16^{-3}$$

Multiplying the base times itself the number of times indicated by the exponent will show the equivalent decimal value:

$$16^3 = 16 \text{ x } 16 \text{ x } 16, \text{ or } 4096_{10}$$

$$16^3 = 16 \text{ x } 16, \text{ or } 256_{10}$$

$$16^1 = 16_{10}$$

$$16^0 = 1_{10}$$

$$16^{-1} = \frac{1}{16}, \text{ or } .0625_{10}$$

$$16^{-2} = \frac{1}{16 \text{ x } 16}, \text{ or } .0039062_{10}$$

$$16^{-3} = \frac{1}{16 \text{ x } 16 \text{ x } 16}, \text{ or } .0002441_{10}$$

You can see from the positional values that usually fewer symbol positions are required to express a number in hex than in decimal. The following example shows this comparison:

625_{16} is equal to 1573_{10}

MSD and LSD

The most significant and least significant digits will be determined in the same manner as the other number systems. The following examples show the MSD and LSD of whole, fractional, and mixed hex numbers:

```
 7   9   E   4   .16
 ↑           ↑   ↑
MSD         LSD  Radix Point
```

```
   .  1  8  2  A16
   ↑  ↑        ↑
Radix MSD     LSD
Point
```

```
3   B   C . E   4   2   F16
↑         ↑             ↑
MSD       Radix         LSD
          Point
```

Addition of Hex Numbers

The addition of hex numbers may seem intimidating at first glance, but it is no different than addition in any other number system. The same rules apply. Certain combinations of symbols produce a carry while others do not. Some numerals combine to produce a sum represented by a letter. After a little practice you will be as confident adding hex numbers as you are adding decimal numbers.

Study the hex addition table in table 1-6. Using the table, add 7 and 7. Locate the number 7 in both columns X and Y. The point in area Z where these two columns intersect is the sum; in this case 7 + 7 = E. As long as the sum of two numbers is 15_{10} or less, only one symbol is used for the sum. A carry will be produced when the sum of two numbers is 16_{10} or greater, as in the following examples:

$$\begin{array}{r} 8_{16} \\ +\ 8_{16} \\ \hline 10_{16} \end{array} \qquad \begin{array}{r} A_{16} \\ +\ D_{16} \\ \hline 17_{16} \end{array} \qquad \begin{array}{r} D_{16} \\ +\ 9_{16} \\ \hline 16_{16} \end{array}$$

Table 1-6. —Hexadecimal Addition Table

+	0	1	2	3	4	5	6	7	8	9	A	B	C	D	E	F
0	0	1	2	3	4	5	6	7	8	9	A	B	C	D	E	F
1	1	2	3	4	5	6	7	8	9	A	B	C	D	E	F	10
2	2	3	4	5	6	7	8	9	A	B	C	D	E	F	10	11
3	3	4	5	6	7	8	9	A	B	C	D	E	F	10	11	12
4	4	5	6	7	8	9	A	B	C	D	E	F	10	11	12	13
5	5	6	7	8	9	A	B	C	D	E	F	10	11	12	13	14
6	6	7	8	9	A	B	C	D	E	F	10	11	12	13	14	15
7	7	8	9	A	B	C	D	E	F	10	11	12	13	14	15	16
8	8	9	A	B	C	D	E	F	10	11	12	13	14	15	16	17
9	9	A	B	C	D	E	F	10	11	12	13	14	15	16	17	18
A	A	B	C	D	E	F	10	11	12	13	14	15	16	17	18	19
B	B	C	D	E	F	10	11	12	13	14	15	16	17	18	19	1A
C	C	D	E	F	10	11	12	13	14	15	16	17	18	19	1A	1B
D	D	E	F	10	11	12	13	14	15	16	17	18	19	1A	1B	1C
E	E	F	10	11	12	13	14	15	16	17	18	19	1A	1B	1C	1D
F	F	10	11	12	13	14	15	16	17	18	19	1A	1B	1C	1D	1E

X

Z

Y

Use the addition table and follow the solution of the following problems:

$$\begin{array}{rl} 456_{16} & \text{Augend} \\ +\ \underline{784}_{16} & \text{Addend} \\ \text{BDA}_{16} & \text{Sum} \end{array}$$

In this example each column is straight addition with no carry.

Now add the addend (784_{16}) and the sum (BDA_{16}) of the previous problem:

$$\begin{array}{rl} 1\ \ 1\quad\ \ & \text{Carry} \\ 784_{16} & \text{Augend} \\ +\downarrow \text{BDA}_{16} & \text{Addend} \\ \hline 1\,3\,5\,\text{E}_{16} & \text{Sum} \end{array}$$

Here the sum of 4 and A is E. Adding 8 and D is 15_{16}; write down 5 and carry a 1. Add the first carry to the 7 in the next column and add the sum, 8, to B. The result is 13_{16}; write down 3 and carry a 1. Since only the last carry is left to add, bring it down to complete the problem.

Now observe the procedures for a more complex addition problem. You may find it easier to add the Arabic numerals in each column first:

$$
\begin{array}{rl}
{}^{1\,1\,1} & \text{Carry} \\
C14_{16} & \text{Augend} \\
19E_{16} & \text{Addend} \\
571_{16} & \text{Addend} \\
+\quad BB3_{16} & \text{Addend} \\
\hline
1ED6_{16} & \text{Sum}
\end{array}
$$

The sum of 4, E, 1, and 3 in the first column is 16_{16}. Write down the 6 and the carry. In the second column, 1, 1, 9, and 7 equals 12_{16}. Write the carry over the next column. Add B and 2 — the sum is D. Write this in the sum line. Now add the final column, 1, 1, 5, and C. The sum is 13_{16}. Write down the carry; then add 3 and B — the sum is E. Write down the E and bring down the final carry to complete the problem.

Now solve the following addition problems:

Q36. Add:

$$
\begin{array}{r}
4A3C_{16} \\
+\quad 93\,5\,1_{16} \\
\hline
\end{array}
$$

Q37. Add:

$$
\begin{array}{r}
4321_{16} \\
+\quad DCBA_{16} \\
\hline
\end{array}
$$

Q38. Add:

$$
\begin{array}{r}
274_{16} \\
+\quad FEB_{16} \\
\hline
\end{array}
$$

Q39. Add:

$$
\begin{array}{r}
79DF_{16} \\
+\quad A641_{16} \\
\hline
\end{array}
$$

Q40. Add:

$$
\begin{array}{r}
ECFD_{16} \\
+\quad A4AE_{16} \\
\hline
\end{array}
$$

Q41. Add:

$$\begin{array}{r} BC_{16} \\ A23_{16} \\ +\ \ FC9_{16} \\ \hline \end{array}$$

Subtraction of Hex Numbers

The subtraction of hex numbers looks more difficult than it really is. In the preceding sections you learned all the rules for subtraction. Now you need only to apply those rules to a new number system. The symbols may be different and the amount of the borrow is different, but the rules remain the same.

Use the hex addition table (table 1-6) to follow the solution of the following problems:

$$\begin{array}{rl} ABC_{16} & \text{Minuend} \\ -\ \ 642_{16} & \text{Subtrahend} \\ \hline \end{array}$$

Working from left to right, first locate the subtrahend (2) in column Y. Follow this line across area Z until you reach C. The difference is located in column X directly above the C — in this case A. Use this same procedure to reach the solution:

$$\begin{array}{rl} ABC_{16} & \text{Minuend} \\ -\ \ 642_{16} & \text{Subtrahend} \\ \hline 47A_{16} & \text{Difference} \end{array}$$

Now examine the following solutions:

$$\begin{array}{rl} 7E5E_{16} & \text{Minuend} \\ -\ \ 471_{16} & \text{Subtrahend} \\ \hline 3744_{16} & \text{Difference} \end{array}$$

$$\begin{array}{rl} 1E9C4_{16} & \text{Minuend} \\ -\ \ F4A1_{16} & \text{Subtrahend} \\ \hline F523_{16} & \text{Difference} \end{array}$$

In the previous example, when F was subtracted from 1E, a borrow was used. Since you cannot subtract F from E and have a positive difference, a borrow of 10_{16} was taken from the next higher value column. The borrow was added to E, and the higher value column was reduced by 1.

The following example shows the use of the borrow in a more difficult problem:

$$
\begin{array}{rccccl}
 & & & & 10_{16} & \text{Borrow} \\
 & & & 2 & & \text{Minuend reduced by 1} \\
 & 4 & A & \cancel{3} & 7_{16} & \text{Minuend} \\
- & 2 & C & 4 & B_{16} & \text{Subtrahend} \\
\hline
 & & & & C_{16} & \text{Difference}
\end{array}
$$

In this first step, B cannot be subtracted from 7, so you take a borrow of 10_{16} from the next higher value column. Add the borrow to the 7 in the minuend; then subtract (17_{16} minus B_{16} equals C_{16}). Reduce the number from which the borrow was taken (3) by 1.

To subtract 4_{16} from 2_{16} also requires a borrow, as shown below:

$$
\begin{array}{rccccl}
 & & & 10_{16} & 10_{16} & \text{Borrow} \\
 & & 9 & 2 & & \text{Minuend reduced by 1} \\
 & 4 & \cancel{A} & \cancel{3} & 7_{16} & \text{Minuend} \\
- & 2 & C & 4 & B_{16} & \text{Subtrahend} \\
\hline
 & & & E & C_{16} & \text{Difference}
\end{array}
$$

Borrow 10_{16} from the A and reduce the minuend by 1. Add the borrow to the 2 and subtract 4_{16} from 12_{16}. The difference is E.

When solved the problem looks like this:

$$
\begin{array}{rccccl}
 & & 10 & 10 & 10 & \text{Borrow (Base 16)} \\
 & 3 & 9 & 2 & & \text{Minuend reduced by 1} \\
 & \cancel{4} & \cancel{A} & \cancel{3} & 7_{16} & \text{Minuend} \\
- & 2 & C & 4 & B_{16} & \text{Subtrahend} \\
\hline
 & 1 & D & E & C_{16} & \text{Difference}
\end{array}
$$

Remember that the borrow is 10_{16} not 10_{10}.

There may be times when you need to borrow from a column that has a 0 in the minuend. In that case, you borrow from the next highest value column, which will provide you with a value in the 0 column that you can borrow from.

$$
\begin{array}{rcccl}
 & & F & & \text{Borrow reduced by 1} \\
 & & \cancel{10} & 10 & \text{Borrow (Base 16)} \\
 & 1 & & & \text{Minuend reduced by 1} \\
 & \cancel{2} & 0 & 7_{16} & \text{Minuend} \\
- & & & A_{16} & \text{Subtrahend} \\
\hline
 & 1 & F & D_{16} & \text{Difference}
\end{array}
$$

To subtract A from 7, you must borrow. To borrow you must first borrow from the 2. The 0 becomes 10_{16}, which can give up a borrow. Reduce the 10_{16} by 1 to provide a borrow for the 7. Reducing 10_{16} by 1 equals F. Subtracting A_{16} from 17_{16} gives you D_{16}. Bring down the 1 and F for a difference of $1FD_{16}$.

Now let's practice what we've learned by solving the following hex subtraction problems:

Q42. *Subtract:*

$$\begin{array}{r} 758_{16} \\ \underline{-\ 423}_{16} \end{array}$$

Q43. *Subtract:*

$$\begin{array}{r} D9F_{16} \\ \underline{-\ 46A}_{16} \end{array}$$

Q44. *Subtract:*

$$\begin{array}{r} A1C6_{16} \\ \underline{+\ \ C95_{16}} \end{array}$$

Q45. *Subtract:*

$$\begin{array}{r} 4057_{16} \\ \underline{-\ 9A4}_{16} \end{array}$$

Q46. *Subtract:*

$$\begin{array}{r} 13579_{16} \\ \underline{-\ 2ABD}_{16} \end{array}$$

Q47. *Subtract:*

$$\begin{array}{r} EFACD_{16} \\ \underline{-\ ACBBE}_{16} \end{array}$$

CONVERSION OF BASES

We mentioned in the introduction to this chapter that digital computers operate on electrical pulses. These pulses or the absence of, are easily represented by binary numbers. A pulse can represent a binary 1, and the lack of a pulse can represent a binary 0 or vice versa.

The sections of this chapter that discussed octal and hex numbers both mentioned that their number systems were beneficial to programmers. You will see later in this section that octal and hex numbers are easily converted to binary numbers and vice versa..

If you are going to work with computers, there will be many times when it will be necessary to convert decimal numbers to binary, octal, and hex numbers. You will also have to be able to convert binary, octal, and hex numbers to decimal numbers. Converting each number system to each of the others will be explained. This will prepare you for converting from any base to any other base when needed.

DECIMAL CONVERSION

Some computer systems have the capability to convert decimal numbers to binary numbers. They do this by using additional circuitry. Many of these systems require that the decimal numbers be converted to another form before entry.

Decimal to Binary

Conversion of a decimal number to any other base is accomplished by dividing the decimal number by the radix of the system you are converting to. The following definitions identify the basic terms used in division:

- DIVIDEND—The number to be divided
- DIVISOR—The number by which a dividend is divided
- QUOTIENT—The number resulting from the division of one number by another
- REMAINDER—The final undivided part after division that is less or of a lower degree than the divisor

To convert a base 10 whole number to its binary equivalent, first set up the problem for division:

$$2\overline{)5_{10}}$$

Step 1—Divide the base 10 number by the radix (2) of the binary system and extract the remainder (this becomes the binary number's LSD).

$$\begin{array}{rrl} & 2 & \text{Quotient} \\ \text{Divisor} & 2\overline{)5_{10}} & \\ & \underline{4} & \\ & 1 & \text{Remainder} \longrightarrow 1 \end{array}$$

Step 2—Continue the division by dividing the quotient of step 1 by the radix (2 x 2).

$$\begin{array}{rl} 1 & \text{(Quotient from step 1)} \\ 2\overline{)2} & \\ \underline{2} & \\ 0 & \text{Remainder} \longrightarrow 0 \end{array}$$

Step 3—Continue dividing quotients by the radix until the quotient becomes smaller that the divisor; then do one more division. The remainder is our MSD.

$$\begin{array}{r} 0 \\ 2\overline{)1} \\ \underline{0} \\ 1 \end{array} \quad \begin{array}{l} \text{(Quotient from step 2)} \\ \\ \\ \text{Remainder} \longrightarrow 1 \end{array}$$

The remainder in step 1 is our LSD. Now rewrite the solution, and you will see that 5_{10} equals 101_2. Now follow the conversion of 23_{10} to binary:

Step 1—Set up the problem for division:

$$2\overline{)23_{10}}$$

Step 2—Divide the number and extract the remainder:

$$\begin{array}{r} 11 \\ 2\overline{)23} \\ \underline{2} \\ 03 \\ \underline{2} \\ 1 \end{array} \quad \text{Remainder} \longrightarrow 1 \text{ (LSD)}$$

$$\begin{array}{r} 5 \\ 2\overline{)11} \\ \underline{10} \\ 1 \end{array} \quad \begin{array}{l} \text{(Quotient from previous step)} \\ \\ \text{Remainder} \longrightarrow 1 \end{array}$$

$$\begin{array}{r} 2 \\ 2\overline{)5} \\ \underline{4} \\ 1 \end{array} \quad \begin{array}{l} \text{(Quotient from previous step)} \\ \\ \text{Remainder} \longrightarrow 1 \end{array}$$

$$\begin{array}{r} 1 \\ 2\overline{)2} \\ \underline{2} \\ 0 \end{array} \quad \begin{array}{l} \text{(Quotient from previous step)} \\ \\ \text{Remainder} \longrightarrow 0 \end{array}$$

$$\begin{array}{r} 0 \\ 2\overline{)1} \\ \underline{0} \\ 1 \end{array} \quad \begin{array}{l} \text{(Quotient from previous step)} \\ \\ \text{Remainder} \longrightarrow 1 \text{ (MSD)} \end{array}$$

Step 3—Rewrite the solution from MSD to LSD:

$$10111_2$$

No matter how large the decimal number may be, we use the same procedure. Let's try the problem below. It has a larger dividend:

$$\begin{array}{r} 52 \\ 2\overline{)105} \\ \underline{10} \\ 05 \\ \underline{4} \\ 1 \end{array} \longrightarrow 1 \text{ (LSD)}$$

$$\begin{array}{r} 26 \\ 2\overline{)52} \\ \underline{4} \\ 12 \\ \underline{12} \\ 0 \end{array} \longrightarrow 0$$

$$\begin{array}{r} 13 \\ 2\overline{)26} \\ \underline{2} \\ 06 \\ \underline{6} \\ 0 \end{array} \longrightarrow 0$$

$$\begin{array}{r} 6 \\ 2\overline{)13} \\ \underline{12} \\ 1 \end{array} \longrightarrow 1$$

$$\begin{array}{r} 3 \\ 2\overline{)6} \\ \underline{6} \\ 0 \end{array} \longrightarrow 0$$

$$\begin{array}{r} 1 \\ 2\overline{)3} \\ \underline{2} \\ 1 \end{array} \longrightarrow 1$$

$$\begin{array}{r} 0 \\ 2\overline{)1} \\ \underline{0} \\ 1 \end{array} \longrightarrow 1 \text{ (MSD)}$$

105_{10} equals 1101001_2

We can convert fractional decimal numbers by multiplying the fraction by the radix and extracting the portion of the product to the *left* of the radix point. Continue to multiply the fractional portion of the previous product until the desired degree of accuracy is attained.

Let's go through this process and convert 0.25_{10} to its binary equivalent:

$$
\begin{array}{rcccr}
 & & & & .25_{10} \\
 & & & & \underline{\times \quad 2} \\
\text{MSD} & \longleftarrow & 0 & \longleftarrow & 0.50 \\
 & & & & \underline{\times \quad 2} \\
\text{LSD} & \longleftarrow & 1 & \longleftarrow & 1.00
\end{array}
$$

The *first* figure to the left of the radix point is the MSD, and the last figure of the computation is the LSD. Rewrite the solution from MSD to LSD preceded by the radix point as shown:

$$.01_2$$

Now try converting $.625_{10}$ to binary:

$$
\begin{array}{rcccr}
 & & & & .625 \\
 & & & & \underline{\times \quad 2} \\
\text{MSD} & \longleftarrow & 1 & \longleftarrow & 1.250 \\
 & & & & \underline{\times \quad 2} \\
 & & 0 & \longleftarrow & 0.500 \\
 & & & & \underline{\times \quad 2} \\
\text{LSD} & \longleftarrow & 1 & \longleftarrow & 1.000 \\
 & & & & \underline{\times \quad 2} \\
 & & & & 0.000
\end{array}
$$

$$.625_{10} \text{ equals } .101_2$$

As we mentioned before, you should continue the operations until you reach the desired accuracy. For example, convert $.425_{10}$ to five places in the binary system:

$$
\begin{array}{rcccr}
 & & & & .425 \\
 & & & & \underline{\times \quad 2} \\
\text{MSD} & \longleftarrow & 0 & \longleftarrow & 0.850 \\
 & & & & \underline{\times \quad 2} \\
 & & 1 & \longleftarrow & 1.700 \\
 & & & & \underline{\times \quad 2} \\
 & & 1 & \longleftarrow & 1.400 \\
 & & & & \underline{\times \quad 2} \\
 & & 0 & \longleftarrow & 0.800 \\
 & & & & \underline{\times \quad 2} \\
 & & 1 & \longleftarrow & 1.600 \\
 & & & & \underline{\times \quad 2} \\
 & & 1 & \longleftarrow & 1.200 \\
 & & & & \underline{\times \quad 2} \\
\text{LSD} & \longleftarrow & 0 & \longleftarrow & 0.400
\end{array}
$$

Although the multiplication was carried out for seven places, you would only use what is required. Write out the solution as shown:

$$.01101_2$$

To convert a mixed number such as 37.625_{10} to binary, split the number into its whole and fractional components and solve each one separately. In this problem carry the fractional part to four places. When the conversion of each is completed, recombine it with the radix point as shown below:

$$37_{10} = 100101_2$$

$$.625_{10} = .1010_2$$

$$37.625_{10} = 100101.1010_2$$

Convert the following decimal numbers to binary:

Q48. 72_{10}.

Q49. 97_{10}.

Q50. 243_{10}.

Q51. 0.875_{10} *(four places).*

Q52. 0.33_{10} *(four places).*

Q53. 17.42_{10} *(five places)*

Decimal to Octal

The conversion of a decimal number to its base 8 equivalent is done by the repeated division method. You simply divide the base 10 number by 8 and extract the remainders. The first remainder will be the LSD, and the last remainder will be the MSD.

Look at the following example. To convert 15_{10} to octal, set up the problem for division:

$$8\overline{)15_{10}}$$

Since 8 goes into 15 one time with a 7 remainder, 7 then is the LSD. Next divide 8 into the quotient (1). The result is a 0 quotient with a 1 remainder. The 1 is the MSD:

$$\begin{array}{l} \quad 1 \\ 8\overline{)15_{10}} \\ \quad \underline{8} \\ \quad 7 \longrightarrow 7\ \text{(LSD)} \\ \quad 0 \\ 8\overline{)1} \\ \quad \underline{0} \\ \quad 1 \longrightarrow 1\ \text{(MSD)} \end{array}$$

Now write out the number from MSD to LSD as shown:

$$17_8$$

The same process is used regardless of the size of the decimal number. Naturally, more divisions are needed for larger numbers, as in the following example:

Convert 264_{10} to octal:

$$\begin{array}{l} \quad\ \ 33 \\ 8\overline{)264_{10}} \\ \quad \underline{24} \\ \quad\ \ 24 \\ \quad\ \ \underline{24} \\ \quad\quad 0 \longrightarrow 0 \text{ (LSD)} \end{array}$$

$$\begin{array}{l} \quad\ \ 4 \\ 8\overline{)33} \\ \quad \underline{32} \\ \quad\ \ 1 \longrightarrow 1 \end{array}$$

$$\begin{array}{l} \quad 0 \\ 8\overline{)4} \\ \quad \underline{0} \\ \quad 4 \longrightarrow 4 \text{ (MSD)} \end{array}$$

By rewriting the solution, you find that the octal equivalent of 264_{10} is as follows:

$$410_8$$

To convert a decimal fraction to octal, *multiply* the fraction by 8. Extract everything that appears to the left of the radix point. The first number extracted will be the MSD and will follow the radix point. The last number extracted will be the LSD.

Convert 0.05_{10} to octal:

$$\begin{array}{rcrcr} & & & & .05 \\ & & & & \underline{\times \quad 8} \\ \text{MSD} & \longleftarrow & 0 & \longleftarrow & 0.40 \\ & & & & \underline{\times \quad 8} \\ & & 3 & \longleftarrow & 3.20 \\ & & & & \underline{\times \quad 8} \\ & & 1 & \longleftarrow & 1.60 \\ & & & & \underline{\times \quad 8} \\ & & 4 & \longleftarrow & 4.80 \\ & & & & \underline{\times \quad 8} \\ \text{LSD} & \longleftarrow & 6 & \longleftarrow & 6.40 \end{array}$$

Write the solution from MSD to LSD:

$$.03146_8$$

You can carry the conversion out to as many places as needed, but usually four or five places are enough.

To convert a mixed decimal number to its octal equivalent, split the number into whole and fractional portions and solve as shown below:

Convert 105.589_{10} to octal:

$$\begin{array}{r} 13 \\ 8\overline{)105} \\ \underline{8} \\ 25 \\ \underline{24} \\ 1 \end{array} \longrightarrow 1 \text{ (LSD)}$$

$$\begin{array}{r} 1 \\ 8\overline{)13} \\ \underline{8} \\ 5 \end{array} \longrightarrow 5$$

$$\begin{array}{r} 0 \\ 8\overline{)1} \\ \underline{0} \\ 1 \end{array} \longrightarrow 1 \text{ (MSD)}$$

$$\begin{array}{rcrcr} & & & & 0.589 \\ & & & & \underline{\times \quad 8} \\ \text{MSD} & \longleftarrow & 4 & \longleftarrow & 4.712 \\ & & & & \underline{\times \quad 8} \\ & & 5 & \longleftarrow & 5.696 \\ & & & & \underline{\times \quad 8} \\ & & 5 & \longleftarrow & 5.568 \\ & & & & \underline{\times \quad 8} \\ \text{LSD} & \longleftarrow & 4 & \longleftarrow & 4.544 \end{array}$$

Combine the portions into a mixed number:

$$151.4554_8$$

Convert the following decimal numbers to octal:

Q54. 7_{10}

Q55. 43_{10}

Q56. 499_{10}

Q57. 0.951_{10} *(four places).*

Q58. 0.004_{10} *(five places).*

Q59. 252.17_{10} *(three places).*

Decimal to Hex

To convert a decimal number to base 16, follow the repeated division procedures you used to convert to binary and octal, only divide by 16. Let's look at an example:

Convert 63_{10} to hex:

$$\begin{array}{r l}
 & 3 \\
16 & \overline{)63_{10}} \\
 & \underline{48} \\
 & 15_{10} \longrightarrow F_{16} \longrightarrow \text{LSD}
\end{array}$$

$$\begin{array}{r l}
 & 0 \\
16 & \overline{)3} \\
 & \underline{0} \\
 & 3 \longrightarrow 3_{16} \longrightarrow \text{MSD}
\end{array}$$

Therefore, the hex equivalent of 63_{10} is $3F_{16}$.

You have to remember that the remainder is in base 10 and must be converted to hex if it exceeds 9. Let's work through another example:

Convert 174_{10} to hex:

$$\begin{array}{r l}
 & 10 \\
16 & \overline{)174} \\
 & \underline{16} \\
 & 14 \\
 & \underline{0} \\
 & 14_{10} \longrightarrow E_{16} \longrightarrow \text{LSD}
\end{array}$$

$$\begin{array}{r l}
 & 0 \\
16 & \overline{)10} \\
 & \underline{0} \\
 & 10_{10} \longrightarrow A_{16} \longrightarrow \text{MSD}
\end{array}$$

Write the solution from MSD to LSD:

$$AE_{16}$$

There will probably be very few times when you will have to convert a decimal fraction to a hex fraction. If the occasion should arise, the conversion is done in the same manner as binary or octal. Use the following example as a pattern:

Convert 0.695_{10} to hex:

$$
\begin{array}{rcccr}
 & & & & .695 \\
 & & & & \underline{\times \quad 16} \\
 & & & & 4.170 \\
 & & & & \underline{6.950} \\
\text{MSD} & \longleftarrow & B_{16} & \longleftarrow & 11.120 \\
 & & & & \underline{\times \quad 16} \\
 & & & & .720 \\
 & & & & \underline{1.200} \\
 & & 1_{16} & \longleftarrow & 1.920 \\
 & & & & \underline{\times \quad 16} \\
 & & & & 5.520 \\
 & & & & \underline{9.200} \\
 & & E_{16} & \longleftarrow & 14.720 \\
 & & & & \underline{\times \quad 16} \\
 & & & & 4.320 \\
 & & & & \underline{7.200} \\
\text{LSD} & \longleftarrow & B_{16} & \longleftarrow & 11.520
\end{array}
$$

The solution: $.B1EB_{16}$

Should you have the need to convert a decimal mixed number to hex, convert the whole number and the fraction separately; then recombine for the solution.

Convert the following decimal numbers to hex:

Q60. 42_{10}.

Q61. 83_{10}.

Q62. 176_{10}.

Q63. 491_{10}.

Q64. 0.721_{10} *(four places).*

The converting of binary, octal, and hex numbers to their decimal equivalents is covered as a group later in this section.

BINARY CONVERSION

Earlier in this chapter, we mentioned that the octal and hex number systems are useful to computer programmers. It is much easier to provide data to a computer in one or the other of these systems. Likewise, it is important to be able to convert data from the computer into one or the other number systems for ease of understanding the data.

Binary to Octal

Look at the following numbers:

$$10111001001101_2$$

$$27115_8$$

You can easily see that the octal number is much easier to say. Although the two numbers look completely different, they are equal.

Since 8 is equal to 2^3, then one octal digit can represent three binary digits, as shown below:

$$0_8 = 000_2$$
$$1_8 = 001_2$$
$$2_8 = 010_2$$
$$3_8 = 011_2$$
$$4_8 = 100_2$$
$$5_8 = 101_2$$
$$6_8 = 110_2$$
$$7_8 = 111_2$$

With the use of this principle, the conversion of a binary number is quite simple. As an example, follow the conversion of the binary number at the beginning of this section.

Write out the binary number to be converted. Starting at the radix point and moving left, break the binary number into groups of three as shown. This grouping of binary numbers into groups of three is called binary-coded octal (BCO). Add 0s to the left of any MSD that will fill a group of three:

$$010\ 111\ 001\ 001\ 101 \bullet_2$$

Radix Point

Next, write down the octal equivalent of each group:

010	111	001	001	$101._2$
2	7	1	1	$5._8$

To convert a binary fraction to its octal equivalent, starting at the radix point and moving right, expand each digit into a group of three:

$$\bullet\ 100\ 001\ 110\ 011_2$$

Radix Point

Add 0s to the right of the LSD if necessary to form a group of three. Now write the octal digit for each group of three, as shown below:

.100	001	110	$011._2$
.4	1	6	3_8

To convert a mixed binary number, starting at the radix point, form groups of three both right and left:

101	101	100.	001	$110._2$
5	5	4.	1	6_8

Radix Point

Convert the following binary numbers to octal:

Q65. 10_2.

Q66. 1010_2.

Q67. 101111_2.

Q68. 0.0011_2.

Q69. 0.110011_2.

Q70. 110111.010101_2.

Binary to Hex

The table below shows the relationship between binary and hex numbers. You can see that four binary digits may be represented by one hex digit. This is because 16 is equal to 2^4.

HEX		BINARY
0	=	0000
1	=	0001
2	=	0010
3	=	0011
4	=	0100
5	=	0101
6	=	0110
7	=	0111
8	=	1000
9	=	1001
A	=	1010
B	=	1011
C	=	1100
D	=	1101
E	=	1110
F	=	1111

Using this relationship, you can easily convert binary numbers to hex. Starting at the radix point and moving either right or left, break the number into groups of four. The grouping of binary into four bit groups is called binary-coded hexadecimal (BCH).

Convert 111010011_2 to hex:

0001	1101	$0011._2$
1	D	$3._{16}$

Radix Point

Add 0s to the left of the MSD of the whole portion of the number and to the right of the LSD of the fractional part to form a group of four.

Convert $.111_2$ to hex:

$$\frac{.1110_2}{.E_{16}}$$

In this case, if a 0 had not been added, the conversion would have been $.7_{16}$, which is incorrect.

Convert the following binary numbers to hex:

Q71. 10_2.

Q72. 1011_2.

Q73. 101111_2.

Q74. 0.0011_2.

Q75. 0.110011_2.

Q76. 110111.010101$_2$.

OCTAL CONVERSION

The conversion of one number system to another, as we explained earlier, is done to simplify computer programming or interpreting of data.

Octal to Binary

For some computers to accept octal data, the octal digits must be converted to binary. This process is the reverse of binary to octal conversion.

To convert a given octal number to binary, write out the octal number in the following format. We will convert octal 567_8:

5	6	7_8

Next, below each octal digit write the corresponding three-digit binary-coded octal equivalent:

5	6	7_8
101	110	111_2

Solution: 567_8 equals 101 110 111_2

Remove the conversion from the format:

101110111_2

As you gain experience, it may not be necessary to use the block format.

An octal fraction ($.123_8$) is converted in the same manner, as shown below:

.1	2	3
.001	010	011_2

Solution: $.123_8$ equals $.001010011_2$

Apply these principles to convert mixed numbers as well.

Convert 32.25_8 to binary:

3	2.	2	5_8
011	010.	010	101_2

Solution: 32.25_8 equals 011010.010101_2

Convert the following numbers to binary:

Q77. 73_8

Q78. 512_8

Q79. 403_8

Q80. 0.456_8

Q81. 0.73_8

Q82. 36.5_8

Octal to Hex

You will probably not run into many occasions that call for the conversion of octal numbers to hex. Should the need arise, conversion is a two-step procedure. Convert the octal number to binary; then convert the binary number to hex. The steps to convert 53.7_8 to hex are shown below:

5	3 .	7_8
101	011.	111_2

Regroup the binary digits into groups of four and add zeros where needed to complete groups; then convert the binary to hex.

0010	1011.	1110_2
2	B .	E_{16}

Solution: 53.7_8 equals $2B.E_{16}$

Convert the following numbers to hex:

Q83. 74_8

Q84. 512_8

Q85. 0.03_8

Q86. 14.42_8

HEX CONVERSION

The procedures for converting hex numbers to binary and octal are the reverse of the binary and octal conversions to hex.

Hex to Binary

To convert a hex number to binary, set up the number in the block format you used in earlier conversions. Below each hex digit, write the four-digit binary equivalent. Observe the following example:

Convert ABC_{16} to binary:

A	B	C_{16}
1010	1011	1100_2

Solution: $ABC_{16} = 101010111100_2$

Hex to Octal

Just like the conversion of octal to hex, conversion of hex to octal is a two-step procedure. First, convert the hex number to binary; and second, convert the binary number to octal. Let's use the same example we used above in the hex to binary conversion and convert it to octal:

A	B	C_{16}
1010	1011	1100_2

101	010	111	100_2
5	2	7	4_8

Convert these base 16 numbers to their equivalent base 2 and base 8 numbers:

Q87. 23_{16}

Q88. $1B_{16}$

Q89. $0.E4_{16}$

Q90. $45.A_{16}$

CONVERSION TO DECIMAL

Computer data will have little meaning to you if you are not familiar with the various number systems. It is often necessary to convert those binary, octal, or hex numbers to decimal numbers. The need for understanding is better illustrated by showing you a paycheck printed in binary. A check in the amount of $\$10,010,101.00_2$ looks impressive but in reality only amounts to $\$149.00_{10}$

Binary to Decimal

The computer that calculates your pay probably operates with binary numbers, so a conversion takes place in the computer before the amount is printed on your check. Some computers, however, don't automatically convert from binary to decimal. There may be times when you must convert mathematically.

To convert a base 2 number to base 10, you must know the decimal equivalent of each power of 2. The decimal value of a power of 2 is obtained by multiplying 2 by itself the number of times indicated by the exponent for whole numbers; for example, $2^4 = 2 \times 2 \times 2 \times 2$ or 16_{10}.

For fractional numbers, the decimal value is equal to 1 divided by 2 multiplied by itself the number of times indicated by the exponent. Look at this example:

$$2^{-3} = \frac{1}{2 \times 2 \times 2} \text{ or } .125_{10}$$

The table below shows a portion of the positions and decimal values of the binary system:

Radix Point

2^5	2^4	2^3	2^2	2^1	2^0	•	2^{-1}	2^{-2}	2^{-3}
32	16	8	4	2	1	•	.5	.25	.125

Remember, earlier in this chapter you learned that any number to the 0 power is equal to 1_{10}.

Another method of determining the decimal value of a position is to multiply the preceding value by 2 for whole numbers and to divide the preceding value by 2 for fractional numbers, as shown below:

Radix Point

2^5	2^4	2^3	2^2	2^1	2^0	•	2^{-1}	2^{-2}	2^{-3}	2^{-4}
32	16	8	4	2	1	•	.5	.25	.125	.0625

MULTIPLY BY 2 DIVIDE BY 2

Let's convert a binary number to decimal by using the positional notation method. First, write out the number to be converted; then, write in the decimal equivalent for each position with a 1 indicated. Add these values to determine the decimal equivalent of the binary number. Look at our example:

Problem: $\underline{1 \quad 0 \quad 1 \quad 0 \quad 0 \quad 1_2}$
Decimal: 32 8 1
Value:

$$\begin{array}{r} 1 \\ 8 \\ +\,32 \\ \hline 41_{10} \end{array}$$

You may want to write the decimal equivalent for each position as we did in the following example. Add only the values indicated by a 1.

Problem: $\underline{1 \quad 0 \quad 1 \quad 1 \quad 0. \quad 0 \quad 1_2}$
Decimal: 16 8 4 2 1. .5 .25
Value:

$$\begin{array}{r} .25 \\ 2. \\ 4. \\ +\,16. \\ \hline 22.25_{10} \end{array}$$

You should make sure that the decimal values for each position are properly aligned before adding. For practice let's convert these binary numbers to decimal:

Q91. 10010_2

Q92. 1111100_2

Q93. 1010101_2

Q94. 0.0101_2

Q95. 0.1010_2

Q96. 1101101.1111_2

Octal to Decimal

Conversion of octal numbers to decimal is best done by the positional notation method. This process is the one we used to convert binary numbers to decimal.

First, determine the decimal equivalent for each position by multiplying 8 by itself the number of times indicated by the exponent. Set up a bar graph of the positions and values as shown below:

Positional Notation:	8^4	8^3	8^2	8^1	$8^0_.$	8^{-1}	8^{-2}	8^{-3}
Decimal Equivalent:	4096	512	64	8	1.	.125	.015625	.0019531

To convert an octal number to decimal, write out the number to be converted, placing each digit under the proper position.

Example:

4096	512	64	8	1
		7	4	3_8

Next, multiply the decimal equivalent by the corresponding digit of the octal number; then, add this column of figures for the final solution:

4096	512	64	8	1
		×7	×4	×3

$$\begin{array}{r} 3 \\ 32 \\ +\ 448 \\ \hline 483_{10} \end{array}$$

Solution: 743_8 is equal to 483_{10}

Now follow the conversion of 26525_8 to decimal:

4096	512	64	8	1
×2	×6	×5	×2	×5

$$\begin{array}{r} 5 \\ 16 \\ 320 \\ 3072 \\ 8192 \\ \hline 11605_{10} \end{array}$$

Solution: $11{,}605_{10}$ is the decimal equivalent of $26{,}525_8$

To convert a fraction or a mixed number, simply use the same procedure.

Example: Change $.5_8$ to decimal:

$$\begin{array}{r} .125 \\ \hline \times\ 5_8 \end{array} \longrightarrow .625_{10}$$

Example: Convert 24.36_8 to decimal:

$$\begin{array}{ccccc} 64 & 8 & 1. & .125 & .015625 \\ \hline & \times 2 & \times 4. & \times 3 & \times 6 \end{array}$$

$$\begin{array}{r} .09375 \\ .37500 \\ 4.00000 \\ +16.00000 \\ \hline 20.46875_{10} \end{array}$$

Solution: 24.36_8 equals 20.46875_{10}

If your prefer or find it easier, you may want to convert the octal number to binary and then to decimal.

Convert the following numbers to decimal:

Q97. 17_8

Q98. 64_8

Q99. 375_8

Q100. 0.4_8

Q101. 0.61_8

Q102. 10.22_8

Hex to Decimal

It is difficult to comprehend the magnitude of a base 16 number until it is presented in base 10; for instance, $E0_{16}$ is equal to 224_{10}. You must remember that usually fewer digits are necessary to represent a decimal value in base 16.

When you convert from base 16 to decimal, you may use the positional notation system for the powers of 16 (a bar graph). You can also convert the base 16 number to binary and then convert to base 10.

Note in the bar graph below that each power of 16 results in a tremendous increase in the decimal equivalent. Only one negative power (16^{-1}) is shown for demonstration purposes:

Radix Point

Positional Notation:	16^4	16^3	16^2	16^1	$16^0.$	16^{-1}
Decimal Equivalent:	65.536	4.096	256	16	1.	.0625

Just as you did with octal conversion, write out the hex number, placing each digit under the appropriate decimal value for that position. Multiply the decimal value by the base 16 digit and add the values. (Convert A through F to their decimal equivalent before multiplying). Let's take a look at an example.

Convert $2C_{16}$ to decimal:

4096 256 16 1.

×2 ×C

(12)

12
+32
44_{10}

The decimal equivalent of $2C_{16}$ is 44_{10}.

Use the same procedure we used with binary and octal to convert base 16 fractions to decimal.

If you choose to convert the hex number to binary and then to decimal, the solution will look like this:

2 C_{16}

× 0010 × 1100_2

4
8
+32
44_{10}

Convert these base 16 numbers to base 10:

Q103. 24_{16}

Q104. $A5_{16}$

Q105. DB_{16}

Q106. $3E6.5_{16}$

BINARY-CODED DECIMAL

In today's technology, you hear a great deal about microprocessors. A microprocessor is an integrated circuit designed for two purposes: data processing and control.

Computers and microprocessors both operate on a series of electrical pulses called words. A word can be represented by a binary number such as 10110011_2. The word length is described by the number of digits or BITS in the series. A series of four digits would be called a 4-bit word and so forth. The most common are 4-, 8-, and 16-bit words. Quite often, these words must use binary-coded decimal inputs.

Binary-coded decimal, or BCD, is a method of using binary digits to represent the decimal digits 0 through 9. A decimal digit is represented by four binary digits, as shown below:

BCD		Decimal
0000	=	0
0001	=	1
0010	=	2
0011	=	3
0100	=	4
0101	=	5
0110	=	6
0111	=	7
1000	=	8
1001	=	9

You should note in the table above that the BCD coding is the binary equivalent of the decimal digit.

Since many devices use BCD, knowing how to handle this system is important. You must realize that BCD and binary are not the same. For example, 49_{10} in binary is 110001_2, but 49_{10} in BCD is 01001001_{BCD}. Each decimal digit is converted to its binary equivalent.

BCD Conversion

You can see by the above table, conversion of decimal to BCD or BCD to decimal is similar to the conversion of hexadecimal to binary and vice versa.

For example, let's go through the conversion of 264_{10} to BCD. We'll use the block format that you used in earlier conversions. First, write out the decimal number to be converted; then, below each digit write the BCD equivalent of that digit:

2	6	4_{10}
0010	0110	0100_{BCD}

The BCD equivalent of 264_{10} is 001001100100_{BCD}. To convert from BCD to decimal, simply reverse the process as shown:

1001	1000	0011_{BCD}
9	8	3_{10}

BCD Addition

The procedures followed in adding BCD are the same as those used in binary. There is, however, the possibility that addition of BCD values will result in invalid totals. The following example shows this:

Add 9 and 6 in BCD:

$$\begin{array}{lrcr} & 1001_{BCD} & = & 9_{10} \\ & \underline{+\ 0110_{BCD}} & = & 6_{10} \\ \text{INVALID BCD} \longrightarrow & 1111 & & 15_{10} \end{array}$$

The sum 1111_2 is the binary equivalent of 15_{10}; however, 1111 is not a valid BCD number. You cannot exceed 1001 in BCD, so a correction factor must be made. To do this, you add 6_{10} (0110_{BCD}) to the sum of the two numbers. The "add 6" correction factor is added to any BCD group larger than 1001_2. Remember, there is no 1010_2, 1011_2, 1100_2, 1101_2, 1110_2, or 1111_2 in BCD:

$$\begin{array}{rl} 1111 & \longleftarrow \text{INVALID BCD} \\ \underline{0110_{BCD}} & \quad \text{Add } 6_{10} \\ 0001\ 0101 & \longleftarrow \text{New BCD} \end{array}$$

The sum plus the add 6 correction factor can then be converted back to decimal to check the answer. Put any carries that were developed in the add 6 process into a new 4-bit word:

0001	0101_{BCD}
1	5_{10}

Now observe the addition of 60_{10} and 55_{10} in BCD:

$$
\begin{array}{rcl}
60_{10} & = & 0110\ 0000_{BCD} \\
55_{10} & = & \underline{0101\ 0101}_{BCD} \\
 & & 1011\ 0101 \longleftarrow \text{INVALID BCD}
\end{array}
$$

In this case, the higher order group is invalid, but the lower order group is valid. Therefore, the correction factor is added only to the higher order group as shown:

$$
\begin{array}{r}
1011\ 0101 \\
\underline{+\ 0110\ 0000} \\
0001\ 0001\ 0101_{BCD}
\end{array}
\qquad \text{Add } 6_{10}
$$

Convert this total to decimal to check your answer:

$$
\begin{array}{ccc}
0001 & 0001 & 0101_{BCD} \\
\hline
1 & 1 & 5_{10}
\end{array}
$$

Remember that the correction factor is added only to groups that exceed 9_{10} (1001_{BCD}).

Convert the following numbers to BCD and add:

Q107.

$$
\begin{array}{r}
3_{10} \\
\underline{+\ 5_{10}}
\end{array}
$$

Q108.

$$
\begin{array}{r}
1_{10} \\
\underline{+\ 8_{10}}
\end{array}
$$

Q109.

$$
\begin{array}{r}
7_{10} \\
\underline{+\ 4_{10}}
\end{array}
$$

Q110.

$$\begin{array}{r} 14_{10} \\ +\ 8_{10} \\ \hline \end{array}$$

SUMMARY

Now that you've completed this chapter, you should have a basic understanding of number systems. The number systems that were dealt with are used extensively in the microprocessor and computer fields. The following is a summary of the emphasized terms and points found in the "Number Systems" chapter.

The **UNIT** represents a single object.

A **NUMBER** is a symbol used to represent one or more units.

The **RADIX** is the base of a positional number system. It is equal to the number of symbols used in that number system.

A **POSITIONAL NOTATION** is a system in which the value or magnitude of a number is defined not only by its digits or symbol value, but also by its position. Each position represents a power of the radix, or base, and is ranked in ascending or descending order.

$$\begin{array}{ccccccc} 2^2 & 2^1 & 2^0 & & 2^{-1} & 2^{-2} & 2^{-3} \\ 1 & 0 & 1 & \bullet & 0 & 1 & 1_2 \\ & & & \uparrow & & & \\ & & & \text{Radix Point} & & & \end{array}$$

The **MOST SIGNIFICANT DIGIT (MSD)** is a digit within a number (whole or fractional) that has the largest effect (weighing power) on that number.

$$\begin{array}{cccccc} 4 & 7 & 9 & 3 & .0 & {}_{10} \\ \uparrow & & & \uparrow & & \\ \text{MSD} & & & \text{LSD} & & \end{array}$$

$$\begin{array}{cccccc} 0 & .1 & 0 & 6 & 6 & {}_{8} \\ & \uparrow & & & \uparrow & \\ & \text{MSD} & & & \text{LSD} & \end{array}$$

The **LEAST SIGNIFICANT DIGIT (LSD)** is a digit within a number (whole or fractional) that has the least effect (weighting power) on that number.

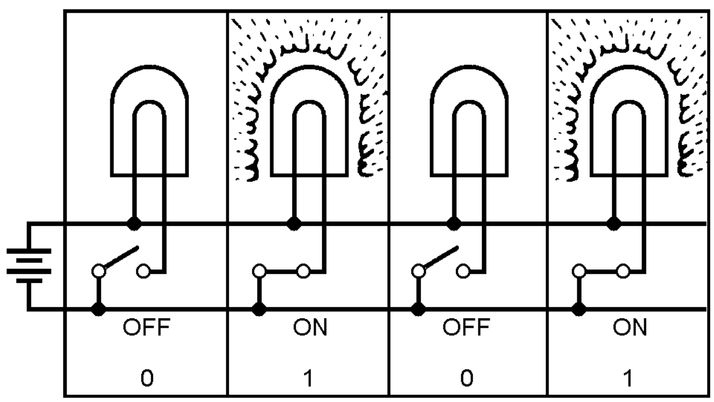
$4\ 3\ A\ F_{16}$

MSD LSD

$.0\ 1\ 0\ 0\ 1\ 1_2$

MSD LSD

The **BINARY NUMBER SYSTEM** is a base 2 system. The symbols 1 and 0 can be used to represent the state of electrical/electronic devices. A binary 1 may indicate the device is active; a 0 may indicate the device is inactive.



The **OCTAL NUMBER SYSTEM** is a base 8 system and is quite useful as a tool in the conversion of binary numbers. This system works because 8 is an integral power of 2; that is, $2^3 = 8$. The use of octal numbers reduces the number of digits required to represent the binary equivalent of a decimal number.

The **HEX NUMBER SYSTEM** is a base 16 system and is sometimes used in computer systems. A binary number can be converted directly to a base 16 number if the binary number is first broken into groups of four digits.

The basic rules of **ADDITION** apply to each of the number systems. Each system becomes unique when carries are produced.

SUBTRACTION in each system is based on certain rules of that number system. The borrow varies in magnitude according to the number system in use. In most computers, subtraction is accomplished by using the complement (R's or R's-1) of the subtrahend and adding it to the minuend.

To **CONVERT A WHOLE BASE 10 NUMBER** to another system, divide the decimal number by the base of the number system to which you are converting. Continue dividing the quotient of the previous division until it can no longer be done. Extract the remainders — the remainder from the first computation will yield the LSD; the last will provide the MSD.

$$\begin{array}{r} 31 \\ 8\overline{)248} \\ \underline{24} \\ 08 \\ \underline{8} \\ 0 \end{array} \longrightarrow 0 \text{ (LSD)}$$

$$\begin{array}{r} 3 \\ 8\overline{)31} \\ \underline{24} \\ 7 \end{array} \longrightarrow 7$$

$$\begin{array}{r} 0 \\ 8\overline{)3} \\ \underline{0} \\ 3 \end{array} \longrightarrow 3 \text{ (MSD)}$$

To **CONVERT DECIMAL FRACTIONS**, multiply the fraction by the base of the desired number system. Extract those digits that move to the left of the radix point. Continue to multiply the fractional product for as many places as needed. The first digit left of the radix point will be the MSD, and the last will be the LSD. The example to the right shows the process of converting 248.32_{10} to the octal equivalent (370.243_8).

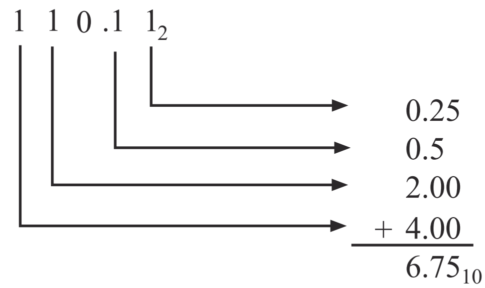
$$\begin{array}{rcr} & & .32 \\ & & \underline{\times \quad 8} \\ \text{(MSD)}\ 2 & \longleftarrow & 2.56 \\ & & \underline{\times \quad 8} \\ 4 & \longleftarrow & 4.48 \\ & & \underline{\times \quad 8} \\ \text{(LSD)}\ 3 & \longleftarrow & 3.84 \end{array}$$

BINARY numbers are converted to **OCTAL** and **HEX** by the grouping method. Three binary digits equal one octal digit; four binary digits equal one hex digit.

$$\underbrace{1\ 0\ 1}_{5} \qquad \underbrace{0\ 1\ 1_2}_{3_8}$$

$$\overbrace{1\ 0\ 1\ 0}^{A} \qquad \overbrace{0\ 1\ 0\ 0_2}^{4_{16}}$$

To **CONVERT** binary, octal, and hex numbers to DECIMAL use the POWERS of the base being converted.



BINARY-CODED DECIMAL (BCD) is a coding system used with some microprocessors. A correction factor is needed to correct invalid numbers

CHAPTER 2

FUNDAMENTAL LOGIC CIRCUITS

LEARNING OBJECTIVES

Upon completing this chapter, you should be able to do the following:

1. Identify general logic conditions, logic states, logic levels, and positive and negative logic as these terms and characteristics apply to the inputs and outputs of fundamental logic circuits.
2. Identify the following logic circuit gates and interpret and solve the associated Truth Tables:
   a. AND
   b. OR
   c. Inverters (NOT circuits)
   d. NAND
   e. NOR
3. Identify variations of the fundamental logic gates and interpret the associated Truth Tables.
4. Determine the output expressions of logic gates in combination.
5. Recognize the laws, theorems, and purposes of Boolean algebra.

INTRODUCTION

In chapter 1 you learned that the two digits of the binary number system can be represented by the state or condition of electrical or electronic devices. A binary 1 can be represented by a switch that is closed, a lamp that is lit, or a transistor that is conducting. Conversely, a binary 0 would be represented by the same devices in the opposite state: the switch open, the lamp off, or the transistor in cut-off.

In this chapter you will study the four basic logic gates that make up the foundation for digital equipment. You will see the types of logic that are used in equipment to accomplish the desired results. This chapter includes an introduction to Boolean algebra, the logic mathematics system used with digital equipment. Certain Boolean expressions are used in explanation of the basic logic gates, and their expressions will be used as each logic gate is introduced.

COMPUTER LOGIC

Logic is defined as the science of reasoning. In other words, it is the development of a reasonable or logical conclusion based on known information.

GENERAL LOGIC

Consider the following example: If it is true that all Navy ships are gray and the USS *Lincoln* is a Navy ship, then you would reach the logical conclusion that the USS *Lincoln* is gray.

To reach a logical conclusion, you must assume the qualifying statement is a condition of truth. For each statement there is also a corresponding false condition. The statement "USS Lincoln is a Navy ship" is true; therefore, the statement "USS *Lincoln* is not a Navy ship" is false. There are no *in-between* conditions.

Computers operate on the principle of logic and use the **TRUE** and **FALSE** logic conditions of a logical statement to make a programmed decision.

The conditions of a statement can be represented by symbols (variables); for instance, the statement "Today is payday" might be represented by the symbol P. If today actually is payday, then P is TRUE. If today is not payday, then P is FALSE. As you can see, a statement has two conditions. In computers, these two conditions are represented by electronic circuits operating in two **LOGIC STATES**. These logic states are 0 (*zero*) and 1 (*one*). Respectively, 0 and 1 represent the FALSE and TRUE conditions of a statement.

When the TRUE and FALSE conditions are converted to electrical signals, they are referred to as **LOGIC LEVELS** called *HIGH* and *LOW*. The 1 state might be represented by the presence of an electrical signal (HIGH), while the 0 state might be represented by the absence of an electrical signal (LOW).

If the statement "Today is payday" is FALSE, then the statement "Today is NOT payday" must be TRUE. This is called the COMPLEMENT of the original statement. In the case of computer math, complement is defined as the opposite or negative form of the original statement or variable. If today were payday, then the statement "Today is not payday" would be FALSE. The complement is shown by placing a bar, or VINCULUM, over the statement symbol (in this case, $\overline{P}$). This variable is spoken as NOT P. Table 2-1 shows this concept and the relationship with logic states and logic levels.

Table 2-1. —Relationship of Digital Logic Concepts and Terms

Example 1: Assume today is payday				
STATEMENT	**SYMBOL**	**CONDITION**	**LOGIC STATE**	**LOGIC LEVEL**
Original: TODAY IS PAYDAY	**P**	**TRUE**	**1**	**HIGH**
Complement: TODAY IS NOT PAYDAY	$\overline{P}$	**FALSE**	**0**	**LOW**
Example 2: Assume today is <u>not</u> payday				
Original: TODAY IS NOT PAYDAY	**P**	**FALSE**	**0**	**LOW**
Complement: TODAY IS NOT PAYDAY	$\overline{P}$	**TRUE**	**1**	**HIGH**

In some cases, more than one variable is used in a single expression. For example, the expression $AB\overline{C}D$ is spoken "A AND B AND NOT C AND D."

POSITIVE AND NEGATIVE LOGIC

To this point, we have been dealing with one type of **LOGIC POLARITY**, positive. Let's further define logic polarity and expand to cover in more detail the differences between positive and negative logic.

Logic polarity is the type of voltage used to represent the logic 1 state of a statement. We have determined that the two logic states can be represented by electrical signals. Any two distinct voltages may be used. For instance, a positive voltage can represent the 1 state, and a negative voltage can represent the 0 state. The opposite is also true.

Logic circuits are generally divided into two broad classes according to their polarity — positive logic and negative logic. The voltage levels used and a statement indicating the use of positive or negative logic will usually be specified on logic diagrams supplied by manufacturers.

In practice, many variations of logic polarity are used; for example, from a high-positive to a low-positive voltage, or from positive to ground; or from a high-negative to a low-negative voltage, or from negative to ground. A brief discussion of the two general classes of logic polarity is presented in the following paragraphs.

Positive Logic

Positive logic is defined as follows: If the signal that activates the circuit (the 1 state) has a voltage level that is more POSITIVE than the 0 state, then the logic polarity is considered to be POSITIVE. Table 2-2 shows the manner in which positive logic may be used.

Table 2-2. —Examples of Positive Logic

EXAMPLE 1	Active signal — TRUE, 1, HIGH = +10 volts Complement — FALSE, 0, LOW = 0 volts
EXAMPLE 2	Active signal — TRUE, 1, HIGH = 0 volts Complement — FALSE, 0, LOW = -10 volts

NTST130202

As you can see, in positive logic the 1 state is at a more positive voltage level than the 0 state.

Negative Logic

As you might suspect, negative logic is the opposite of positive logic and is defined as follows: If the signal that activates the circuit (the 1 state) has a voltage level that is more NEGATIVE than the 0 state, then the logic polarity is considered to be NEGATIVE. Table 2-3 shows the manner in which negative logic may be used.

Table 2-3.—Examples of Negative Logic

EXAMPLE 1	Active signal —TRUE, 1, LOW = +5 volts Complement —FALSE, 0, HIGH = +10 volts
EXAMPLE 2	Active signal —TRUE, 1, LOW = -10 volts Complement — FALSE, 0, HIGH = -5 volts

NTST130203

NOTE: The logic level LOW now represents the 1 state. This is because the 1 state voltage is more negative than the 0 state.

In the examples shown for negative logic, you notice that the voltage for the logic 1 state is more negative with respect to the logic 0 state voltage. This holds true in example 1 where both voltages are positive. In this case, it may be easier for you to think of the TRUE condition as being less positive than the FALSE condition. Either way, the end result is negative logic.

The use of positive or negative logic for digital equipment is a choice to be made by design engineers. The difficulty for the technician in this area is limited to understanding the type of logic being used and keeping it in mind when troubleshooting.

NOTE:

UNLESS OTHERWISE NOTED, THE REMAINDER OF THIS BOOK WILL DEAL ONLY WITH POSITIVE LOGIC.

LOGIC INPUTS AND OUTPUTS

As you study logic circuits, you will see a variety of symbols (variables) used to represent the inputs and outputs. The purpose of these symbols is to let you know what inputs are required for the desired output.

If the symbol A is shown as an input to a logic device, then the logic level that represents A must be **HIGH** to activate the logic device. That is, it must satisfy the input requirements of the logic device before the logic device will issue the TRUE output.

Look at view A of figure 2-1. The symbol X represents the input. As long as the switch is open, the lamp is not lit. The open switch represents the logic 0 state of variable X.

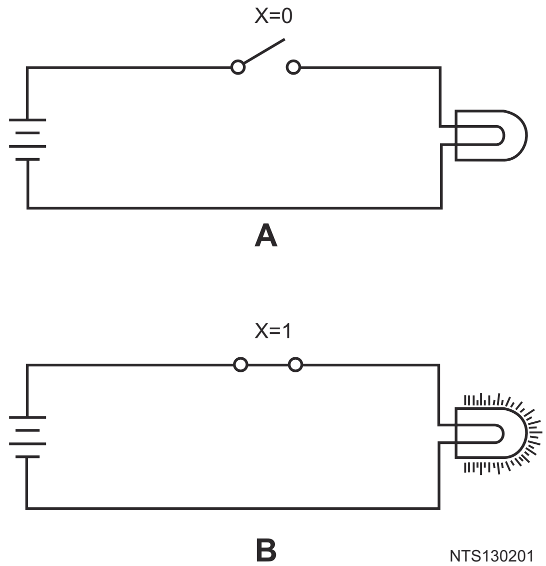

Figure 2-1. —Logic switch: A. Logic 0 state; B. Logic 1 state.

Closing the switch (view B), represents the logic 1 state of X. Closing the switch completes the circuit causing the lamp to light. The 1 state of X satisfied the input requirement and the circuit therefore produced the desired output (logic HIGH); current was applied to the lamp causing it to light.

If you consider the lamp as the output of a logic device, then the same conditions exist. The TRUE (1 state) output of the logic device is to have the lamp lit. If the lamp is not lit, then the output of the logic device is FALSE (0 state).

As you study logic circuits, it is important that you remember the state (1 or 0) of the inputs and outputs.

So far in this chapter, we have discussed the two conditions of logical statements, the logic states representing these two conditions, logic levels and associated electrical signals and positive and negative logic. We are now ready to proceed with individual logic device operations. These make up the majority of computer circuitry.

As each of the logic devices are presented, a chart called a TRUTH TABLE will be used to illustrate all possible input and corresponding output combinations. Truth Tables are particularly helpful in understanding a logic device and for showing the differences between devices.

The logic operations you will study in this chapter are the AND, OR, NOT, NAND, and NOR. The devices that accomplish these operations are called *logic gates*, or more informally, *gates*. These gates are the foundation for all digital equipment. They are the "decision-making" circuits of computers and other types of digital equipment. By making decisions, we mean that certain conditions must exist to produce the desired output.

In studying each gate, we will introduce various mathematical SYMBOLS known as **BOOLEAN ALGEBRA** expressions. These expressions are nothing more than descriptions of the input requirements necessary to activate the circuit and the resultant circuit output.

THE AND GATE

The **AND** gate is a logic circuit that requires all inputs to be TRUE at the same time in order for the output to be TRUE.

LOGIC SYMBOL

The standard symbol for the AND gate is shown in figure 2-2. Variations of this standard symbol may be encountered. These variations become necessary to illustrate that an AND gate may have more than one input.

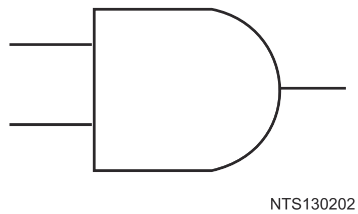

Figure 2-2. —AND gate.

If we apply two variables, A and B, to the inputs of the AND gate, then both A and B would have to be TRUE at the same time to produce the desired TRUE output. . The symbol f designates the output function. The *Boolean expression* for this operation is $f = A \cdot B$ or $f = AB$. The expression is spoken, "f = A AND B." The dot, or lack of, indicates the AND function.

AND GATE OPERATION

We can demonstrate the operation of the AND gate with a simple circuit that has two switches in series as shown in figure 2-3. You can see that both switches would have to be closed at the same time to light the lamp (view A). Any other combination of switch positions (view B) would result in an open circuit and the lamp would not light (logic 0).

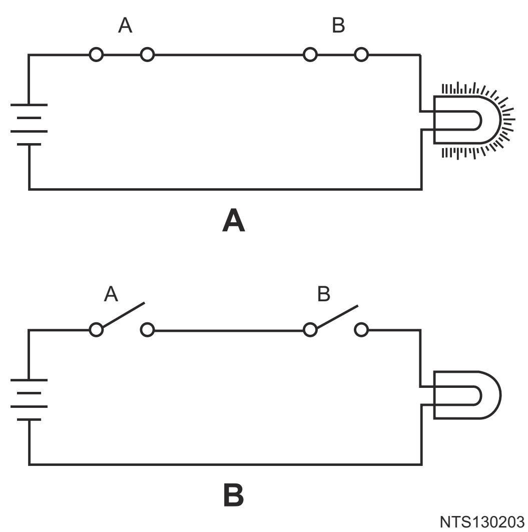

Figure 2-3.—AND gate equivalent circuit: A. Logic 1 state; B. Logic 0 state.

Now look at figure 2-4. Signal A is applied to one input of the AND gate and signal B to the other. At time T_0, both inputs are LOW (logic 0) and f is LOW. At T_1, A goes HIGH (logic 1); B remains LOW; and as a result, f remains LOW. At T_2, A goes LOW and B goes HIGH; f, however, is still LOW, because the proper input conditions have not been satisfied (A and B both HIGH at the same time). At T_4, both A and B are HIGH. As a result, f is HIGH. The input requirements have been satisfied, so the output is HIGH (logic 1).

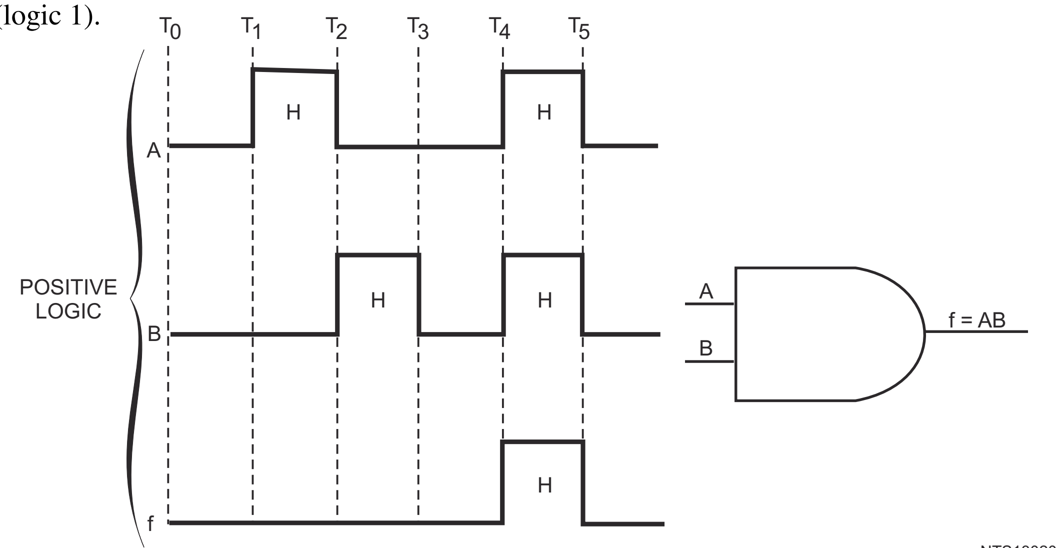

Figure 2-4. —AND gate input and output signals.

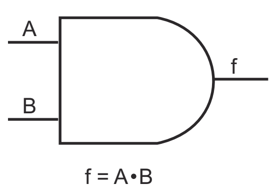
TRUTH TABLE

Now let’s refer to figure 2-5. As you can see, a Truth Table and a Table of Combinations are shown. The latter is a deviation of the Truth Table. It uses the HIGH and LOW logic levels to depict the gate’s inputs and resultant output combinations rather than the 1 and 0 logic states. By comparing the inputs and outputs of the two tables, you see how one can easily be converted to the other (remember, 1 = HIGH and 0 = LOW). The Table of Combinations is shown here only to familiarize you with its existence, it will not be seen again in this book. As we mentioned earlier, the Truth Table is a chart that shows all possible combinations of inputs and the resulting outputs. Compare the AND gate Truth Table (figure 2-5) with the input signals shown in figure 2-4.



A	B	f
0	0	0
0	1	0
1	0	0
1	1	1

TABLE OF COMBINATIONS

NTS130205

Figure 2-5. —AND gate logic symbol, Truth Table, and Table of Combinations.

The first combination (A = 0, B = 0) corresponds to T_0 in figure 2-4; the second to T_1; the third to T_2; and the last to T_4. When constructing a Truth Table, you must include all possible combinations of the inputs, including the all 0s combination.

A Truth Table representing an AND gate with three inputs (X, Y, and Z) is shown below. Remember that the two-input AND gate has four possible combinations, with only one of those combinations providing a HIGH output. An AND gate with three inputs has eight possible combinations, again with only one combination providing a HIGH output. Make sure you include all possible combinations. To check if you have all combinations, raise 2 to the power equal to the number of input variables. This will give you the total number of possible combinations. For example:

EXAMPLE 1-AB = 2^2 = 4 combinations

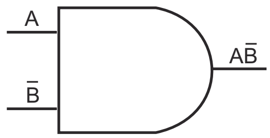
EXAMPLE 2-XYZ = 2^3 = 8 combinations

X	**Y**	**Z**	**f**
0	**0**	**0**	**0**
0	**0**	**1**	**0**
0	**1**	**0**	**0**
0	**1**	**1**	**0**
1	**0**	**0**	**0**
1	**0**	**1**	**0**
1	**1**	**0**	**0**
1	**1**	**1**	**1**
f = XYZ			

As with all AND gates, all the inputs must be HIGH at the same time to produce a HIGH output. Don't be confused if the complement of a variable is used as an input. When a complement is indicated as an input to an AND gate, it must also be HIGH to satisfy the input requirements of the gate. The Boolean expression for the output is formulated based on the TRUE inputs that give a TRUE output. Here is an adage that might help you better understand the AND gate:

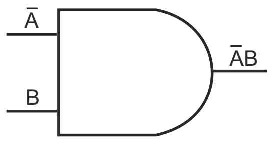
In order to produce a 1 output, all the inputs must be 1. If any or all of the inputs is/are 0, then the output will be 0.

Referring to the following examples should help you cement this concept in your mind. Remember, the inputs, whether the original variable or the complement must be high in order for the output to be high. The three examples given are all AND gates with two inputs. Keep in mind the Boolean expression for the output is the result of all the inputs being HIGH.



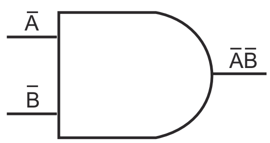
A	$\overline{B}$	f
0	0	0
0	1	0
1	0	0
1	1	1

$f = A\,\overline{B}$



$\overline{A}$	B	f
0	0	0
0	1	0
1	0	0
1	1	1

$f = \overline{A}\,B$



$\overline{A}$	$\overline{B}$	f
0	0	0
0	1	0
1	0	0
1	1	1

$f = \overline{A}\,\overline{B}$

NTS130205a

Figure 2-5a. —AND gate logic with two inputs, Truth Table.

You will soon be able to recognize the Truth Table for the other types of logic gates without having to look at the logic symbol.

Q1. What is defined as "the science of reasoning?"

Q2. With regard to computer logic circuits, what is meant by "complement?"

Q3. What are the complements of the following terms?

a. Q

b. R

c. V

d. Z

Q4. If logic 1 = –5 vdc and logic 0 = –10 vdc, what logic polarity is being used?

Q5. If logic 1 = +2 vdc and logic 0 = –2 vdc, what logic polarity is being used?

Q6. If logic 1 = –5 vdc and logic 0 = 0 vdc, what logic polarity is being used?

Q7. What is the Boolean expression for the output of an AND gate that has R and S as inputs?

Q8. What must be the logic state of R and S to produce the TRUE output?

Q9. How many input combinations exist for a four-input AND gate?

THE OR GATE

The OR gate differs from the AND gate in that only ONE input has to be HIGH to produce a HIGH output. An easy way to remember the OR gate is that any HIGH input will yield a HIGH output.

LOGIC SYMBOL

Figure 2-6shows the standard symbol for the OR gate. The number of inputs will vary according to the needs of the designer.

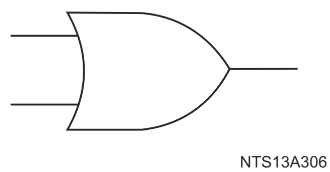


Figure 2-6. —OR gate.

The OR gate may also be represented by a simple circuit as shown in figure 2-7. In the OR gate, two switches are placed in parallel. If either or both of the switches are closed (view A), the lamp will light. The only time the lamp will not be lit is when both switches are open (view B).

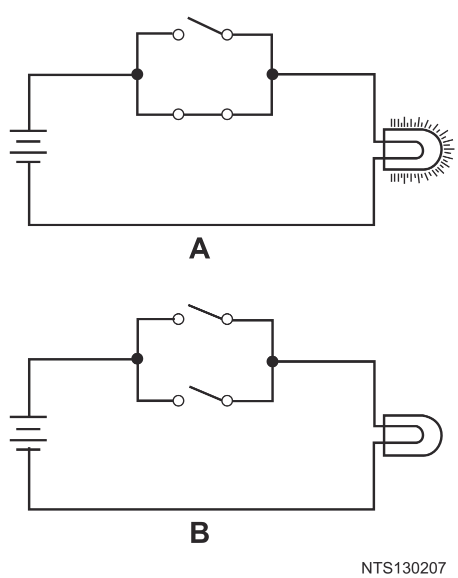

Figure 2-7. —OR gate equivalent circuit: A. Logic 1 state; B. Logic 0 state.

Let's assume we are applying two variables, X and Y, to the inputs of an OR gate. For the circuit to produce a HIGH output, either variable X, variable Y, or both must be HIGH. The Boolean expression for this operation is f = X+Y and is spoken "f equals X OR Y." The plus sign indicates the OR function and should not be confused with addition.

OR GATE OPERATION

Look at figure 2-8. At time T_0, both X and Y are LOW and f is LOW. At T_1, X goes HIGH producing a HIGH output. At T_2 when both inputs go LOW, f goes LOW. When Y goes HIGH at T_3, f also goes HIGH and remains HIGH until both inputs are again LOW. At T_5, both X and Y go HIGH causing f to go HIGH.

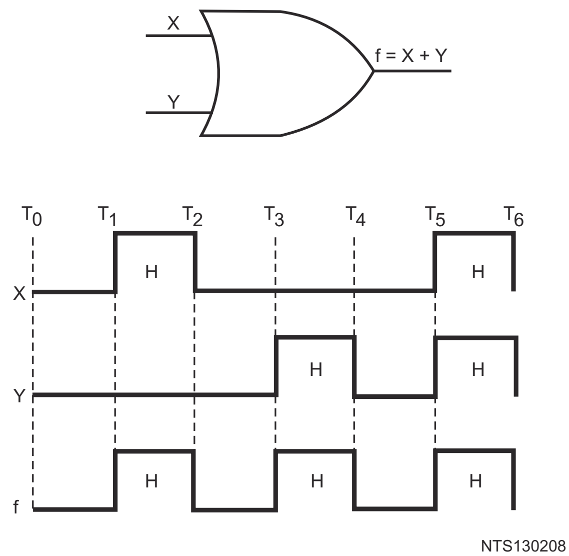

Figure 2-8. —OR gate input and output signals.

TRUTH TABLE

Using the inputs X and Y, let's construct a Truth Table for the OR gate. You can see from the discussion of figure 2-8 that there are four combinations of inputs. List each of these combinations of inputs and the respective outputs and you have the Truth Table for the OR gate.

X	Y	f
0	0	0
0	1	1
1	0	1
1	1	1
f = X + Y		

When writing or stating the Boolean expression for an OR gate with more than two inputs, simply place the OR sign (+) between each input and read or state the sign as OR. For example, the Boolean expression for an OR gate with the inputs of A, B, C, and D would be:

f = A+B+C+D

This expression is spoken "f equals A OR B OR C OR D."

You can substitute the complements for the original statements as we did with the AND gate or use negative logic; but for an output from an OR gate, at least one of the inputs must be TRUE.

Q10. Write the Boolean expression for an OR gate having G, K, and L as inputs.

Q11. How many input combinations are possible using G, K, and L?

Q12. How many of those combinations will produce a HIGH output?

THE INVERTER

The INVERTER, often referred to as a NOT gate, is a logic device that has an output opposite of the input. It is sometimes called a NEGATOR. It may be used alone or in combination with other logic devices to fulfill equipment requirements.

When an inverter is used alone, it is represented by the symbol shown in figure 2-9 (view A). It will more often be seen in conjunction with the symbol for an amplifier (view B). Symbols for inverters used in combination with other devices will be shown later in the chapter.

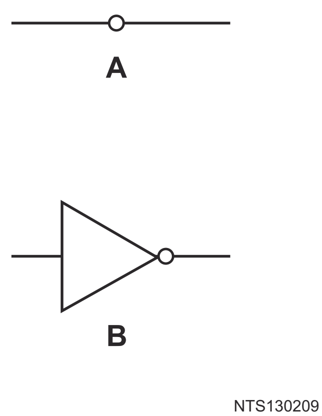

Figure 2-9. —Inverter: A. Symbol for inverter used alone; B. Symbol for an amplifier/inverter.

Let's go back to the statement "Today is payday." We stated that P represents the TRUE state. If we apply P to the input of the inverter as shown in figure 2-10, then the output will be the opposite of the input. The output, in this case, is $\overline{P}$. At times T_0 through T_2, P is LOW. Consequently, the output ($\overline{P}$) is HIGH. At T_2, P goes HIGH and as a result $\overline{P}$ goes LOW. $\overline{P}$ remains LOW as long as P is HIGH and vice versa. The Boolean expression for the output of this gate is $f = \overline{P}$.

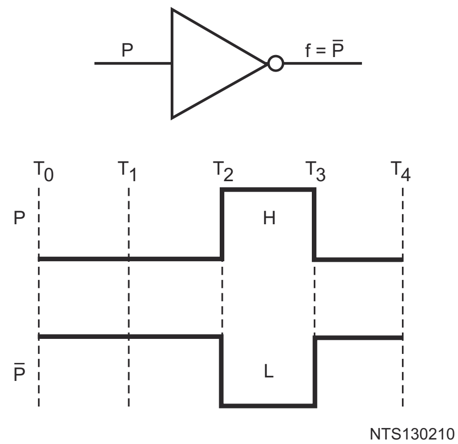

Figure 2-10. —Inverter input and resultant output.

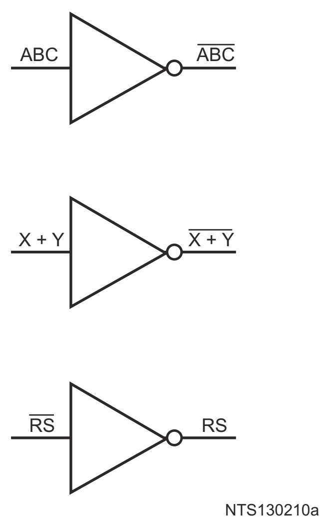
You will recall that $\overline{P}$ is the complement of P.

The Truth Table for an inverter is shown below.

P	**f**
0	**1**
1	**0**

The output of an inverter will be the complement of the input. The following examples show various inputs to inverters and the resulting outputs:



The vinculum, or NOT sign, is placed over the entire output or removed from the output, depending on the input. If we applied $A\overline{B}C$ to an inverter, the output would be $\overline{A\overline{B}C}$. And if we ran that output through another inverter, the output would be $A\overline{B}C$

Q13. What is the complement of XYZ?

Q14. The input to an inverter is $\overline{\overline{X} + (YZ)}$. *What is the output*

Q15. In a properly functioning circuit, can both the input and output of an inverter be HIGH at the same time?

THE NAND GATE

The NAND gate is another logic device commonly found in digital equipment. This gate is simply an AND gate with an inverter (NOT gate) at the output.

LOGIC SYMBOL

The logic symbol for the NAND gate is shown in figure 2-11.

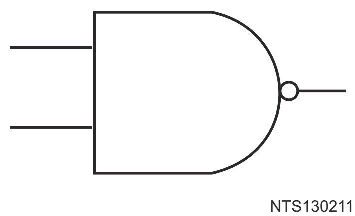


Figure 2-11. —NAND gate.

The NAND gate can have two or more inputs. The output will be LOW only when all the inputs are HIGH. Conversely, the output will be HIGH when any or all of the inputs are LOW.

The NAND gate performs two functions, AND and NOT. Separating the NAND symbol to show these two functions would reveal the equivalent circuits depicted in figure 2-12. This should help you better understand how the NAND gate functions.

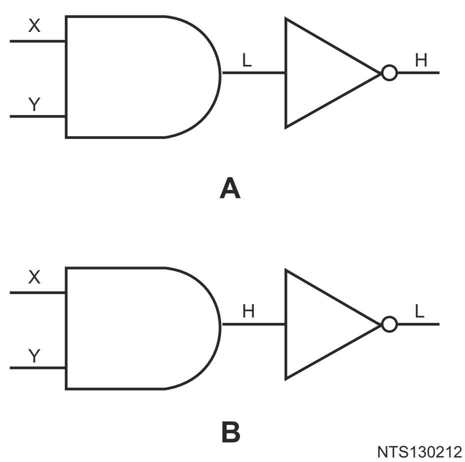

Figure 2-12. —NAND gate equivalent circuit: A. Either X or Y or both are LOW; B. Both X and Y are HIGH.

Inputs X and Y are applied to the AND gate. If either X or Y or both are LOW (view A), then the output of the AND gate is LOW. A LOW (logic 0) on the input of the inverter results in a HIGH (logic 1) output. When both X and Y are HIGH (view B), the output of the AND gate is HIGH; thus the output of the inverter is LOW. The Boolean expression for the output of a NAND gate with these inputs is $f = \overline{XY}$. The expression is spoken "X AND Y quantity NOT." The output of any NAND gate is the negation of the input. For example, if our inputs are X and $\overline{Y}$, the output will be $\overline{X\overline{Y}}$.

NAND GATE OPERATION

Now, let's observe the logic level inputs and corresponding outputs as shown in figure 2-13. At time T_0, X and Y are both LOW. The output is HIGH; the opposite of an AND gate with the same inputs. At T_1, X goes HIGH and Y remains LOW. As a result, the output remains HIGH. At T_2, X goes LOW and Y goes HIGH. Again, the output remains HIGH. When both X and Y are HIGH at T_4, the output goes LOW. The output will remain LOW only as long as both X and Y are HIGH.

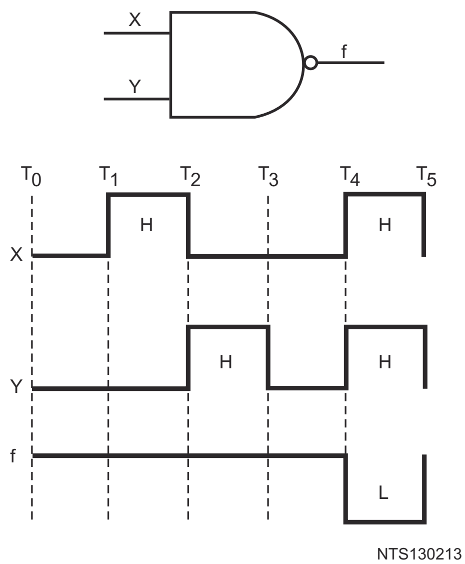

Figure 2-13. —NAND gate input and output signals.

TRUTH TABLE

The Truth Table for a NAND gate with X and Y as inputs is shown below.

X	Y	f
0	0	1
0	1	1
1	0	1
1	1	0
$F = \overline{XY}$		

Q16. A NAND gate has Z and X as inputs. What will be the output logic level if Z is HIGH and X is LOW?

Q17. What must be the state of the inputs to a NAND gate in order to produce a LOW output?

Q18. What is the output Boolean expression for a NAND gate with inputs A, $\overline{B}$*, and C?*

Q19. A NAND gate has inputs labeled as A, $\overline{B}$*, and C. If A and* $\overline{B}$ *are HIGH, C must be at what logic level to produce a HIGH output?*

THE NOR GATE

As you might expect, the NOR gate is an OR gate with an inverter on the output.

LOGIC SYMBOL

The standard logic symbol for this gate is shown in figure 2-14. More than just the two inputs may be shown.

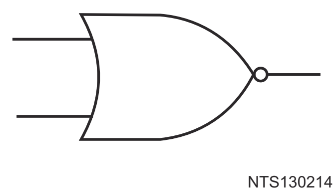

Figure 2-14. —NOR gate.

The NOR gate will have a HIGH output only when all the inputs are LOW.

When broken down, the two functions performed by the NOR gate can be represented by the equivalent circuit depicted in figure 2-15. When both inputs to the OR gate are LOW, the output is LOW. A LOW applied to an inverter gives a HIGH output. If either or both of the inputs to the OR gate are HIGH, the output will be HIGH. When this HIGH output is applied to the inverter, the resulting output is LOW. The Boolean expression for the output of this NOR gate is $f = \overline{K + L}$. The expression is spoken, "K OR L quantity NOT."

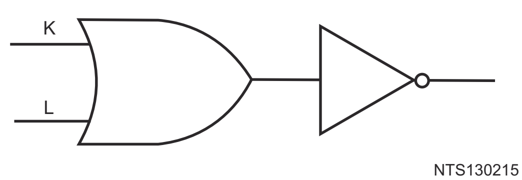

Figure 2-15. —NOR gate equivalent circuit.

NOR GATE OPERATION

The logic level inputs and corresponding outputs for a NOR gate are shown in figure 2-16. At time T_0, both K and L are LOW; as a result, f is HIGH. At T_1, K goes HIGH, L remains LOW, and f goes LOW. At T_2, K goes LOW, L goes HIGH, and the output remains LOW. The output goes HIGH again at T_3 when both inputs are LOW. At T_4 when both inputs are HIGH, the output goes LOW and remains LOW until T_5 when both inputs go LOW. Remember the output is just opposite of what it would be for an OR gate.

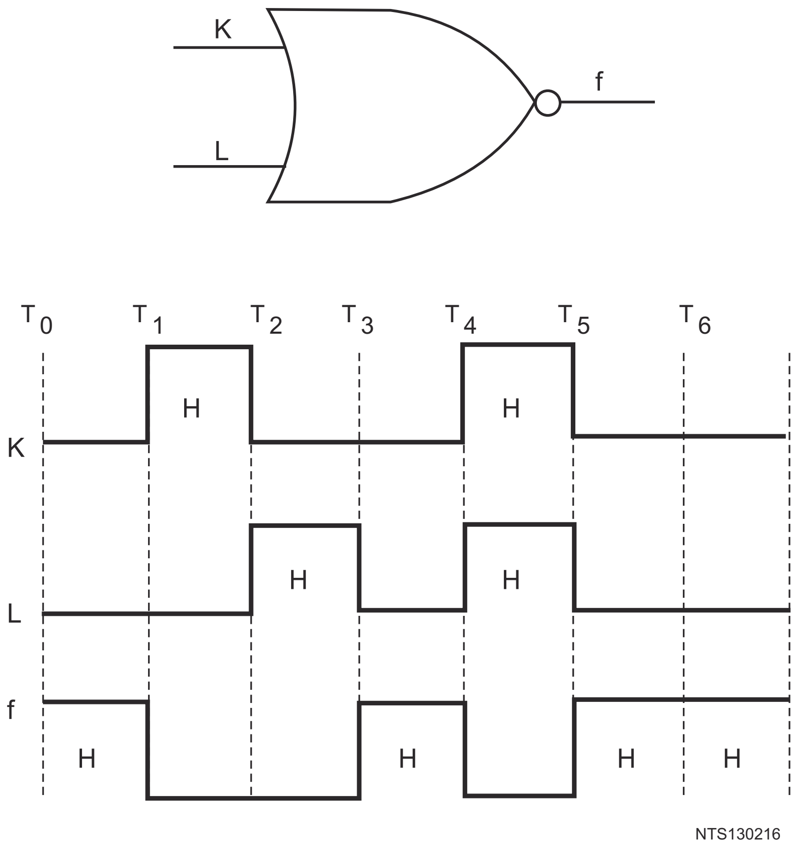

Figure 2-16.—NOR gate input and output signals.

TRUTH TABLE

The Truth Table for a NOR gate with K and L as inputs is shown below.

K	L	f
0	0	1
0	1	0
1	0	0
1	1	0
f = $\overline{K + L}$		

Q20. How does a NOR gate differ from an OR gate?

Q21. What will be the output of a NOR gate when both inputs are HIGH?

Q22. What is the output Boolean expression for a NOR gate with R and T as inputs?

Q23. In what state must the inputs to a NOR gate be in order to produce a logic 1 output?

VARIATIONS OF FUNDAMENTAL GATES

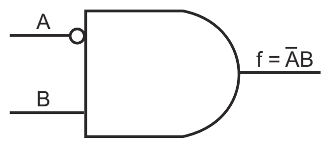
Now that you are familiar with fundamental logic gates, let's look at some variations of these gates that you may encounter.

Up to now you have seen inverters used alone or on the output of AND and OR gates. Inverters may also be used on one or more of the inputs to the logic gates. Take a look at the examples as discussed in the following paragraphs.

AND/NAND GATE VARIATIONS

If we place an inverter on one input of a two-input AND gate, the output will be quite different from that of the standard AND gate.

In figure 2-17, we have placed an inverter on the A input. When A is HIGH, the inverter makes it a LOW going into the AND gate. In order for the output to be HIGH, A would have to be LOW while B is HIGH, as shown in the Truth Table. If the inverter were on the B input, the output expression would then be $f = A\overline{B}$.



A	B	f
0	0	0
0	1	1
1	0	0
1	1	0

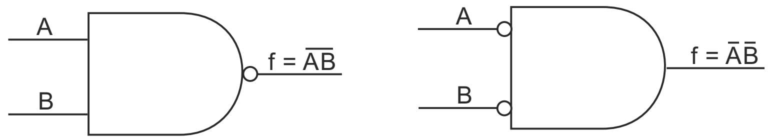
$f = \overline{A}B$

NTS130217

Figure 2-17. —AND gate with one inverted input.

Now let's compare a NAND gate to an AND gate with an inverter on each input. Figure 2-18 shows these gates and the associated Truth Tables. With the NAND gate (view A), the output is HIGH when either or both inputs is/are LOW. The AND gate with inverters on each input (view B), produces a HIGH output only when both inputs are LOW. This comparison also points out the differences between the expressions $f = A\overline{B}$ (A AND B quantity NOT) and $f = \longrightarrow \overline{A}\ \overline{B}$ (NOT A AND NOT B).

Now, look over the Truth Tables for figures 2-17, 2-18, and 2-19; look at how the outputs vary with inverters in different positions.



A	B	f
0	0	1
0	1	1

1	0	0
1	1	0

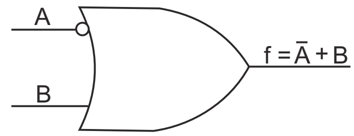
NTS130219

Figure 2-19. —NAND gate with one inverted input.

OR/NOR GATE VARIATIONS

The outputs of OR and NOR gates may also be changed with the use of inverters.

An OR gate with one input inverted is shown in figure 2-20. The output of this OR gate requires that A be LOW, B be HIGH, or both of these conditions existing at the same time in order to have a HIGH output. Since the A input is inverted, it must be LOW if B is LOW in order to produce a HIGH output. Therefore the output is f = $\overline{A}$ +B.

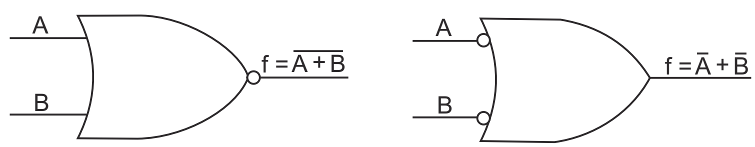


A	B	f
0	0	1
0	1	1
1	0	0
1	1	1

NTS130220

Figure 2-20. —OR gate with one inverted input.

Figure 2-21compares a NOR gate (view A), to an OR gate with inverters on both inputs (view B), and shows the respective Truth Tables. The NOR gate will produce a HIGH output only when both inputs are LOW. The OR gate with inverted inputs produces a HIGH output with all input combinations EXCEPT when both inputs are HIGH. This figure also illustrates the differences between the expressions f = $\overline{A + B}$ (A OR B quantity NOT) and f = $\overline{A} + \overline{B}$ (NOT A OR NOT B).



A	B	f

1	0	0
1	1	0

$f = \overline{A + B}$

A

A	B	f
0	0	1
0	1	1
1	0	1
1	1	0

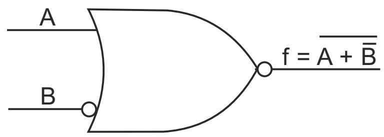
$f = \overline{A} + \overline{B}$

B

NTS130221

Figure 2-21. —Comparison of NOR gate and OR gate with inverted inputs: A. NOR gate; B. OR gate with inverters on both inputs.

As with the NAND gate, one or more inputs to NOR gates may be inverted. Figure 2-22 shows the result of inverting a NOR gate input. In this case, because of the inversion of the B input and the inversion of the output, the only time this gate will produce a HIGH output is when A is LOW and B is HIGH. The output Boolean expression for this gate is f = $\overline{A + \overline{B}}$, spoken “A OR NOT B quantity NOT.”



A	B	f
0	0	0
0	1	1
1	0	0
1	1	0

f = $\overline{A + \overline{B}}$

NTS130222

Figure 2-22. —NOR gate with one inverted input.

Table 2-4 illustrates AND, NOR, NAND, and OR gate combinations that produce the same output. You can see by the table that there is more than one way to achieve a desired output. Although the gates have only two inputs, the table can be extended to more than two inputs.

Table 2-4.—Equivalent AND and NOR, NAND and OR Gates

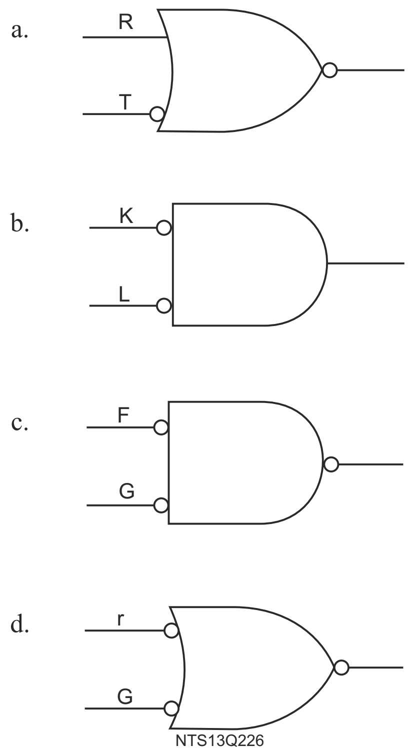
NTS13T0204

Q24. What is the output Boolean expression for an AND gate with A and B as inputs when the B input is inverted?

Q25. What is the equivalent logic gate of a two-input NAND gate with both inputs inverted?

Q26. What is the output Boolean expression for the following gates?



LOGIC GATES IN COMBINATION

When you look at logic circuit diagrams for digital equipment, you are not going to see just a single gate, but many combinations of gates. At first it may seem confusing and complex. If you interpret one gate at a time, you can work your way through any network. In this section, we will analyze several combinations of gates and then provide you with some practice problems.

Figure 2-23 (view A) shows a simple combination of AND gates. The outputs of gates 1 and 2 are the inputs to gate 3. You already know that both inputs to an AND gate must be HIGH at the same time in order to produce a HIGH output.

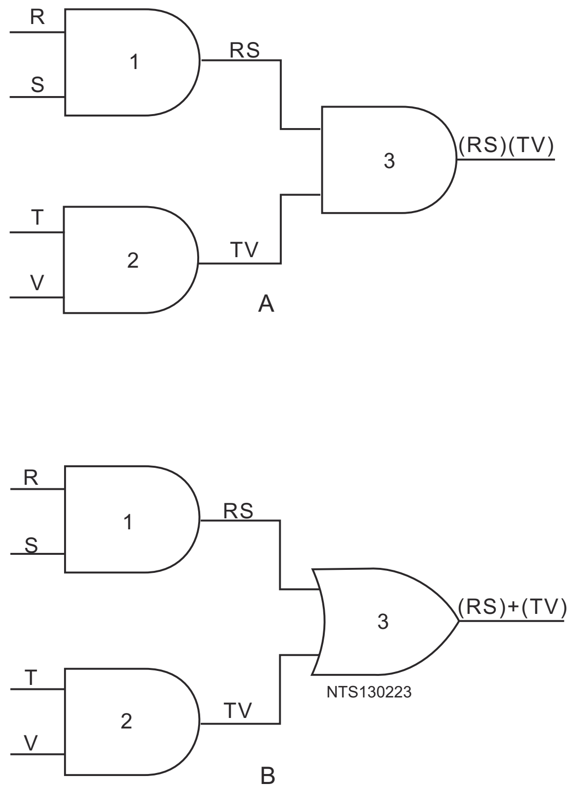


Figure 2-23. —Logic gate combinations: A. Simple combination of AND gates; B. Simple combination of AND gates and OR gate.

The output Boolean expression of gate 1 is RS, and the output expression of gate 2 is TV. These two output expressions become the inputs to gate 3. Remember, the output Boolean expression is the result of the inputs, in this case (RS)(TV); spoken "quantity R AND S AND quantity T AND V."

In view B we have changed gate 3 to an OR gate. The outputs of gates 1 and 2 remain the same but the output of gate 3 changes as you would expect. The output of gate 3 is now (RS)+(TV); spoken "quantity R AND S OR quantity T AND V."

In figure 2-24 (view A), the outputs of two OR gates are being applied as the input to third OR gate. The output for gate 1 is R+S, and the output for gate 2 is T+V. With these inputs, the output expression of gate 3 is (R+S)+(T+V).

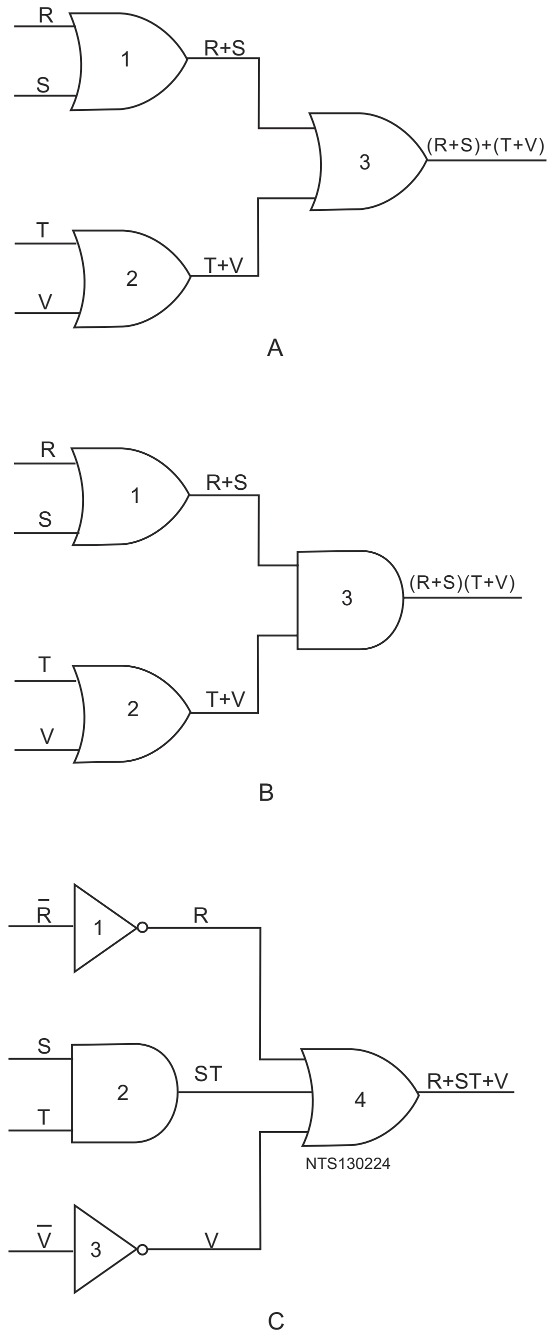

Figure 2-24. —Logic gate combinations: A. Simple combination of OR gates; B. Simple combination of OR gates and AND gate; C. Output expression without the parentheses.

In view B, gate 3 has been changed to an AND gate. The outputs of gates 1 and 2 do not change, but the output expression of gate 3 does. In this case, the gate 3 output expression is (R+S)(T+V). This expression is spoken, "quantity R OR S AND quantity T OR V." The parentheses are used to separate the input terms and to indicate the AND function. Without the parentheses the output expression would read R+ST+V, which is representative of the circuit in view C. As you can see, this is not the same circuit as the one depicted in view B. It is very important that the Boolean expressions be written and spoken correctly.

The Truth Table for the output expression of gate 3 (view B) will help you better understand the output. When studying this Truth Table, notice that the only time f is HIGH (logic 1) is when either or both R and S AND either or both T and V are HIGH (logic 1).

R	S	T	V	f
0	0	0	0	0
0	0	0	1	0
0	0	1	0	0
0	0	1	1	0
0	1	0	0	0
0	1	0	1	1
0	1	1	0	1
0	1	1	1	1
1	0	0	0	0
1	0	0	1	1
1	0	1	0	1
1	0	1	1	1
1	1	0	0	0
1	1	0	1	1
1	1	1	0	1
1	1	1	1	1
f = (R+S) (T+V)				

Now let's determine the output expression for the NOR gate in figure 2-25. First write the outputs of gates 1, 2, and 3:

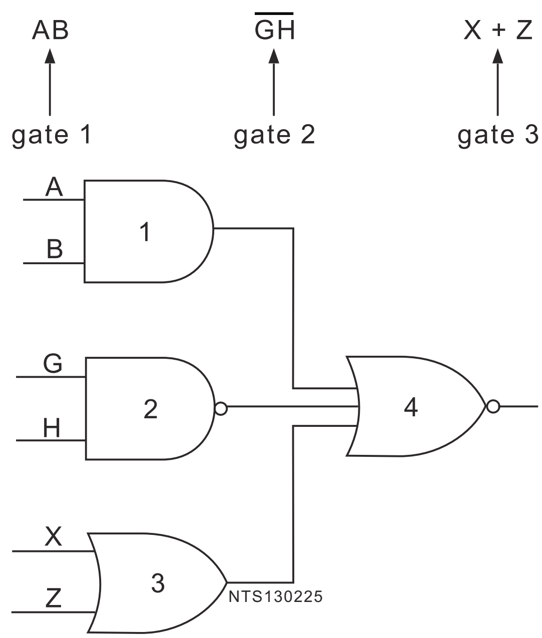

Figure 2-25. —Logic gate combinations.

Since all three outputs are applied to gate 4, proceed as you would for any NOR gate. We separate each input to gate 4 with an OR sign (+) and then place a vinculum over the entire expression. The output expression of gate 4 is:

$$\overline{(AB) + (\overline{GH}) + (X + Z)}$$

The Truth Table shown below is only for gate 4.

(AB)	(GH)	(X+Z)	f
0	0	0	1
0	0	1	0
0	1	0	0
0	1	1	0
1	0	0	0
1	0	1	0
1	1	0	0
1	1	1	0
$f = \overline{(AB) + (\overline{GH}) + (X + Z)}$

BOOLEAN ALGEBRA

Boolean logic, or Boolean algebra as it is called today, was developed by an English mathematician, George Boole, in the 19th century. He based his concepts on the assumption that most quantities have two possible conditions — TRUE and FALSE. This is the same theory you were introduced to at the beginning of this chapter.

Throughout our discussions of fundamental logic gates, we have mentioned Boolean expressions. A Boolean expression is nothing more than a description of the input conditions necessary to get the desired output. These expressions are based on Boole's laws and theorems.

PURPOSE

Boolean algebra is used primarily by design engineers. Using this system, they are able to arrange logic gates to accomplish desired tasks. Boolean algebra also enables the engineers to achieve the desired output by using the fewest number of logic gates. Since space, weight, and cost are important factors in the design of equipment, you would usually want to use as few parts as possible.

Figure 2-26 (view A), shows a rather complex series of gates. Through proper application of Boolean algebra, the circuit can be simplified to the single OR gate shown in view B. Figure 2-27 shows the simplification process and the Boolean laws and theorem used to accomplish it.

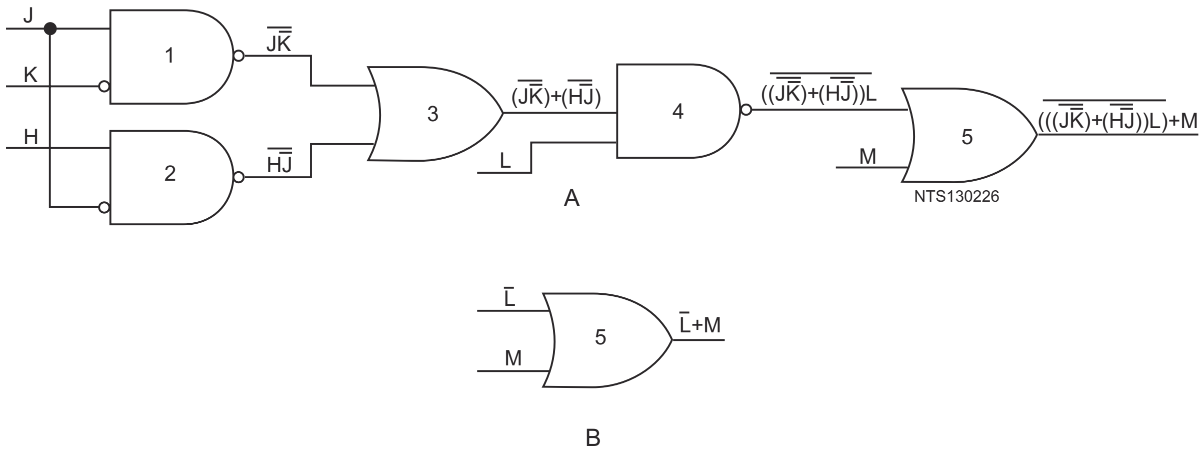

Figure 2-26. —Logic simplification: A. Complex series of gates; B. Simplified single OR gate.

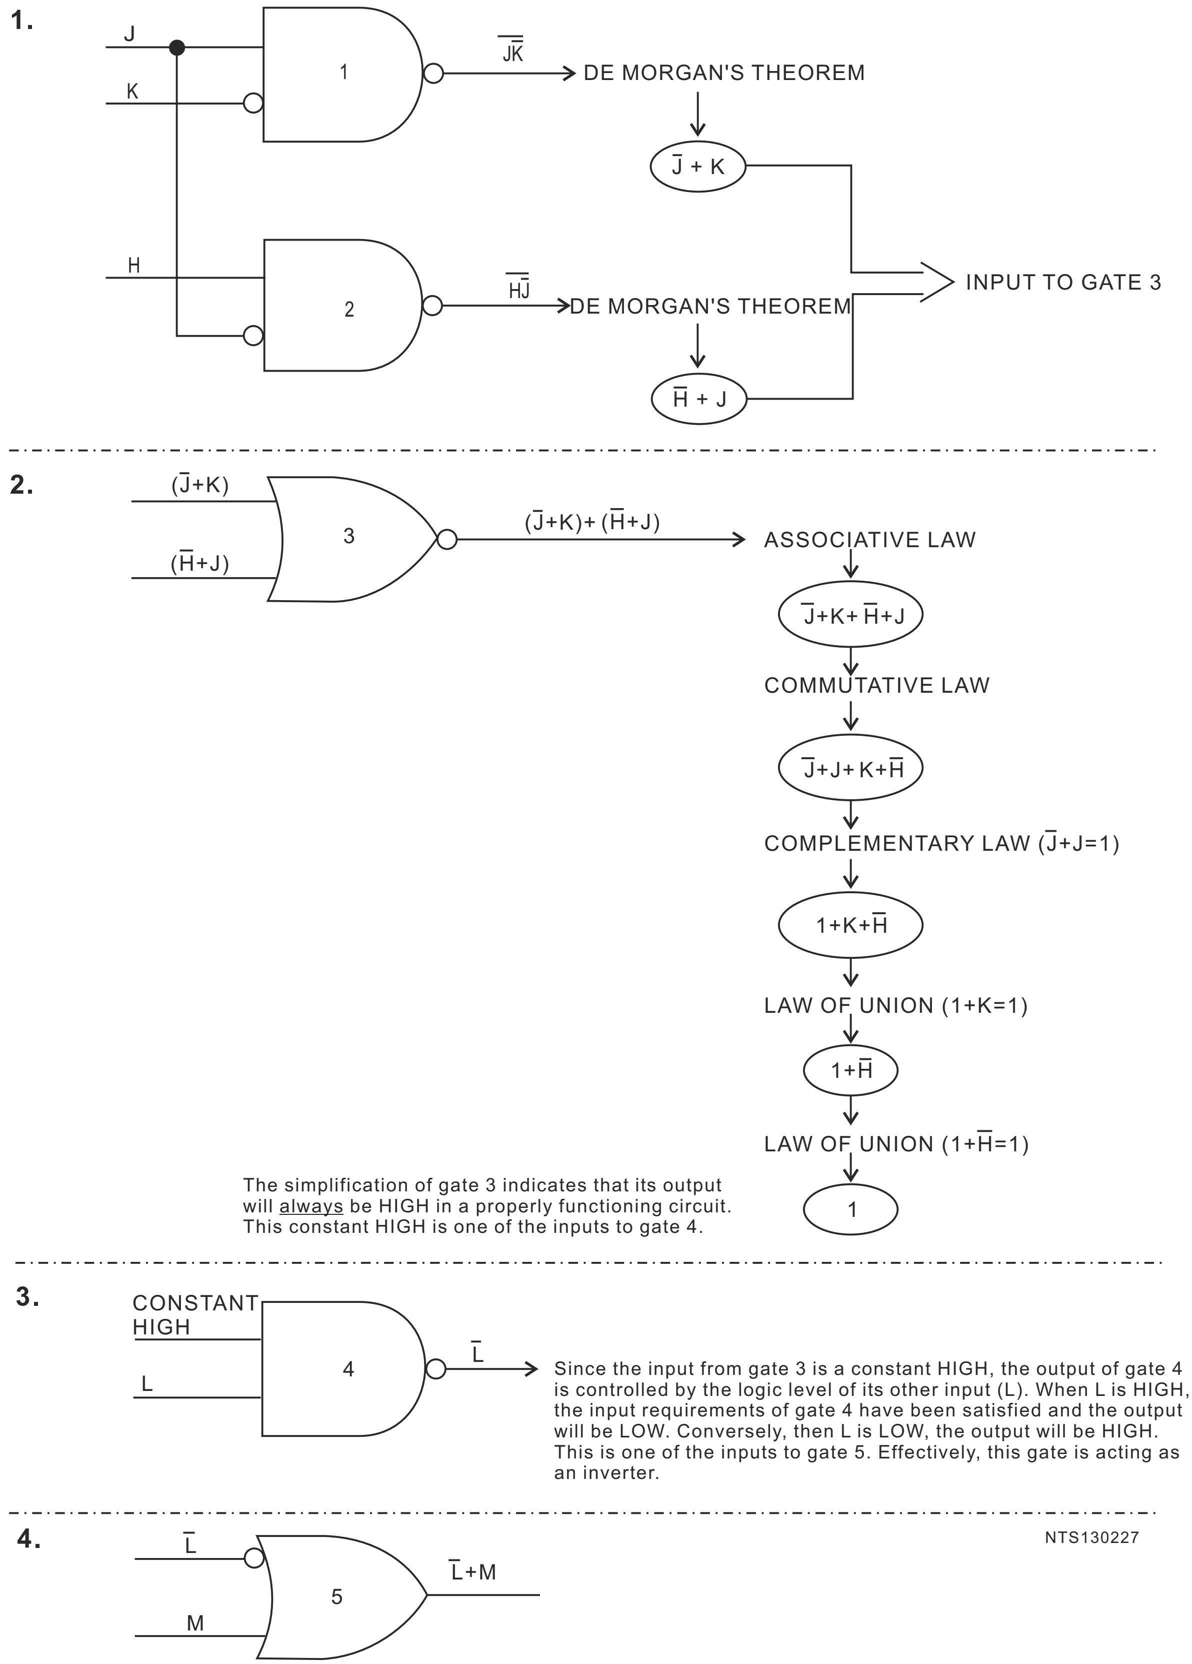

Figure 2-27. —Logic circuit simplification process.

LAWS AND THEOREMS

Each of the laws and theorems of Boolean algebra, along with a simple explanation, is listed below.

LAW OF IDENTITY —a term that is TRUE in one part of an expression will be TRUE in all parts of the expression (A = A or A = A).

COMMUTATIVE LAW —the order in which terms are written does not affect their value (AB = BA, A+B = B+A).

ASSOCIATIVE LAW —a simple equality statement A(BC) = ABC or A+(B+C) = A+B+C.

IDEMPOTENT LAW —a term ANDed with itself or ORed with itself is equal to that term (AA = A, A+A = A).

DOUBLE NEGATIVE LAW —a term that is inverted twice is equal to the term $\overline{\overline{A}}$ = **A.**

COMPLEMENTARY LAW —a term ANDed with its complement equals 0, and a term ORed with its complement equals 1 ($A\overline{A} = 0$, $A+\overline{A} = 1$).

LAW OF INTERSECTION —a term ANDed with 1 equals that term and a term ANDed with 0 equals 0 ($A\cdot1 = A$, $A\cdot0 = 0$).

LAW OF UNION —a term ORed with 1 equals 1 and a term ORed with 0 equals that term (A+1 = 1, A+0 = A).

DeMORGAN'S THEOREM —this theorem consists of two parts: (1) $\overline{AB} = \overline{A} + \overline{B}$ and (2) $\overline{A + B} = \overline{A} \cdot \overline{B}$ (Look at the fourth and eighth sets of gates in table 2-4).

DISTRIBUTIVE LAW —(1) a term (A) ANDed with an parenthetical expression (B+C) equals that term ANDed with each term within the parenthesis: $A\cdot(B+C) = AB+AC$; (2) a term (A) ORed with a parenthetical expression (B ·C) equals that term ORed with each term within the parenthesis: $A+(BC) = (A+B)\cdot(A+C)$.

LAW OF ABSORPTION —this law is the result of the application of several other laws: $A\cdot(A+B) = A$ or $A+(AB) = A$.

LAW OF COMMON IDENTITIES —the two statements $A\cdot(\overline{A}+B) = AB$ and $A+\overline{A}B = A+B$ are based on the complementary law.

Table 2-5. —Boolean Laws and Theorems

1.	Law of Identity	$A = A$ $\overline{A} = \overline{A}$
2.	Commutative Law	$A \cdot B = B \cdot A$ $A + B = B + A$
3.	Associative Law	$A \cdot (B \cdot C) = A \cdot B \cdot C$ $A + (B + C) = A + B + C$
4.	Idempotent Law	$A \cdot A = A$ $A + A = A$
5.	Double Negative Law	$\overline{\overline{A}} = A$
6.	Complementary Law	$A \cdot \overline{A} = 0$ $A + \overline{A} = 1$
7.	Law of Intersection	$A \cdot 1 = A$ $A \cdot 0 = 0$
8.	Law of Union	$A + 1 = 1$ $A + 0 = A$
9.	DeMorgan's Theorem	$\overline{AB} = \overline{A} + \overline{B}$ $\overline{A + B} = \overline{A}\,\overline{B}$
10.	Distributive Law	$A \cdot (B + C) = (A \cdot B) + (A \cdot C)$ $A + (BC) = (A + B) \cdot (A + C)$
11.	Law of Absorption	$A \cdot (A + B) = A$ $A + (AB) = A$
12.	Law of Common Identities	$A \cdot (\overline{A} + B) = AB$ $A + (\overline{A}B) = A + B$

NTS13T205

If you wish a more detailed study of Boolean algebra, we suggest you obtain *Mathematics, Volume 3*, NAVEDTRA 10073-A1.

Q33. Boolean algebra is based on the assumption that most quantities have _______ conditions.

Q34. Boolean algebra is used primarily by _______ to simplify circuits.

SUMMARY

This chapter has presented information on logic, fundamental logic gates, and Boolean laws and theorems. The information that follows summarizes the important points of this chapter.

LOGIC is the development of a logical conclusion based on known information.

Computers operate on the assumption that statements have two conditions — **TRUE** and **FALSE.**

POSITIVE LOGIC is defined as follows: If the signal that activates the circuit (the 1 state) has a voltage level that is more POSITIVE than the 0 state, then the logic polarity is considered to be POSITIVE.

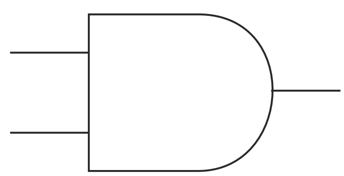
NEGATIVE LOGIC is defined as follows: If the signal that activates the circuit (the 1 state) has a voltage level that is more NEGATIVE than the 0 state, then the logic polarity is considered to be NEGATIVE.

In **DIGITAL LOGIC** (positive or negative), the TRUE condition of a statement is represented by the logic 1 state and the FALSE condition is represented by the logic 0 state.

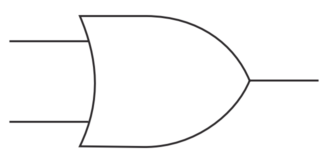
LOGIC LEVELS High and LOW represent the voltage levels of the two logic states. Logic level HIGH represents the more positive voltage while logic level LOW represents the less positive (more negative) voltage. In positive logic, the HIGH level corresponds to the TRUE or 1 state and the LOW level corresponds to the FALSE or 0 state. In negative logic, the HIGH level corresponds to the FALSE or 0 state and the LOW level corresponds to the TRUE or 1 state.

A **BOOLEAN EXPRESSION** is a statement that represents the inputs and outputs of logic gates.

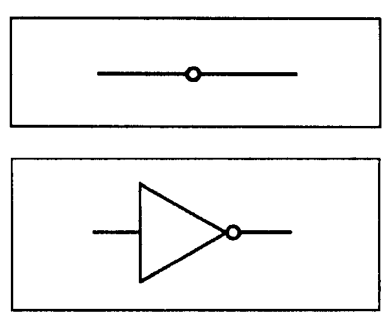
The **AND GATE** requires all inputs to be HIGH at the same time in order to produce a HIGH output.



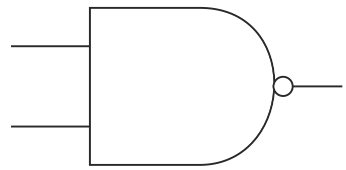
The **OR GATE** requires one or both inputs to be HIGH in order to produce a HIGH output.



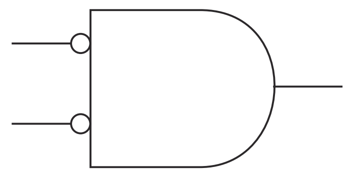
INVERTER (NOT function or negator) is a logic gate used to complement the state of the input variable; that is, a 1 becomes a 0 or a 0 becomes a 1. It may be used on any input or output of any gate to obtain the desired result.

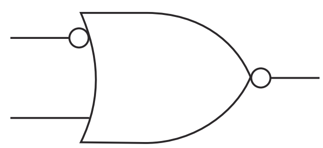


The NAND GATE functions as an AND gate with an inverted output.



The NOR GATE functions as an OR gate with an inverted output.





When deriving the output Boolean expression of a combination of gates, solve one gate at a time.

Boolean algebra is used primarily for the design and simplification of circuits.

CHAPTER 3

SPECIAL LOGIC CIRCUITS

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to do the following:

1. Recognize the types of special logic circuits used in digital equipment.
2. Identify exclusive OR and exclusive NOR circuits and interpret their respective Truth Tables.
3. Identify adder and subtracter circuits.
4. Identify the types of flip-flops used in digital equipment and their uses.
5. Identify counters, registers, and clock circuits.
6. Describe the elements that make up logic families — RTL, DTL, TTL, CMOS.

INTRODUCTION

Figure 3-1 is a portion of a typical logic diagram. It is similar to the diagrams you will encounter as your study of digital circuitry progresses.

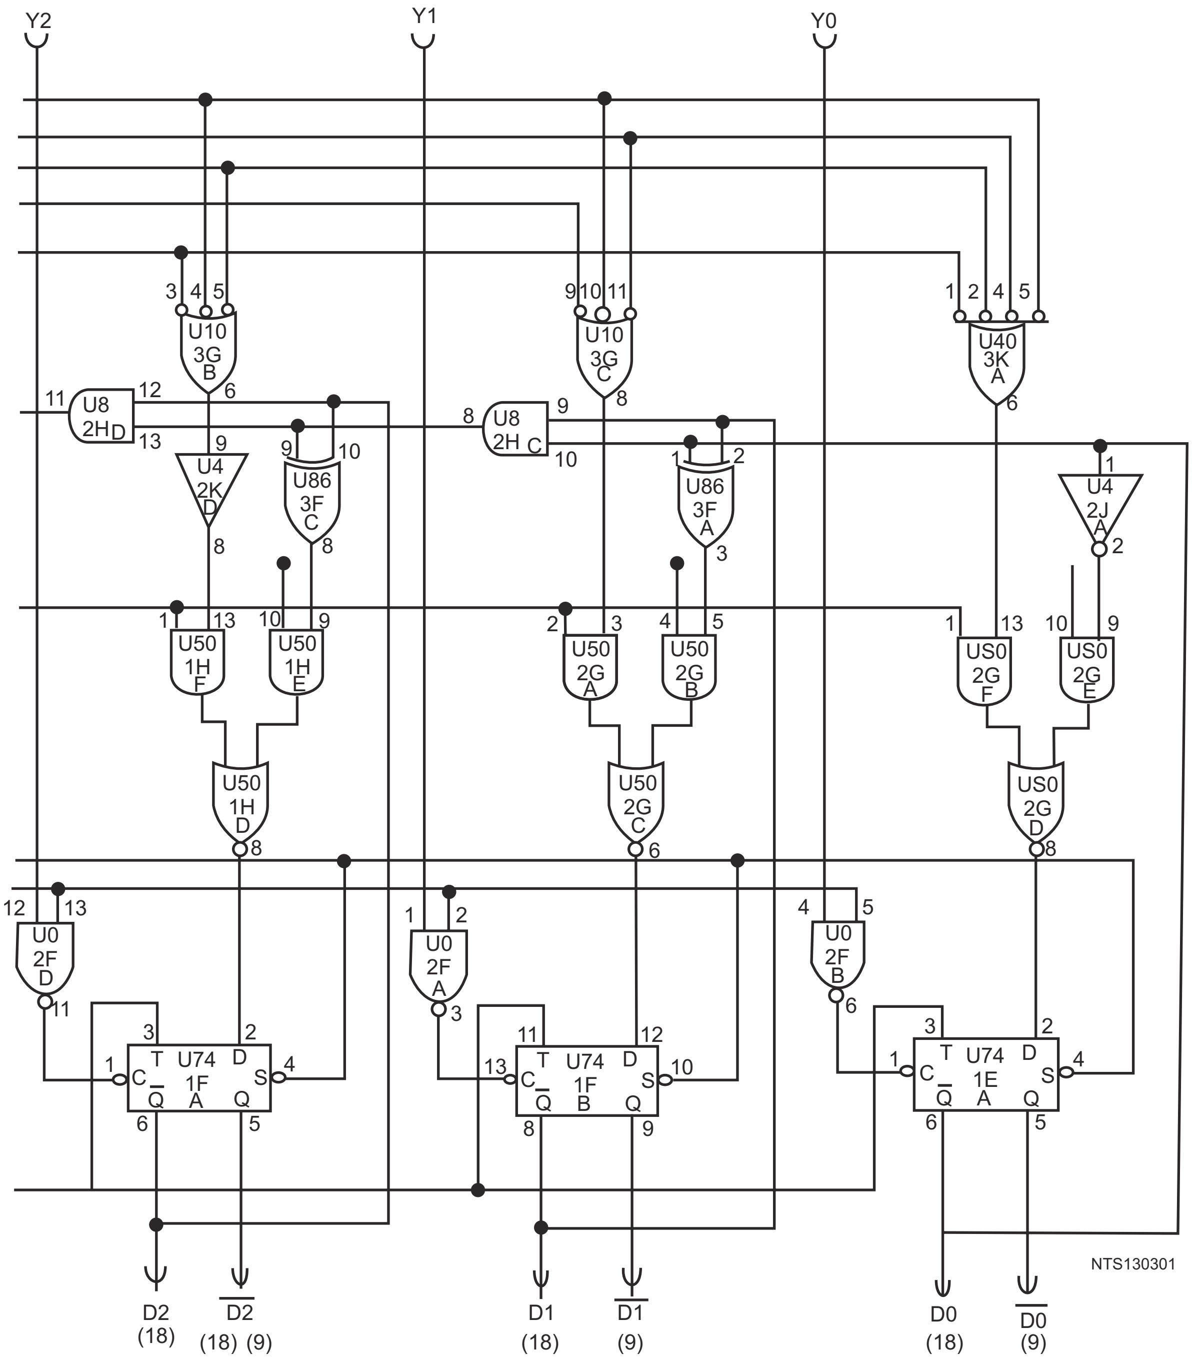

Figure 3-1. —Typical logic diagram.

Look closely at the figure. You will see many familiar logic gates. You will also see several that you may not recognize.

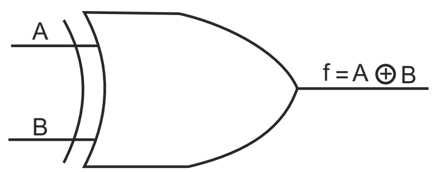
Digital equipment must be capable of many more operations than those described in chapter 2. Provisions must be made for accepting information; performing arithmetic or logic operations; and transferring, storing, and outputting information. Timing circuits are included to ensure that all operations occur at the proper time.

In this chapter you will become acquainted with the logic circuits used to perform the operations mentioned above.

THE EXCLUSIVE OR GATE

The exclusive OR gate is a modified OR gate that produces a HIGH output when only one of the inputs is HIGH. You will often see the abbreviation X-OR used to identify this gate. When both inputs are HIGH or when both inputs are LOW, the output is LOW.

The standard symbol for an exclusive OR gate is shown in figure 3-2 along with the associated Truth Table. The operation function sign for the exclusive OR gate is ⊕.



A	B	f
0	0	0
0	1	1
1	0	1
1	1	0

NTS130302

Figure 3-2. —Exclusive OR gate and Truth Table.

If you were to observe the input and output signals of an X-OR gate, the results would be similar to those shown in figure 3-3. At T_0, both inputs are LOW and the output is LOW. At T_1, A goes to HIGH and remains HIGH until T_2. During this time the output is HIGH. At T_3, B goes HIGH and remains HIGH through T_5. At T_4, A again goes HIGH and remains HIGH through T_5. Between $T_3$and T_4 , the output is HIGH. At T_4, when both A and B are HIGH, the output goes LOW.

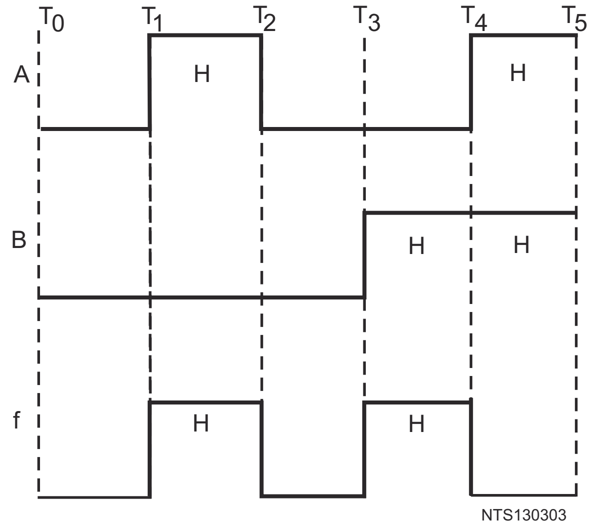


Figure 3-3. —Exclusive OR gate timing diagram.

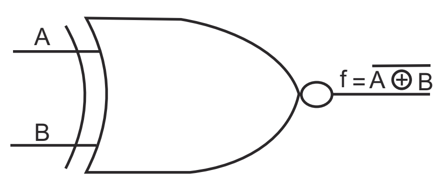
THE EXCLUSIVE NOR GATE

The exclusive NOR (X-NOR) gate is nothing more than an X-OR gate with an inverted output. It produces a HIGH output when the inputs are either all HIGH or all LOW. The standard symbol and the Truth Table are shown in figure 3-4. The operation function sign is ⊕ with a vinculum over the entire expression.



A	B	f
0	0	1
0	1	0
1	0	0
1	1	1

NTS130304

Figure 3-4. —Exclusive NOR gate and Truth Table.

A timing diagram for the X-NOR gate is shown in figure 3-5. You can see that from T_0 to T_1, when both inputs are LOW, the output is HIGH. The output goes LOW when the inputs are opposite; one HIGH and the other LOW. At time T_3, both inputs go HIGH causing the output to go HIGH.

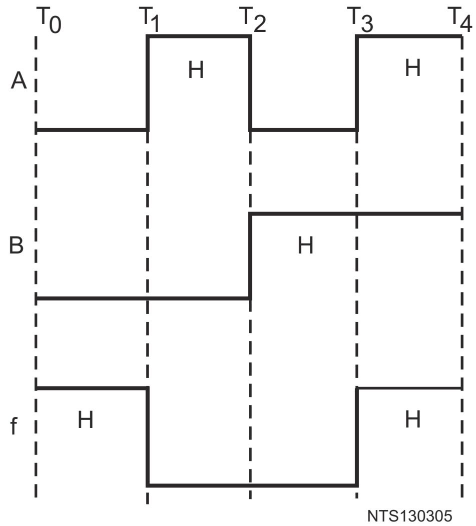


Figure 3-5. —Exclusive NOR gate timing diagram.

Q1. What is the sign of operation for the X-OR gate?

Q2. What will be the output of an X-OR gate when both inputs are HIGH?

Q3. A two-input X-OR gate will produce a HIGH output when the inputs are at what logic levels?

Q4. What type of gate is represented by the output Boolean expression $\overline{T \oplus R}$ *?*

Q5. What will be the output of an X-NOR gate when both inputs are LOW?

ADDERS

Adders are combinations of logic gates that combine binary values to obtain a sum. They are classified according to their ability to accept and combine the digits. In this section we will discuss quarter adders, half adders, and full adders.

QUARTER ADDER

A quarter adder is a circuit that can add two binary digits but will not produce a carry. This circuit will produce the following results:

0 plus 0 = 0

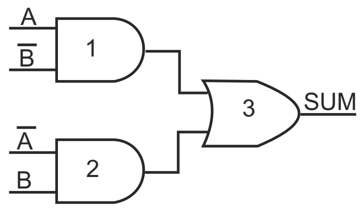
0 plus 1 = 1

1 plus 0 = 1

1 plus 1 = 0 (no carry)

You will notice that the output produced is the same as the output for the Truth Table of an X-OR. Therefore, an X-OR gate can be used as a quarter adder.

The combination of gates in figure 3-6 will also produce the desired results. When A and B are both LOW (0), the output of each AND gate is LOW (0); therefore, the output of the OR gate is LOW (0). When A is HIGH and B is LOW, then $\overline{B}$ is HIGH and AND gate 1 produces a HIGH output, resulting in a sum of 1 at gate 3. With A LOW and B HIGH, gate 2 output is HIGH, and the sum is 1. When both A and B are HIGH, neither AND gate has an output, and the output of gate 3 is LOW (0); no carry is produced.



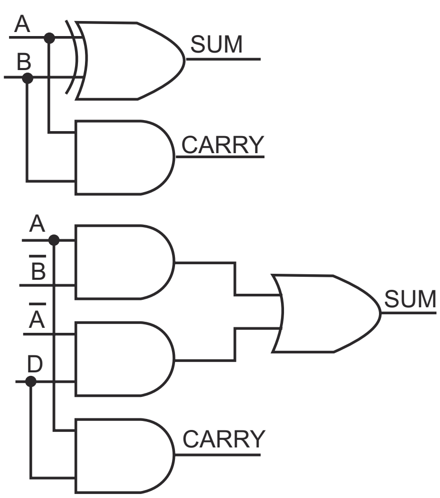
NTS130306

Figure 3-6. —Quarter adder.

HALF ADDER

A half adder is designed to combine two binary digits and produce a carry.

Figure 3-7 shows two ways of constructing a half adder. An AND gate is added in parallel to the quarter adder to generate the carry. The SUM column of the Truth Table represents the output of the quarter adder, and the CARRY column represents the output of the AND gate.



A	D	SUM	CARRY
0	0	0	0
0	1	1	0
1	0	1	0
1	1	0	1

NTS130307

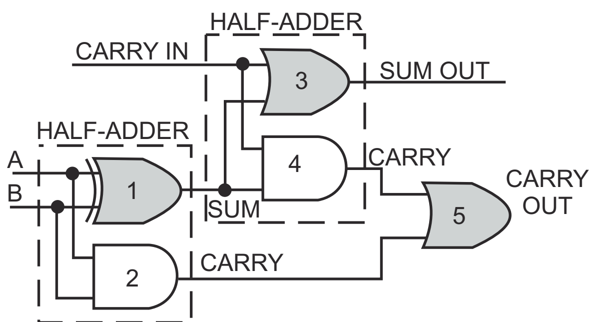
Figure 3-7. —Half adders and Truth Table.

We have seen that the output of the quarter adder is HIGH when either input, but not both, is HIGH. It is only when both inputs are HIGH that the AND gate is activated and a carry is produced. The largest sum that can be obtained from a half adder is 10_2 (1_2 plus 1_2).

FULL ADDER

The full adder becomes necessary when a carry input must be added to the two binary digits to obtain the correct sum. A half adder has no input for carries from previous circuits.

One method of constructing a full adder is to use two half adders and an OR gate as shown in figure 3-8. The inputs A and B are applied to gates 1 and 2. These make up one half adder. The sum output of this half adder and the carry-from a previous circuit become the inputs to the second half adder. The carry from each half adder is applied to gate 5 to produce the carry-out for the circuit.



A	B	CARRY IN	SUM OUT	CARRY OUT
0	0	0	0	0
0	1	0	1	0
1	0	0	1	0
1	1	0	0	1
0	0	1	1	0
0	1	1	0	1
1	0	1	0	1
1	1	1	1	1

NTS130308

Figure 3-8. —Full adder and Truth Table.

Now let's add a series of numbers and see how the circuit operates.

First, let's add 1 and 0. When either A or B is HIGH, gate 1 has an output. This output is applied to gates 3 and 4. Since the carry-in is 0, only gate 3 will produce an output. The sum of 1_2 and 0 is 1_2.

Now let's add 1_2 and 1_2. If A and B are both HIGH, the output of gate 1 is LOW. When the carry-in is 0 (LOW), the output of gate 3 is LOW. Gate 2 produces an output that is applied to gate 5, which produces the carry-out. The sum of 1_2 and 1_2 is 10_2, just as it was for the half adder.

When A and B are both LOW and the carry-in is 1, only gate 3 has an output and produces a sum of 1_2 with no carry-out.

Now, let's add A or B and a carry-in. For example, let's assume that A is HIGH and B is LOW. With these conditions, gate 1 will have an output. This output and the carry-in applied to gates 3 and 4 will produce a sum out of 0 and a carry of 1. This carry from gate 4 will cause gate 5 to produce a carry-out. The sum of A and a carry (1_2 plus 1_2) is 10_2.

When A, B, and the carry-in are all HIGH, a sum of 1 and a carry-out are produced. First, consider A and B. When both are HIGH, the output of gate 1 is LOW, and the output of gate 2 is HIGH, giving us a carry-out at gate 5. The carry-in produces a 1 output at gate 3, giving us a sum of 1. The output of the full adder is 11_2. The sum of 1_2 plus 1_2 plus 1_2 is 11_2.

PARALLEL ADDERS

The adders discussed in the previous section have been limited to adding single-digit binary numbers and carries. The largest sum that can be obtained using a full adder is 11_2.

Parallel adders let us add multiple-digit numbers. If we place full adders in parallel, we can add two- or four-digit numbers or any other size desired.

Figure 3-9 uses STANDARD SYMBOLS to show a parallel adder capable of adding two, two-digit binary numbers. In previous discussions we have depicted circuits with individual logic gates shown. Standard symbols (blocks) allow us to analyze circuits with inputs and outputs only. One standard symbol may actually contain many and various types of gates and circuits. The addend would be input on the A inputs (A_2 = MSD, A_1 = LSD), and the augend input on the B inputs (B_2 = MSD, B_1 = LSD). For this explanation we will assume there is no input to C_0 (carry from a previous circuit).

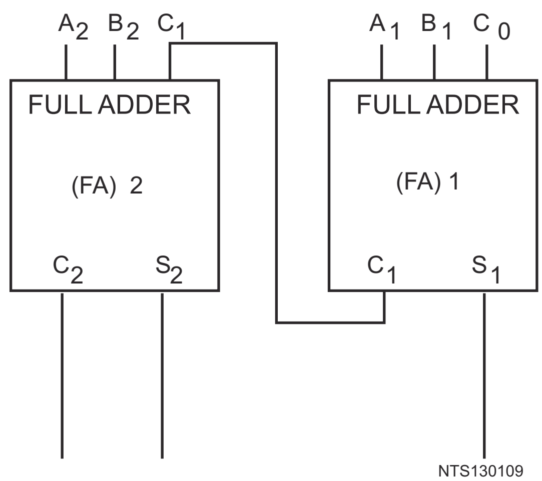


Figure 3-9. —Parallel binary adder.

Now let's add some two-digit numbers. To add 10_2 (addend) and 01_2 (augend), assume there are numbers at the appropriate inputs. The addend inputs will be 1 on A_2 and 0 on A_1. The augend inputs will be 0 on B_2 and 1 on B_1. Working from right to left, as we do in normal addition, let's calculate the outputs of each full adder.

With A_1 at 0 and B_1 at 1, the output of adder 1 will be a sum (S_1) of 1 with no carry (C_1). Since A_2 is 1 and B_2 is 0, we have a sum (S_2) of 1 with no carry (C_2) from adder 1. To determine the sum, read the outputs (C_2, S_2, and S_1) from left to right. In this case, $C_2 = 0$, $S_2 = 1$, and $S_1 = 1$. The sum, then, of 10_2 and 01_2 is 011_2 or 11_2.

To add 11_2 and 01_2, assume one number is applied to A_1 and A_2, and the other to B_1 and B_2, as shown in figure 3-10. Adder 1 produces a sum (S_1) of 0 and a carry (C_1) of 1. Adder 2 gives us a sum (S_2)

of 0 and a carry (C_2) of 1. By reading the outputs (C_2, S_2, and S_1), we see that the sum of 11_2 and 01_2 is 100_2.

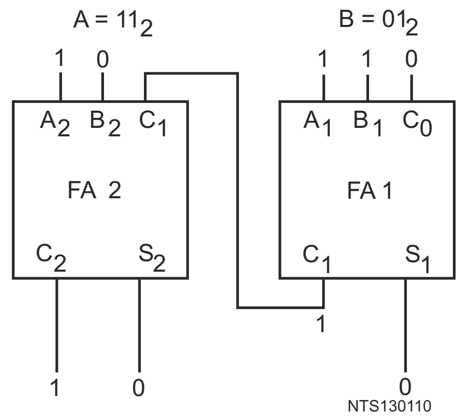

Figure 3-10. —Parallel addition.

As you know, the highest binary number with two digits is 11_2. Using the parallel adder, let's add 11_2 and 11_2.

First, apply the addend and augend to the A and B inputs. Calculate the output of each full adder beginning with full adder 1. With A_1 and B_1 at 1, S_1 is 0 and C_1 is 1. Since all three inputs (A_2, B_2, and C_1) to full adder 2 are 1, the output will be 1 at S_2 and 1 at C_2. The output of the circuit, as you read left to right, is 110_2, the sum of 11_2 and 11_2.

Parallel adders may be expanded by combining more full adders to accommodate the number of digits in the numbers to be added. There must be one full adder for each digit.

Q6. What advantage does a half adder have over a quarter adder?

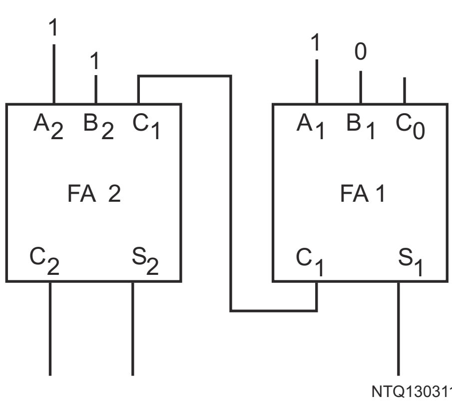
Q7. An X-OR gate may be used as what type of adder?

Q8. What will be the output of a half adder when both inputs are 1s?

Q9. What type of adder is used to handle a carry from a previous circuit?

Q10. How many full adders are required to add four-digit numbers?

Q11. With the inputs shown below, what will be the output of S_1, S_2, and C_2?



Q12. What is the output of C_1?

SUBTRACTION

Subtraction is accomplished in computers by the R's complement and add method. This is the same method you used in chapter 1 to subtract binary numbers.

R's complement subtraction allows us to use fewer circuits than would be required for separate add and subtract functions. Adding X-OR gates to full adders, as shown in figure 3-11, enables the circuit to perform R's complement subtraction as well as addition.

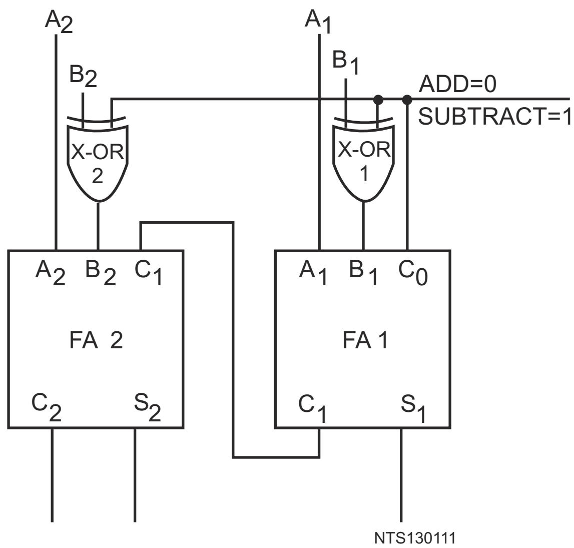


Figure 3-11. —R's complement adder/subtracter.

To add two numbers using this circuit, the addend and augend are applied to the A and B inputs. The B inputs are applied to one input of the X-OR gates. A control signal is applied to the other input of the X-OR gates. When the control signal is LOW, the circuit will add; and when it is HIGH, the circuit will subtract.

In the add mode, the outputs of the X-OR gates will be the same as the B inputs. Addition takes place in the same manner as described in parallel addition.

Before we attempt to show subtraction, let's review R's complement subtraction. To subtract 10_2 from 11_2, write down the minuend (11_2). Perform the R's complement on the subtrahend. Now add the minuend and the complemented subtrahend.

11_2	minuend
$+ \quad 10_2$	R's complement
101	Difference

Disregard the most significant 1, and the difference between 11_2 and 10_2 is 01_2. The most significant 1 will not be used in the example shown in the following paragraph.

Now let's subtract 10_2 from 11_2 using the adder/subtracter circuit. The minuend (11_2) is input on the A terminals, and the subtrahend (10_2) is input on the B terminals. In the subtract mode, a 1 from the control circuit is input to each of the X-OR gates and to the C_0 carry input. By applying a 1 to each of the X-OR gates, you find the output will be the complement of the subtrahend input at B_1 and B_2. Since B_1 is a 0, the output of X-OR 1 will be 1. The input B_2 to X-OR 2 will be inverted to a 0. The HIGH input to C_0 acts as a carry from a previous circuit. The combination of the X-OR gates and the HIGH at C_0 produces the R's complement of the subtrahend. The full adders add the minuend and the R's complement of the subtrahend and produce the difference. The output of C_2 is not used. The outputs of S_2 and S_1 are 0 and 1, respectively, indicating a difference of 01_2. Therefore, 11_2 minus 10_2 equals 01_2.

Q13. What type of logic gates are added to a parallel adder to enable it to subtract?

Q14. How many of these gates would be needed to add a four-digit number?

Q15. In the add mode, what does the output of C_2 indicate?

Q16. In the subtract mode, a 1 at C_0 performs what portion of the R's complement?

Q17. In the subtract mode, which portion of the problem is complemented?

FLIP-FLOPS

Flip-flops (FFs) are devices used in the digital field for a variety of purposes. When properly connected, flip-flops may be used to store data temporarily, to multiply or divide, to count operations, or to receive and transfer information.

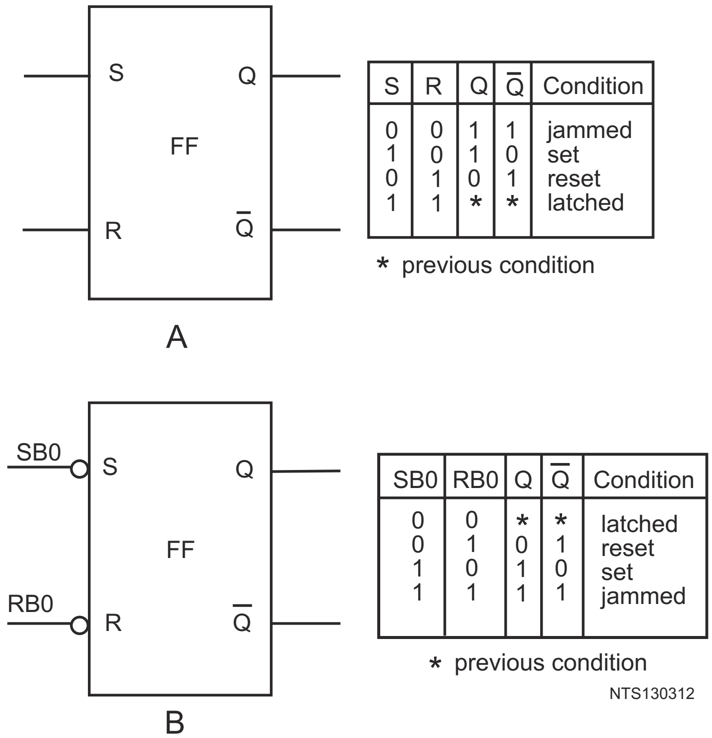
Flip-flops are bistable multivibrators. The types used in digital equipment are identified by the inputs. They may have from two up to five inputs depending on the type. They are all common in one respect. They have two, and only two, distinct output states. The outputs are normally labeled Q and $\overline{Q}$ and should always be complementary. When Q = 1, then $\overline{Q}$ = 0 and vice versa.

In this section we will discuss four types of FFs that are common to digital equipment. They are the R-S, D, T, and J-K FFs.

R-S FLIP-FLOP

The R-S FF is used to temporarily hold or store information until it is needed. A single R-S FF will store one binary digit, either a 1 or a 0. Storing a four-digit binary number would require four R-S FFs.

The standard symbol for the R-S FF is shown in figure 3-12, view A. The name is derived from the inputs, R for reset and S for set. It is often referred to as an R-S LATCH. The outputs Q and $\overline{Q}$ are complements, as mentioned earlier.



S	R	Q	$\overline{Q}$	Condition
0	0	1	1	jammed
1	0	1	0	set
0	1	0	1	reset
1	1	*	*	latched

SB0	RB0	Q	$\overline{Q}$	Condition
0	0	*	*	latched
0	1	0	1	reset
1	0	1	0	set
1	1	1	1	jammed

Figure 3-12. —R-S flip-flop: A. Standard symbol; B. R-S FF with inverted inputs.

The R-S FF has two output conditions. When the Q output is HIGH and $\overline{Q}$ is LOW, the FF is set. When Q is LOW and $\overline{Q}$ is HIGH, the FF is reset. When the R and S inputs are both LOW, the Q and $\overline{Q}$ outputs will both be HIGH. When this condition exists, the FF is considered to be JAMMED and the outputs cannot be used. The jammed condition is corrected when either S or R goes HIGH.

To set the flip-flop requires a HIGH on the S input and a LOW on the R input. To reset, the opposite is required; S input LOW and R input HIGH. When both R and S are HIGH, the FF will hold or "latch" the condition that existed before both inputs went HIGH.

Because the S input of this FF requires a logic LOW to set, a more easily understood symbol is shown in figure 3-12, view B. Refer to this view while reading the following paragraph.

In our description of R-S FF operation, let's assume that the signals applied to the S and R inputs are the LSDs of two different binary numbers. Let's also assume that these two binary numbers represent the speed and range of a target ship. The LSDs will be called SB0 (Speed Bit 0) and RB0 (Range Bit 0) and will be applied to the S and R inputs respectively. Refer to figure 3-12, view B, and figure 3-13. At time T_0, both SB0 and RB0 are HIGH, as a result, both Q and $\overline{Q}$ are HIGH. This is the jammed state and as mentioned earlier, cannot be used in logic circuitry. At T_1, SB0 goes LOW and RB0 remains HIGH; Q goes LOW and $\overline{Q}$ remains HIGH; the FF is reset. At T_2 RB0 goes LOW and SB0 remains LOW; the FF is latched in the reset condition. At T_3, SB0 goes HIGH and RB0 remains LOW; the FF sets. At T_4 SB0 goes LOW and RB0 goes HIGH; the FF resets. When SB0 and RB0 input conditions reverse at T_5, the FF sets. The circuit is put in the latch condition at T_6 when SB0 goes LOW. Notice that the output changes states ONLY when the inputs are in opposite states.

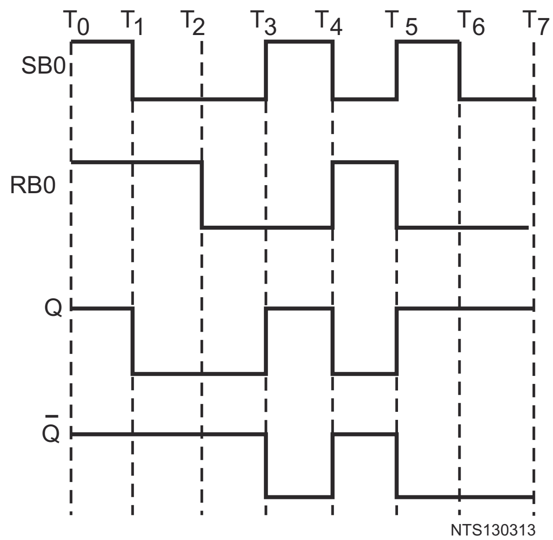


Figure 3-13. —R-S flip-flop with inverted inputs timing diagram.

Figure 3-14 shows two methods of constructing an R-S FF. We can use these diagrams to prove the Truth Table for the R-S FF.

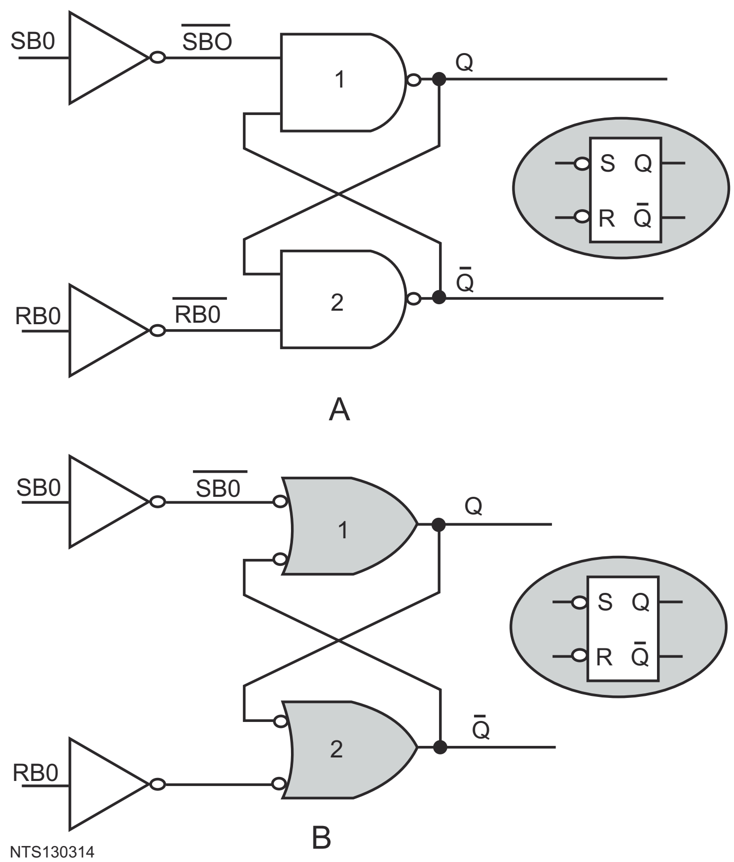

Figure 3-14. —R-S FF construction: A. Using cross-coupled NAND gates; B. Using cross-coupled OR gates.

Look at figure 3-14, view A. Let's assume SB0 is HIGH and RB0 is LOW. You should remember from chapter 2 that the output of an inverter is the complement of the input. In this case, since SB0 is HIGH, $\overline{\text{SBO}}$ will be LOW. The LOW input to NAND gate 1 causes the Q output to go HIGH. This HIGH Q output is also fed to the input of NAND gate 2. The other input to NAND gate 2, $\overline{\text{RBO}}$, is HIGH. With both inputs to gate 2 HIGH, the output goes LOW. The LOW $\overline{\text{Q}}$ output is also fed to NAND gate 1 to be used as the "latch" signal. If SB0 goes LOW while this condition exists, there will be no change to the outputs because the FF would be in the latched condition; both SB0 and RB0 LOW.

When RB0 is HIGH and SB0 is LOW, $\overline{\text{RBO}}$ being LOW drives the output, $\overline{\text{Q}}$, to a HIGH condition. The HIGH $\overline{\text{Q}}$ and HIGH $\overline{\text{SBO}}$ inputs to gate 1 cause the output, Q, to go LOW. This LOW is also fed to NAND gate 2 to be used as the latch signal. Since SB0 is LOW, the FF will again go into the latched mode if RB0 goes LOW.

The cross-coupled OR gates in figure 3-14, view B, perform the same functions as the NAND gate configuration of view A. A HIGH input at SB0 produces a HIGH Q output, and a LOW at RB0 produces a LOW $\overline{\text{Q}}$ output. The cross-coupled signals ($\overline{\text{Q}}$ to gate 1 and Q to gate 2) are used as the latch signals just as in view A. You can trace other changes of the inputs using your knowledge of basic logic gates.

Q18. What are R-S FFs used for?

Q19. How many R-S FFs are required to store the number 100101_2?

Q20. For an R-S FF to change output conditions, the inputs must be in what states?

Q21. How may R-S FFs be constructed?

TOGGLE FLIP-FLOP

The toggle, or T, flip-flop is a bistable device that changes state on command from a common input terminal.

The standard symbol for a T FF is illustrated in figure 3-15, view A. The T input may be preceded by an inverter. An inverter indicates a FF will toggle on a HIGH-to-LOW transition of the input pulse. The absence of an inverter indicates the FF will toggle on a LOW-to-HIGH transition of the pulse.

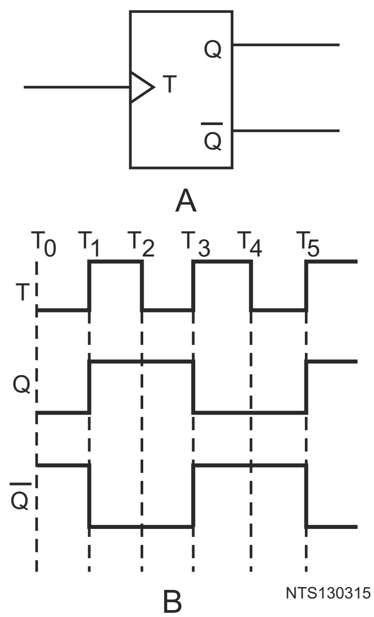

Figure 3-15. —Toggle (T) flip-flop: A. Standard symbol; B. Timing diagram.

The timing diagram in figure 3-15, view B, shows the toggle input and the resulting outputs. We will assume an initial condition (T_0) of Q being LOW and $\overline{Q}$ being HIGH. At T_1, the toggle changes from a LOW to a HIGH and the device changes state; Q goes HIGH and $\overline{Q}$ goes LOW. The outputs remain the same at T_2 since the device is switched only by a LOW-to-HIGH transition. At T_3, when the toggle goes HIGH, Q goes LOW and $\overline{Q}$ goes HIGH; they remain that way until T_5.

Between T_1 and T5, two complete cycles of T occur. During the same time period, only one cycle is observed for Q or $\overline{Q}$. Since the output cycle is one-half the input cycle, this device can be used to divide the input by 2.

The most commonly used T FFs are J-K FFs wired to perform a toggle function. This use will be demonstrated later in this section.

Q22. How many inputs does a T FF have?

Q23. What is the purpose of using T FFs?

D FLIP-FLOP

The D FF is a two-input FF. The inputs are the data (D) input and a clock (CLK) input. The clock is a timing pulse generated by the equipment to control operations. The D FF is used to store data at a predetermined time and hold it until it is needed. This circuit is sometimes called a delay FF. In other words, the data input is delayed up to one clock pulse before it is seen in the output.

The simplest form of a D FF is shown in figure 3-16, view A. Now, follow the explanation of the circuit using the Truth Table and the timing diagram shown in figure 3-16, views B and C.

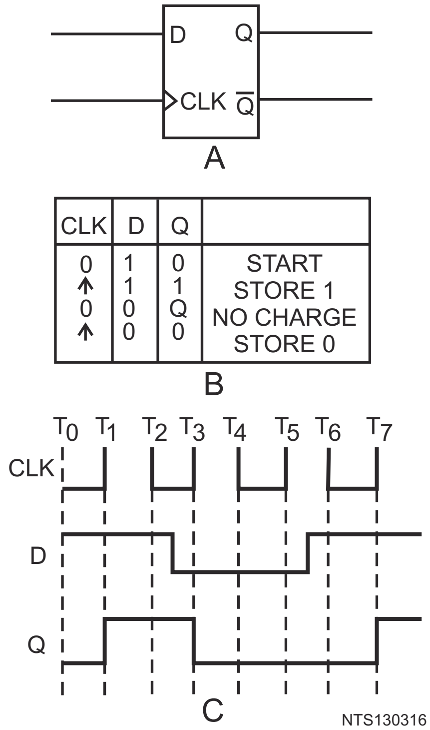

Figure 3-16. —D flip-flop: A. Standard symbol; B. Truth Table; C. Timing diagram.

Depending on the circuit design, the clock (CLK) can be a square wave, a constant frequency, or asymmetrical pulses. In this example the clock (CLK) input will be a constant input at a given frequency. This frequency is determined by the control unit of the equipment. The data (D) input will be present when there is a need to store information. Notice in the Truth Table that output Q reflects the D input only when the clock transitions from 0 to 1 (LOW to HIGH).

Let's assume that at T_0, CLK is 0, D is 1, and Q is 0. Input D remains at 1 for approximately 2 1/2 clock pulses. At T_1, when the clock goes to 1, Q also goes to 1 and remains at 1 even though D goes to 0 between T_2 and T_3. At T_3, the positive-going pulse of the clock causes Q to go to 0, reflecting the condition of D. The positive-going clock pulse at T_5 causes no change in the output because D is still LOW. Between T_5 and T_6, D goes HIGH, but Q remains LOW until T_7 when the clock goes HIGH.

The key to understanding the output of the D FF is to remember that the data (D) input is seen in the output only after the clock has gone HIGH.

You may see D FF symbols with two additional inputs — CLR (clear) and PR (preset). These inputs are used to set the start condition of the FF — CLR sets Q to 0; PR sets Q to 1. Figure 3-17 shows the standard symbol with the CLR and PR inputs. Since these inputs are preceded by inverters (part of the FF), a LOW-going signal is necessary to activate the FF. These signals (CLR and PR) override any existing condition of the output.

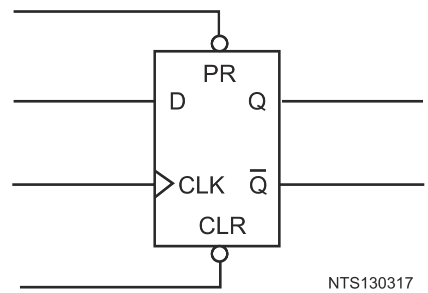

Figure 3-17. —D flip-flop with PR and CLR inputs.

You may also see an inverter at the clock input. In this case, the output will change on the negative-going transition of the clock pulse.

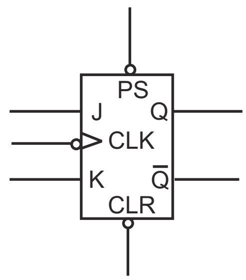
Q24. What are the inputs to a D FF?

Q25. How long is data delayed by a D FF?

Q26. What condition must occur to have a change in the output of a D FF?

J-K FLIP-FLOP

The J-K FF is the most widely used FF because of its versatility. When properly used it may perform the function of an R-S, T, or D FF. The standard symbol for the J-K FF is shown in view A of figure 3-18.

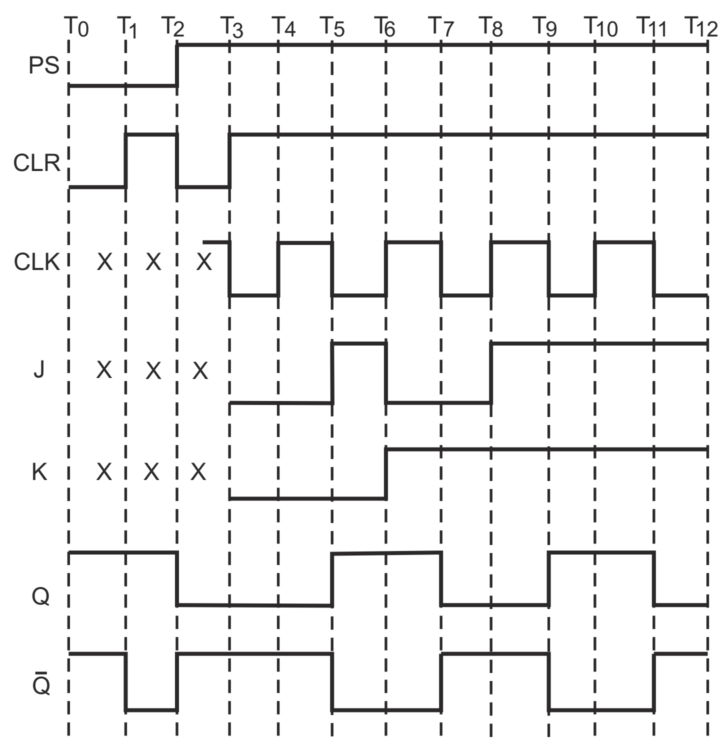


A

	INPUTS					OUTPUTS	
	PRESET	CLEAR	CLOCK	J	K	Q	$\overline{Q}$
1	0	0	X	X	X	1	1
2	0	1	X	X	X	1	0
3	1	0	X	X	X	0	1
4	1	1	↓	0	0	0	$\overline{Q}$
5	1	1	↓	1	0	1	0
6	1	1	↓	0	1	0	1
7	1	1	↓	1	1	TOGGLE	
8	1	1	0	X	X	Q	$\overline{Q}$

X = IRRELEVANT

B



C

Figure 3-18. —J-K flip-flop: A. Standard symbol; B. Truth Table; C. Timing diagram.

The J-K is a five-input device. The J and K inputs are for data. The CLK input is for the clock; and the PS and CLR inputs are the preset and clear inputs, respectively. The outputs Q and $\overline{Q}$ are the normal complementary outputs.

Observe the Truth Table and timing diagram in figure 3-18, views B and C, as the circuit is explained.

Line 1 of the Truth Table corresponds to T_0 in the timing diagram. The PS and CLR inputs are both LOW. The CLK, J, and K inputs are irrelevant. At this point the FF is jammed, and both Q and $\overline{Q}$ are HIGH. As with the R-S FF, this state cannot be used.

At T_1, PS remains LOW while CLR goes HIGH. The Q output remains HIGH and $\overline{Q}$ goes LOW. The FF is in the PRESET condition (line 2 of the Truth Table).

At T_2, PS goes HIGH, CLR goes LOW, Q goes LOW, and $\overline{Q}$ goes HIGH. At this point the FF is CLEARED (line 3 of the Truth Table). The condition of the CLK, J, and K inputs have no effect on the PS and CLR actions since these inputs override the other inputs. Starting at T_3, PS and CLR will be held at HIGHs so as not to override the other actions of the FF. Using the PS and CLR inputs only, the circuit will function as an R-S FF.

Between T_2 and T_3, the CLK input is applied to the device. Since the CLK input has an inverter, all actions will take place on the negative-going transition of the clock pulse.

Line 4 of the Truth Table shows both PS and CLR HIGH, a negative-going CLK, and J and K at 0, or LOW. This corresponds to T_3 on the timing diagram. In this condition the FF holds the previous condition of the output. In this case the FF is reset. If the circuit were set when these inputs occurred, it would remain set.

At time T_5, we have a negative-going clock pulse and a HIGH on the J input. This causes the circuit to set, Q to go HIGH, and $\overline{Q}$ to go LOW. See line 5 of the Truth Table.

At T_6, J goes LOW, K goes HIGH, and the clock is in a positive-going transition. There is no change in the output because all actions take place on the negative clock transition.

At T_7, when J is LOW, K is HIGH; the clock is going negative, the FF resets, Q goes LOW, and $\overline{Q}$ goes HIGH (line 6).

With both J and K HIGH and a negative-going clock (as at T_9 and line 7), the FF will toggle or change state with each clock pulse. It will continue to toggle as long as J and K both remain HIGH.

Line 8 of the Truth Table indicates that as long as the clock is in any condition other than a negative-going transition, there will be no change in the output regardless of the state of J or K.

As mentioned at the beginning of this section, J-K FFs may be used as R-S, T, or D FFs.

Figure 3-19 shows how a J-K can be made to perform the other functions.

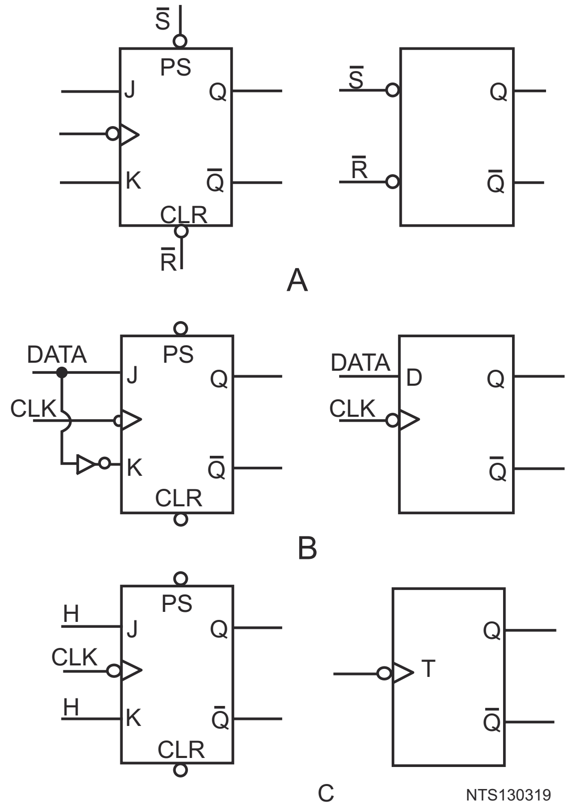


Figure 3-19. —J-K versatility: A. Using just the PS and CLR inputs; B. Data applied to the J input; C. Both J and K inputs held HIGH.

In view A, using just the PS and CLR inputs of the J-K will cause it to react like an R-S FF.

In view B, data is applied to the J input. This same data is applied to the K input through an inverter to ensure that the K input is in the opposite state. In this configuration, the J-K performs the same function as a D FF.

View C shows both the J and K inputs held at 1, or HIGH. The FF will change state or toggle with each negative-going transition of the clock just as a T FF will.

Now you can see the versatility of the J-K FF.

Q27. What type of FF can be used as an R-S, a T, or a D FF?

Q28. What will be the output of Q if J is HIGH, PS and CLR are HIGH, and the clock is going negative?

Q29. Assume that K goes HIGH and J goes LOW; when will the FF reset?

Q30. What logic levels must exist for the FF to be toggled by the clock?

Q31. What two inputs to a J-K FF will override the other inputs?

Q32. How is the J-K FF affected if PS and CLR are both LOW?

CLOCKS AND COUNTERS

Clocks and counters are found in all types of digital equipment. Although they provide different functions, they are all constructed of circuits with which you are familiar. By changing the way the circuits are interconnected, we can build timing circuits, multipliers and dividers, and storage units. In this section we will discuss the purpose, construction, and operation of these important digital circuits.

CLOCKS

Clocks have been mentioned in the preceding section with regard to their action with FFs. You will recall that the clock is a timing signal generated by the equipment to control operations. This control feature is demonstrated in both the D and J-K FFs. Remember that the clock output had to be in a certain condition for the FFs to perform their functions.

The simplest form of a clock is the astable or free-running multivibrator. A schematic diagram of a typical free-running multivibrator is shown in figure 3-20 along with its output waveforms. This multivibrator circuit is called free running because it alternates between two different output voltages during the time it is active. Outputs 1 and 2 will be equal and opposite since Q_1 and Q_2 conduct alternately. The frequency of the outputs may be altered within certain limits by varying the values of R_2C_1 and R_3C_2. You may want to review the operation of the astable multivibrator in NEETS, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*. Although the astable multivibrator circuit seems to produce a good, balanced square wave, it lacks the frequency stability necessary for some types of equipment.

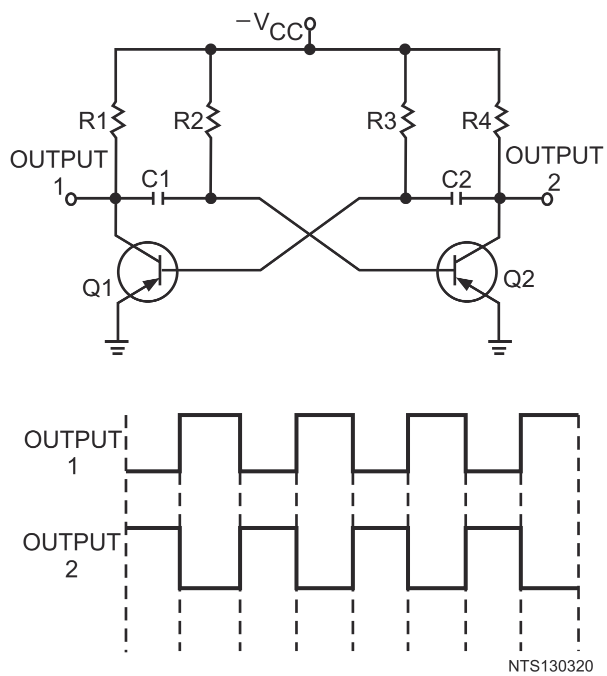

Figure 3-20. —Free-running multivibrator.

The frequency stability of the astable multivibrator can be increased by applying a trigger pulse to the circuit. The frequency of the trigger must be higher than the free-running frequency of the multivibrator. The output frequency will match the trigger frequency and produce a more stable output.

Another method of producing a stable clock pulse is to use a triggered monostable or one-shot multivibrator. You will recall from NEETS, Module 9, that a one-shot multivibrator has one stable state and will only change states when acted on by an outside source (the trigger). A block diagram of a monostable multivibrator with input and output signals is shown in figure 3-21. The duration of the output pulse is dependent on the charge time of an RC network in the multivibrator. Each trigger input results in a complete cycle in the output, as shown in figure 3-21. Trigger pulses are supplied by an oscillator.

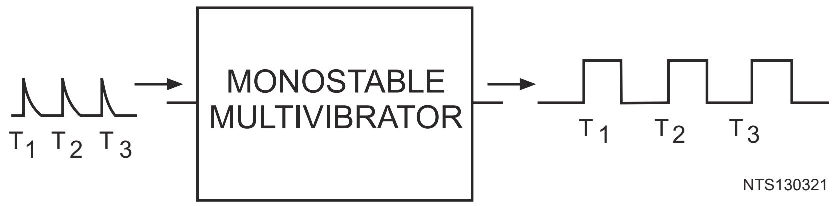

Figure 3-21. —Monostable multivibrator block diagram.

The circuits described previously are very simple clocks. However, as the complexity of the system increases, so do the timing requirements. Complex systems have multiphase clocks to control a variety of operations. Multiphase clocks allow functions involving more than one operation to be completed during a single clock cycle. They also permit an operation to extend over more than one clock cycle.

A block diagram of a two-phase clock system is shown in figure 3-22, view A. The astable multivibrator provides the basic timing for the circuit, while the one-shot multivibrators are used to shape the pulses. Outputs Q and $\overline{Q}$ are input to one-shot multivibrators 1 and 2, respectively. The resulting outputs are in phase with the inputs, but the duration of the pulse is greatly reduced as shown in view B.

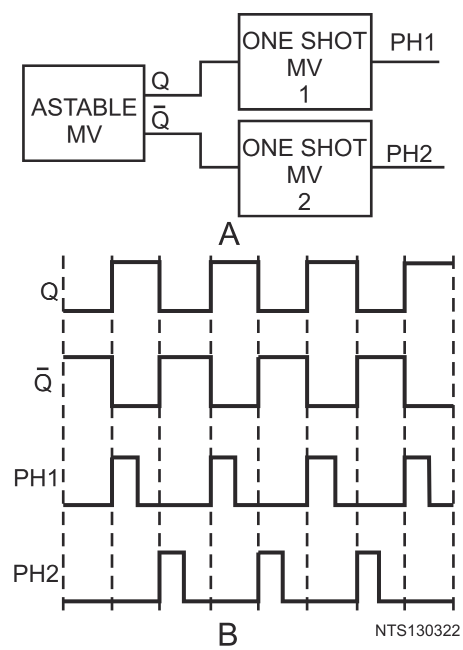

Figure 3-22. —Two-phase clock: A. Block diagram; B. Timing diagram.

Clocks are designed to provide the most efficient operation of the equipment. During the design phase, the frequency, pulse width, and the number of phases required is determined; and the clock circuit is built to meet those requirements.

Most modern high-speed equipment uses crystal-controlled oscillators as the basis for their timing networks. Crystals are stable even at extremely high frequencies.

Q33. What is a clock with regard to digital equipment?

Q34. What is the simplest type of clock circuit?

Q35. What is needed to use a monostable or one-shot multivibrator for a clock circuit?

Q36. What type of clock is used when more than one operation is to be completed during one clock cycle?

COUNTERS

A counter is simply a device that counts. Counters may be used to count operations, quantities, or periods of time. They may also be used for dividing frequencies, for addressing information in storage, or for temporary storage.

Counters are a series of FFs wired together to perform the type of counting desired. They will count up or down by ones, twos, or more.

The total number of counts or stable states a counter can indicate is called MODULUS. For instance, the modulus of a four-stage counter would be 16_{10}, since it is capable of indicating 0000_2 to 1111_2. The term *modulo* is used to describe the count capability of counters; that is, modulo-16 for a four-stage binary counter, modulo-11 for a decade counter, modulo-8 for a three-stage binary counter, and so forth.

Ripple Counters

Ripple counters are so named because the count is like a chain reaction that ripples through the counter because of the time involved. This effect will become more evident with the explanation of the following circuit.

Figure 3-23, view A, shows a basic four-stage, or modulo-16, ripple counter. The inputs and outputs are shown in view B. The four J-K FFs are connected to perform a toggle function; which, you will recall, divides the input by 2. The HIGHs on the J and K inputs enable the FFs to toggle. The inverters on the clock inputs indicate that the FFs change state on the negative-going pulse.

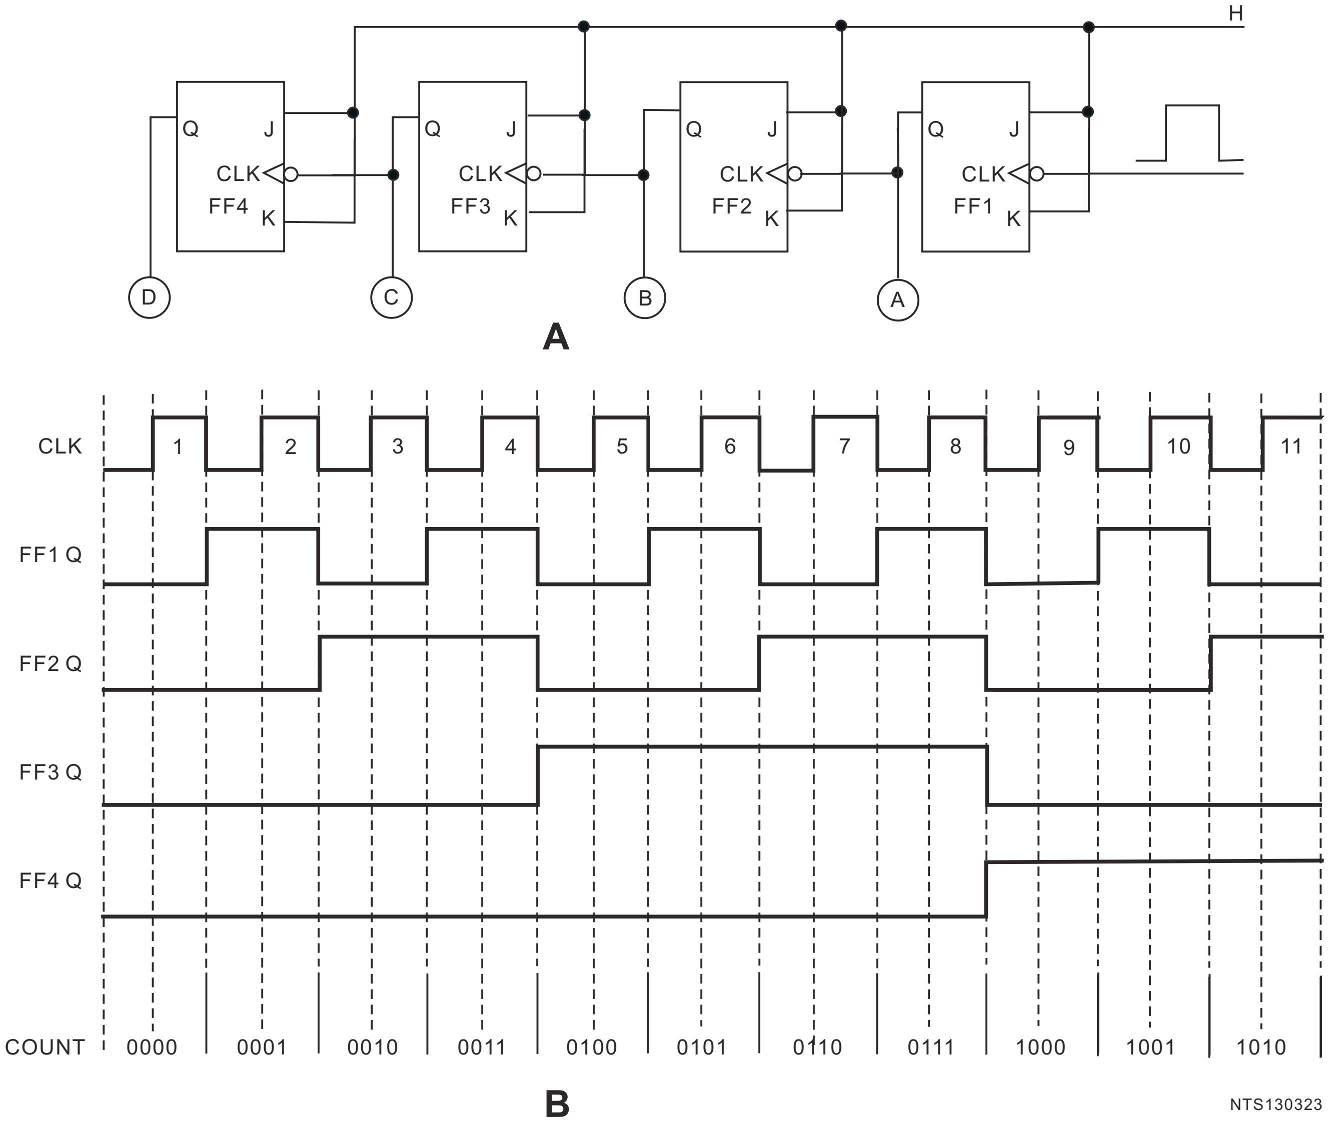

Figure 3-23. —Four-stage ripple counter: A. Logic diagram; B. Timing diagram.

Assume that A, B, C, and D are lamps and that all the FFs are reset. The lamps will all be out, and the count indicated will be 0000_2. The negative-going pulse of clock pulse 1 causes FF1 to set. This lights lamp A, and we have a count of 0001_2. The negative-going pulse of clock pulse 2 toggles FF1, causing it to reset. This negative-going input to FF2 causes it to set and causes B to light. The count after two clock pulses is 0010_2, or 2_{10}. Clock pulse 3 causes FF1 to set and lights lamp A. The setting of FF1 does not affect FF2, and lamp B stays lit. After three clock pulses, the indicated count is 0011_2.

Clock pulse 4 causes FF1 to reset, which causes FF2 to reset, which causes FF3 to set, giving us a count of 0100_2. This step shows the ripple effect.

This setting and resetting of the FFs will continue until all the FFs are set and all the lamps are lit. At that time the count will be 1111_2 or 15_{10}. Clock pulse 16 will cause FF1 to reset and lamp A to go out. This will cause FF2 through FF4 to reset, in order, and will extinguish lamps B, C, and D. The counter would then start at 0001_2 on clock pulse 17. To display a count of 16_{10} or 10000_2, we would need to add another FF.

The ripple counter is also called an ASYNCHRONOUS counter. Asynchronous means that the events (setting and resetting of FFs) occur one after the other rather than all at once. Because the ripple count is asynchronous, it can produce erroneous indications when the clock speed is high. A high-speed clock can cause the lower stage FFs to change state before the upper stages have reacted to the previous clock pulse. The errors are produced by the FFs' inability to keep up with the clock.

Synchronous Counter

High-frequency operations require that all the FFs of a counter be triggered at the same time to prevent errors. We use a SYNCHRONOUS counter for this type of operation.

The synchronous counter is similar to a ripple counter with two exceptions: The clock pulses are applied to each FF, and additional gates are added to ensure that the FFs toggle in the proper sequence.

A logic diagram of a three-state (modulo-8) synchronous counter is shown in figure 3-24, view A. The clock input is wired to each of the FFs to prevent possible errors in the count. A HIGH is wired to the J and K inputs of FF1 to make the FF toggle. The output of FF1 is wired to the J and K inputs of FF2, one input of the AND gate, and indicator A. The output of FF2 is wired to the other input of the AND gate and indicator B. The AND output is connected to the J and K inputs of FF3. The C indicator is the only output of FF3.

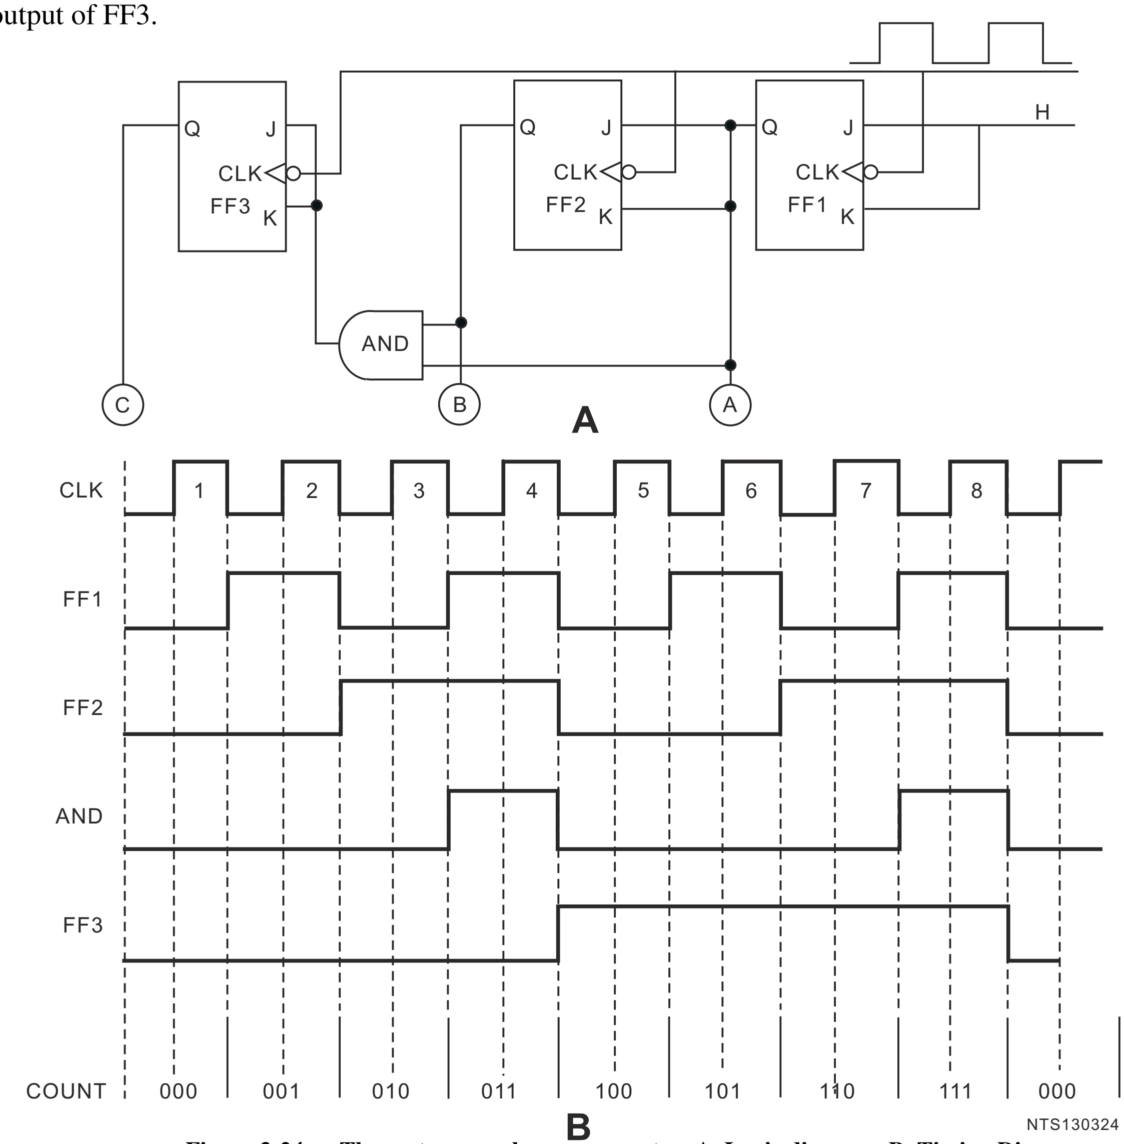

Figure 3-24. —Three-stage synchronous counter: A. Logic diagram; B. Timing Diagram.

During the explanation of this circuit, you should follow the logic diagram, view A, and the pulse sequences, view B.

Assume the following initial conditions: The outputs of all FFs, the clock, and the AND gate are 0; the J and K inputs to FF1 are HIGH. The negative-going portion of the clock pulse will be used throughout the explanation.

Clock pulse 1 causes FF1 to set. This HIGH lights lamp A, indicating a binary count of 001. The HIGH is also applied to the J and K inputs of FF2 and one input of the AND gate. Notice that FF2 and

FF3 are unaffected by the first clock pulse because the J and K inputs were LOW when the clock pulse was applied.

As clock pulse 2 goes LOW, FF1 resets, turning off lamp A. In turn, FF2 will set, lighting lamp B and showing a count of 010_2. The HIGH from FF2 is also felt by the AND gate. The AND gate is not activated at this time because the signal from FF1 is now a LOW. A LOW is present on the J and K inputs of FF3, so it is not toggled by the clock.

Clock pulse 3 toggles FF1 again and lights lamp A. Since the J and K inputs to FF2 were LOW when pulse 3 occurred, FF2 does not toggle but remains set. Lamps A and B are lit, indicating a count of 011_2. With both FF1 and FF2 set, HIGHs are input to both inputs of the AND gate, resulting in HIGHs to J and K of FF3. No change occurred in the output of FF3 on clock pulse 3 because the J and K inputs were LOW at the time.

Just before clock pulse 4 occurs, we have the following conditions: FF1 and FF2 are set, and the AND gate is outputting a HIGH to the J and K inputs of FF3. With these conditions all of the FFs will toggle with the next clock pulse.

At clock pulse 4, FF1 and FF2 are reset, and FF3 sets. The output of the AND gate goes to 0, and we have a count of 100_2.

It appears that the clock pulse and the AND output both go to 0 at the same time, but the clock pulse arrives at FF3 before the AND gate goes LOW because of the transit time of the signal through FF1, FF2, and the AND gate.

Between pulses 4 and 8, FF3 remains set because the J and K inputs are LOW. FF1 and FF2 toggle in the same sequence as they did on clock pulses 1, 2, and 3.

Clock pulse 7 results in all of the FFs being set and the AND gate output being HIGH. Clock pulse 8 causes all the FFs to reset and all the lamps to turn off, indicating a count of 000_2 . The next clock pulse (9) will restart the count sequence.

Q37. What is the modulus of a five-stage binary counter?

Q38. An asynchronous counter is also called a ___________ counter.

Q39. J-K FFs used in counters are wired to perform what function?

Q40. What type of counter has clock pulses applied to all FFs?

Q41. In figure 3-24, view A, what logic element enables FF3 to toggle with the clock?

Q42. What is the largest count that can be indicated by a four-stage counter?

Decade Counter

A decade counter is a binary counter that is designed to count to 10_{10}, or 1010_2. An ordinary four-stage counter can be easily modified to a decade counter by adding a NAND gate as shown in figure 3-25. Notice that FF2 and FF4 provide the inputs to the NAND gate. The NAND gate outputs are connected to the CLR input of each of the FFs.

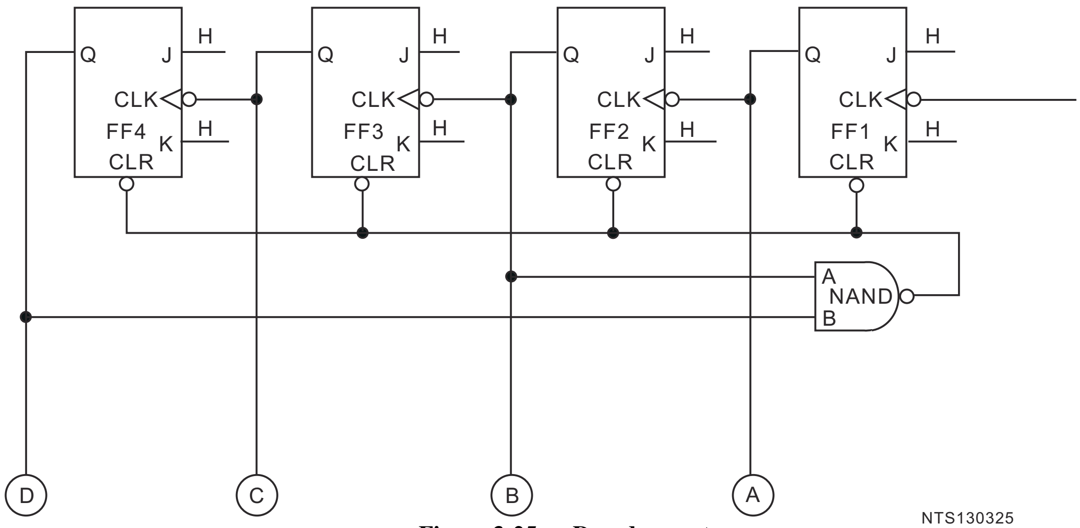

Figure 3-25. —Decade counter.

The counter operates as a normal counter until it reaches a count of 1010_2, or 10_{10}. At that time, both inputs to the NAND gate are HIGH, and the output goes LOW. This LOW applied to the CLR input of the FFs causes them to reset to 0. Remember from the discussion of J-K FFs that CLR and PS or PR override any existing condition of the FF. Once the FFs are reset, the count may begin again. The following table shows the binary count and the inputs and outputs of the NAND gate for each count of the decade counter:

BINARY COUNT	NAND GATE INPUTS		NAND GATE OUTPUT
*******	A	B	*******
0000	0	0	1
0001	0	0	1
0010	1	0	1
0011	1	0	1
0100	0	0	1
0101	0	0	1
0110	1	0	1
0111	1	0	1
1000	0	1	1
1001	0	1	1
1010	1	1	0

Changing the inputs to the NAND gate can cause the maximum count to be changed. For instance, if FF4 and FF3 were wired to the NAND gate, the counter would count to 1100_2 (12_{10}), and then reset.

Q43. How many stages are required for a decade counter?

Q44. In figure 3-25, which two FFs must be HIGH to reset the counter?

Ring Counter

A ring counter is defined as a loop of bistable devices (flip-flops) interconnected in such a manner that only one of the devices may be in a specified state at one time. If the specified condition is HIGH, then only one device may be HIGH at one time. As the clock, or input, signal is received, the specified state will shift to the next device at a rate of 1 shift per clock, or input, pulse.

Figure 3-26, view A, shows a typical four-stage ring counter. This particular counter is composed of R-S FFs. J-K FFs may be used as well. Notice that the output of each AND gate is input to the R, or reset side, of the nearest FF and to the S, or set side, of the next FF. The Q output of each FF is applied to the B input of the AND gate that is connected to its own R input.

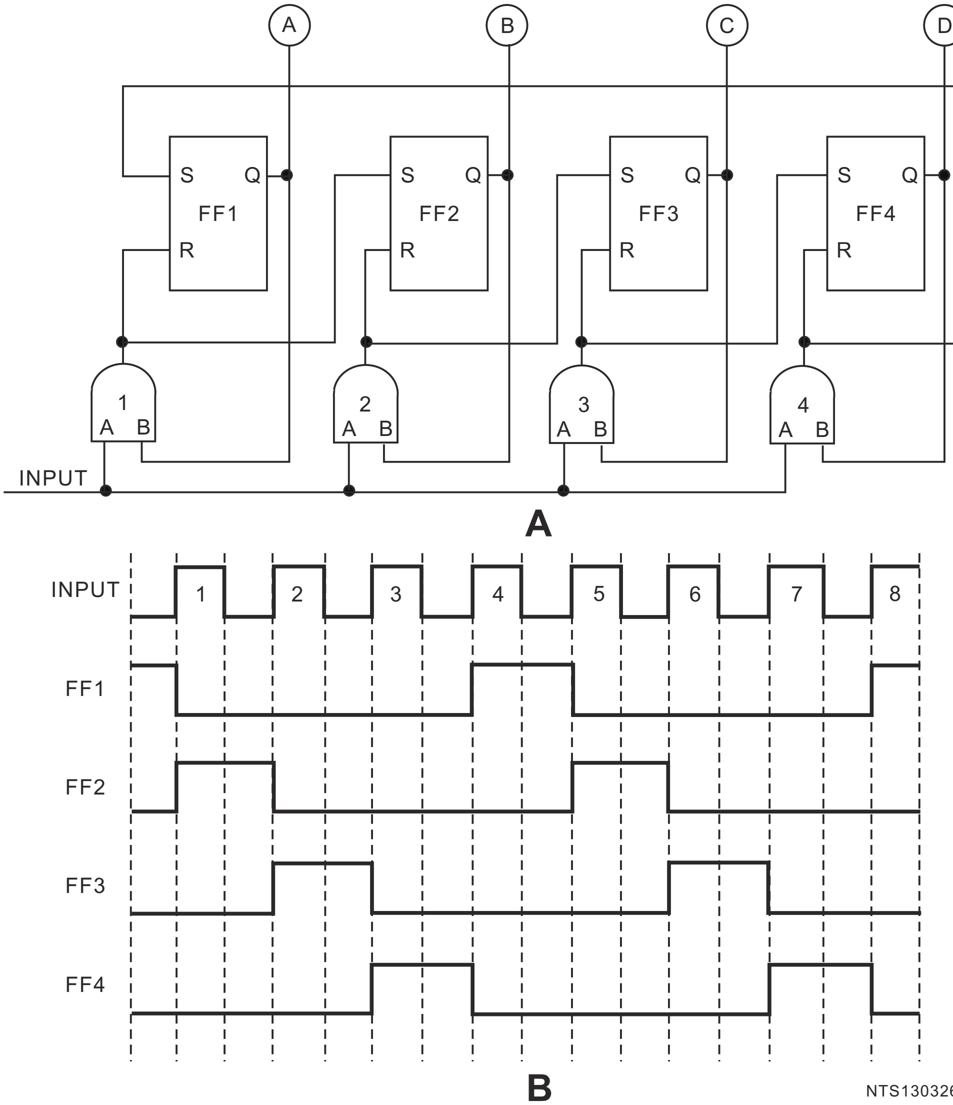

Figure 3-26. —Ring counter: A. Logic diagram; B. Timing diagram.

The circuit input may be normal CLK pulses or pulses from elsewhere in the equipment that would indicate some operation has been completed.

Now, let's look at the circuit operation and observe the signal flow as shown in figure 3-26, view B.

For an initial condition, let's assume that the output of FF1 is HIGH and that the input and FF2, FF3, and FF4 are LOW. Under these conditions, lamp A will be lit; and lamps B, C, and D will be extinguished. The HIGH from FF1 is also applied to the B input of AND gate 1.

The first input pulse is applied to the A input of each of the AND gates. The B inputs to AND gates 2, 3, and 4 are LOW since the outputs of FF2, FF3, and FF4 are LOW. AND gate 1 now has HIGHs on both inputs and produces a HIGH output. This HIGH simultaneously resets FF1 and sets FF2. Lamp A then goes out, and lamp B goes on. We now have a HIGH on AND gate 2 at the B input. We also have a LOW on AND gate 1 at input B.

Input pulse 2 will produce a HIGH output from AND gate 2 since AND gate 2 is the only one with HIGHs on both inputs. The HIGH from AND gate 2 causes FF2 to reset and FF3 to set. Indicator B goes out and C goes on.

Pulse 3 will cause AND gate 3 to go HIGH. This results in FF3 being reset and FF4 being set. Pulse 4 causes FF4 to reset and FF1 to set, bringing the counter full circle to the initial conditions. As long as the counter is operational, it will continue to light the lamps in sequence — 1, 2, 3, 4; 1, 2, 3, 4, etc.

As we stated at the beginning of this section, only one FF may be in the specified condition at one time. The specified condition shifts one position with each input pulse.

Q45. In figure 3-26, view A, which AND gate causes FF3 to set?

Q46. Which AND gate causes FF3 to reset?

Q47. What causes the specified condition to shift position?

Q48. If the specified state is OFF, how many FFs may be off at one time?

Down Counters

Up to this point the counters that you have learned about have been up counters (with the exception of the ring counter). An up counter starts at 0 and counts to a given number. This section will discuss DOWN counters, which start at a given number and count down to 0.

Up counters are sometimes called INCREMENT counters. Increment means to increase. Down counters are called DECREMENT counters. Decrement means to decrease.

A three-stage, ripple down counter is shown in figure 3-27, view A. Notice that the PS (preset) input of the J-K FFs is used in this circuit. HIGHs are applied to all the J and K inputs. This enables the FFs to toggle on the input pulses.

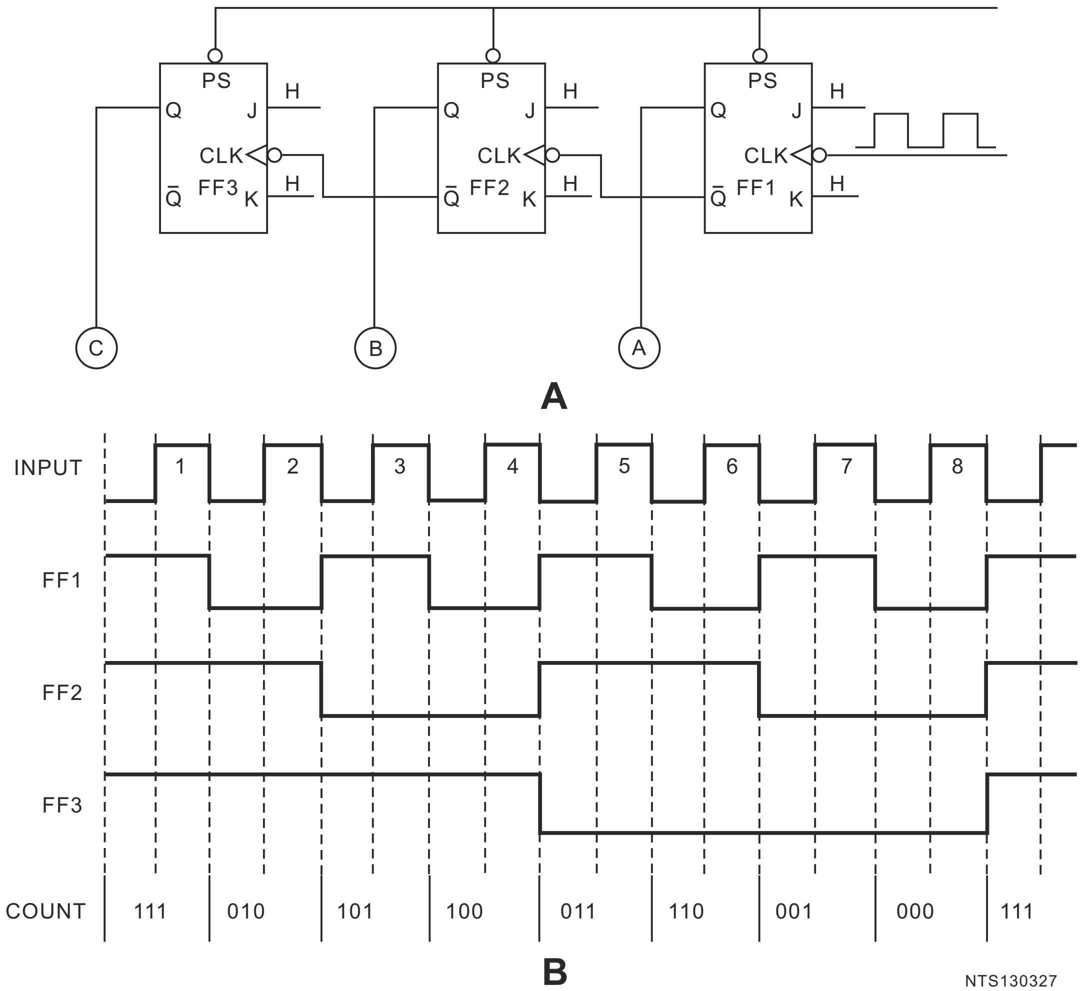

Figure 3-27. —Down counter: A. Logic diagram; B. Timing diagram.

A negative-going pulse is applied to all PS terminals to start the countdown. This causes all the FFs to set and also lights indicators A, B, and C. The beginning count is 111_2 (7_{10}). At the same time, LOWs are applied to the CLK inputs of FF2 and FF3, but they do not toggle because the PS overrides any change. All actions in the counter will take place on the negative-going portion of the input pulse. Let's go through the pulse sequences in figure 3-27, view B.

CP1 causes FF1 to toggle and output Q to go LOW. Lamp A is turned off. Notice that $\overline{Q}$ goes HIGH but no change occurs in FF2 or FF3. Lamps B and C are now on, A is off, and the indicated count is 110_2 (6_{10}).

CP2 toggles FF1 again and lights lamp A. When Q goes HIGH, $\overline{Q}$ goes LOW. This negative-going signal causes FF2 to toggle and reset. Lamp B is turned off, and a HIGH is felt at the CLK input of FF3. The indicated count is 101_2 (5_{10}); lamps A and C are on, and B is off.

At CP3, FF1 toggles and resets. Lamp A is turned off. A positive-going signal is applied to the CLK input of FF2. Lamp B remains off and C remains on. The count at this point is 100_2 (4_{10}).

CP4 toggles FF1 and causes it to set, lighting lamp A. Now FF1, output $\overline{Q}$, goes LOW causing FF2 to toggle. This causes FF2 to set and lights lamp B. Output of FF2, $\overline{Q}$, then goes LOW, which causes FF3 to reset and turn off lamp C. The indicated count is now 011_2 (3_{10}).

The next pulse, CP5, turns off lamp A but leaves B on. The count is now 010_2. CP6 turns on lamp A and turns off lamp B, for a count of 001_2. CP7 turns off lamp A. Now all the lamps are off, and the counter indicates 000.

On the negative-going signal of CP8, all FFs are set, and all the lamps are lighted. The CLK pulse toggles FF1, making output Q go HIGH. As output $\overline{Q}$ goes LOW, the negative-going signal causes FF2 to toggle. As FF2, output Q, goes HIGH, output $\overline{Q}$ goes LOW, causing FF3 to toggle and set. As each FF sets, its indicator lamp lights. The counter is now ready to again start counting down from 111_2 with the next CLK pulse.

Q49. How many FFs are required to count down from 15_{10}?

Q50. What signal causes FF2 to toggle?

REGISTERS

A register is a temporary storage device. Registers are used to store data, memory addresses, and operation codes. Registers are normally referred to by the number of stages they contain or by the number of bits they will store. For instance, an eight-stage register would be called an 8-bit register. The contents of the register is also called a WORD. The contents of an 8-bit register is an 8-bit word. The contents of a 4-bit register is a 4-bit word and so forth.

Registers are also used in the transfer of data to and from input and output devices such as teletypes, printers, and cathode-ray tubes.

Most registers are constructed of FFs and associated circuitry. They permit us to load or store data and to transfer the data at the proper time.

PARALLEL REGISTERS

Parallel registers are designed to receive or transfer all bits of data or information simultaneously.

A 4-bit parallel register is shown in figure 3-28. The data inputs are A, B, C, and D. The FFs store the data until it is needed. AND gates 5, 6, 7, and 8 are the transfer gates.

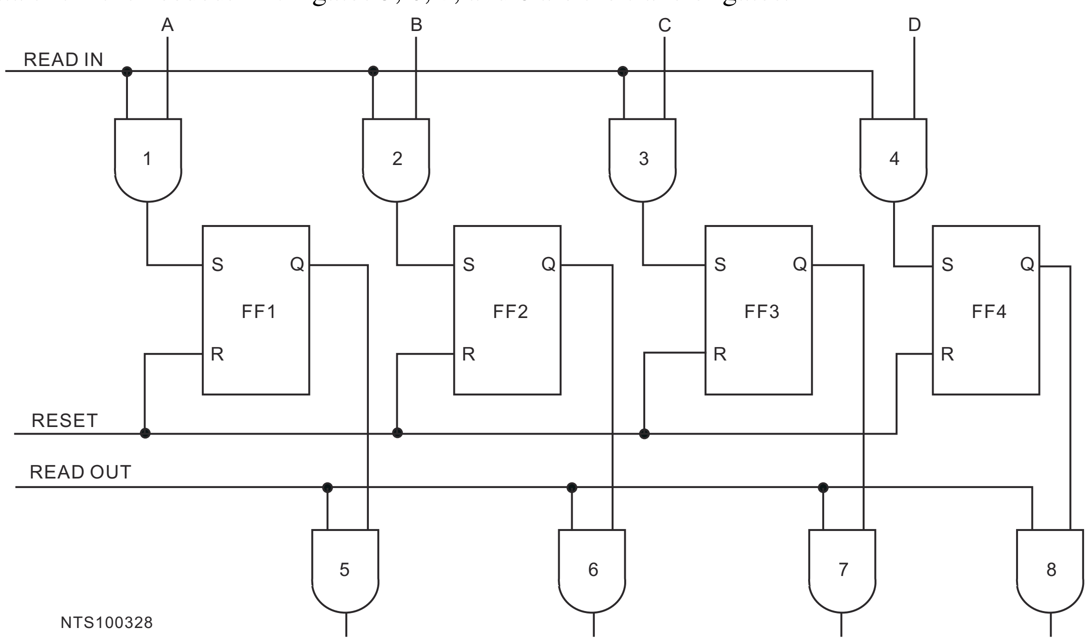

Figure 3-28. —Four-bit parallel register.

Before we go through the operation of the register, let's set some initial conditions. Assume that inputs A, B, and D are HIGH and that FF2 and FF4 are set from a previous operation. The READ IN, READ OUT, and RESET inputs are all LOW.

To begin the operation, we apply a reset pulse to the RESET input of all the FFs, clearing the Q outputs to LOWs. This step ensures against any erroneous data transfer that would occur because of the states of FF2 and FF4.

Inputs A, B, C, and D are input to gates 1, 2, 3, and 4, respectively. When the READ IN input goes HIGH, AND gates 1, 2, and 4 go HIGH, causing FF1, FF2, and FF4 to set. The output of AND gate 3 does not change since the C input is LOW. The 4-bit word, 1101, is now stored in the register. The outputs of FFs 1, 2, 3, and 4 are applied to AND gates 5, 6, 7, and 8, respectively.

When the data is required for some other operation, a positive-going pulse is applied to the READ OUT inputs of the AND gates. This HIGH, along with the HIGHs from the FFs, causes the outputs of AND gates 5, 6, and 8 to go HIGH. Since the Q output of FF3 is LOW, the output of gate 7 will be LOW. The 4-bit word, 1101, is transferred to where it is needed.

Q51. How many stages are required to store a 16-bit word?

Q52. Simultaneous transfer of data may be accomplished with what type of register?

Q53. How are erroneous transfers of data prevented?

SHIFT REGISTERS

A shift register is a register in which the contents may be shifted one or more places to the left or right. This type of register is capable of performing a variety of functions. It may be used for serial-to-parallel conversion and for scaling binary numbers.

Before we get into the operation of the shift register, let's discuss serial-to-parallel conversion, parallel-to-serial conversion, and scaling.

Serial and Parallel Transfers and Conversion

Serial and parallel are terms used to describe the method in which data or information is moved from one place to another. **SERIAL TRANSFER** means that the data is moved along a single line one bit at a time. A control pulse is required to move each bit. **PARALLEL TRANSFER** means that each bit of data is moved on its own line and that all bits transfer simultaneously as they did in the parallel register. A single control pulse is required to move all bits.

Figure 3-29 shows how both of these transfers occur. In each case, the four-bit word 1101 is being transferred to a storage device. In view A, the data moves along a single line. Each bit of the data will be stored by an individual control pulse. In view B, each bit has a separate input line. One control pulse will cause the entire word to be stored.

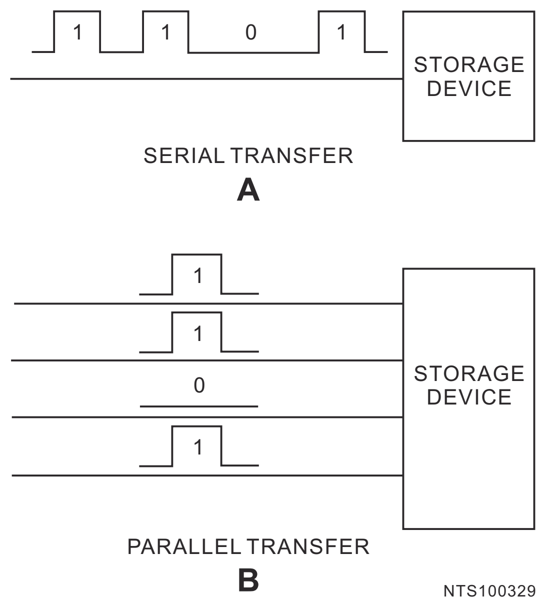

Figure 3-29. —Data transfer methods: A. Serial transfer; B. Parallel transfer.

Serial-to-parallel conversion or parallel-to-serial conversion describes the manner in which data is stored in a storage device and the manner in which that data is removed from the storage device.

Serial-to-parallel conversion means that data is transferred into the storage device or register in serial fashion and removed in parallel fashion, as in figure 3-30, view A. Parallel-to-serial conversion means the data is transferred into the storage device in parallel and removed as serial data, as shown in view B.

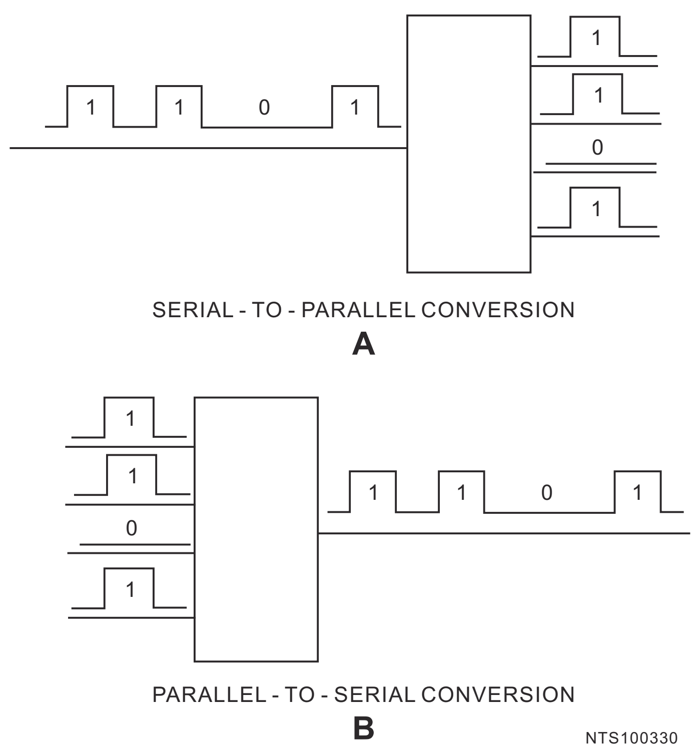

Figure 3-30. —Data conversion methods: A. Serial-to-parallel; B. Parallel-to-serial.

Serial transfer takes time. The longer the word length, the longer the transfer will take. Although parallel transfer is much faster, it requires more circuitry to transfer the data.

Scaling

SCALING means to change the magnitude of a number. Shifting binary numbers to the left increases their value, and shifting to the right decreases their value. The increase or decrease in value is based on powers of 2.

A shift of one place to the left increases the value by a power of 2, which in effect is multiplying the number by 2. To demonstrate this, let's assume that the following block diagram is a 5-bit shift register containing the binary number 01100.

0	1	1	0	0

Shifting the entire number one place to the left will put the register in the following condition:

1	1	0	0	0

The binary number 01100 has a decimal equivalent of 12. If we convert 11000_2 to decimal, we find it has a value of 24_{10}. By shifting the number one place to the left, we have multiplied it by 2. A shift of two places to the left would be the equivalent of multiplying the number by 2^2, or 4; three places by 2^3, or 8; and so forth.

Shifting a binary number to the right decreases the value of the number by a power of 2 for each place. Let's look at the same 5-bit register containing 01100_2 and shift the number to the right.

0	1	1	0	0

A shift of one place to the right will result in the register being in the following condition:

0	0	1	1	0

By comparing decimal equivalents you can see that we have decreased the value from 12_{10} to 6_{10}. We have effectively divided the number by 2. A shift of two places to the right is the equivalent of dividing the number by 2^2, or 4; three places by 2^3; or 8; and so forth.

Shift Register Operations

Figure 3-31shows a typical 4-bit shift register. This particular register is capable of left shifts only. There are provisions for serial and parallel input and serial and parallel output. Additional circuitry would be required to make right shifts possible.

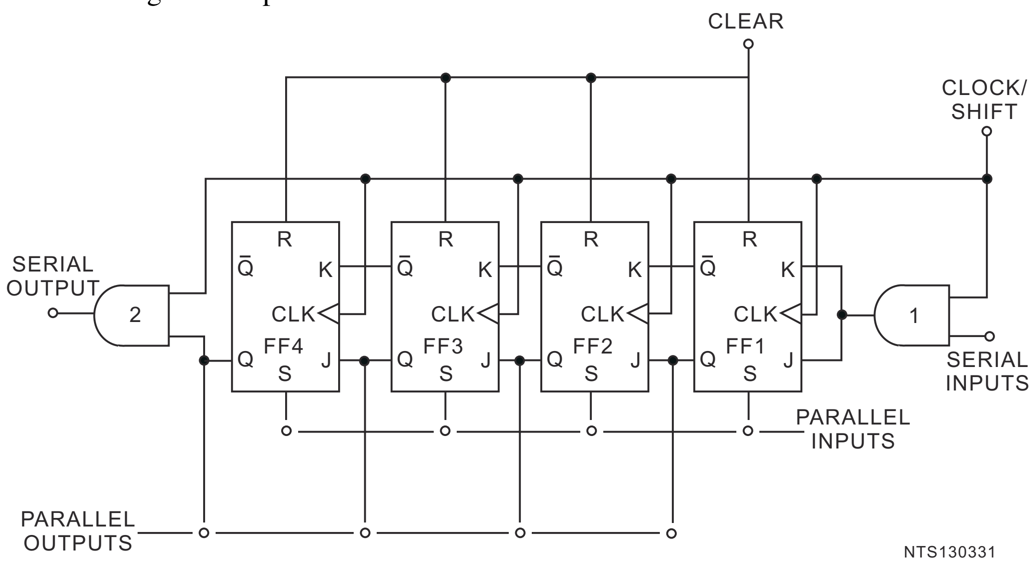

Figure 3-31. —Shift register.

Before any operation takes place, a CLEAR pulse is applied to the RESET terminal of each FF to ensure that the Q output is LOW.

The simplest modes of operation for this register are the parallel inputs and outputs. Parallel data is applied to the SET inputs of the FFs and results in either a 1 or 0 output, depending on the input. The outputs of the FFs may be sampled for parallel output. In this mode, the register functions just like the parallel register covered earlier in this section.

Parallel-to-Serial Conversion

Now let's look at parallel-to-serial conversion. We will use the 4-bit shift register in figure 3-31 and the timing sequence in figure 3-32 to aid you in understanding the operations.

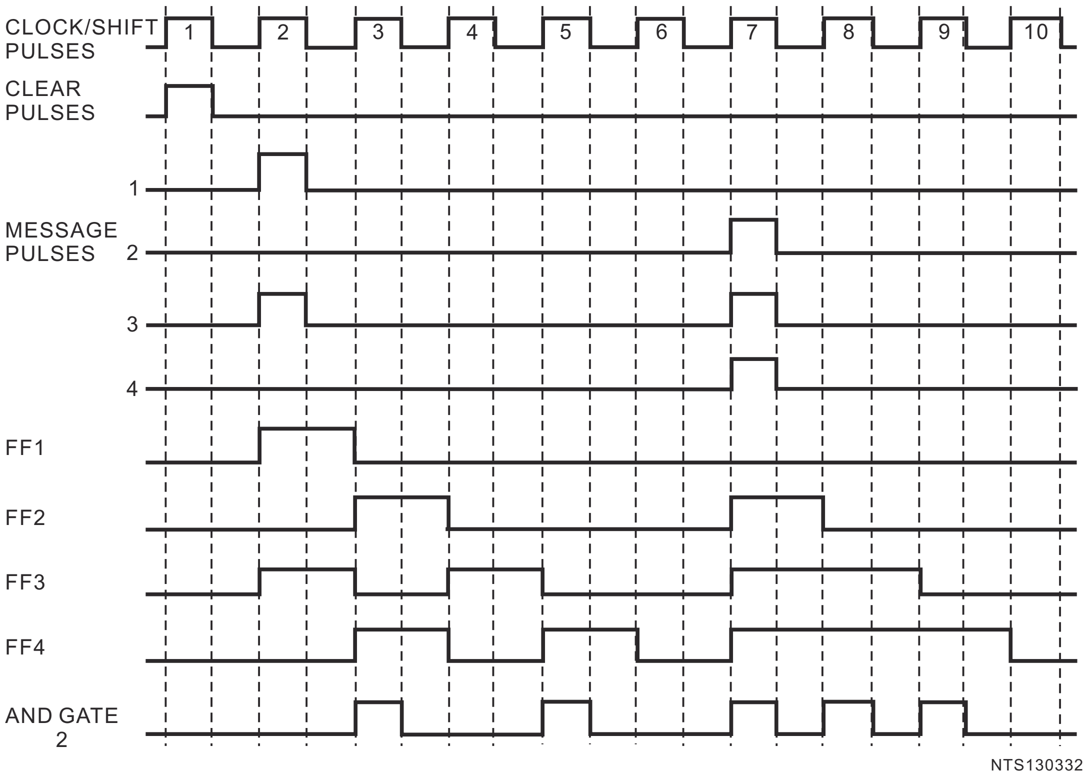

Figure 3-32. —Parallel-to-serial conversion timing diagram.

At CP1, a CLEAR pulse is applied to all the FFs, resetting the register to a count of 0. The number 0101_2 is applied to the parallel inputs at CP2, causing FF1 and FF3 to set. At this point, the J inputs of FF2 and FF4 are HIGH. AND gate 2 has a LOW output since the FF4 output is LOW. This LOW output represents the first digit of the number 0101_2 to be output in serial form. At the same time we have HIGHs on the K inputs of FF1 and FF3. (Notice the NOT symbol on FF1 at input K. With no serial input to AND gate 1, the output is LOW; therefore, the K input to FF1 is held HIGH). With these conditions CP3 causes FF1 and FF3 to reset and FF2 and FF4 to set. The HIGH output of FF4, along with CP3, causes AND gate 2 to output a HIGH. This represents the second digit of the number 0101_2.

At CP4, FF2 and FF4 reset, and FF3 sets. FF1 remains reset because of the HIGH at the K input. The output of AND gate 2 goes LOW because the output of FF4 is LOW and the third digit of the number is output on the serial line. CP5 causes FF4 to set and FF3 to reset. CP5 and the HIGH from FF4 cause AND gate 2 to output the last digit of the number on the serial line. It took a total of four CLK pulses to input the number in parallel and output it in serial.

CP6 causes FF4 to reset and effectively clears the register for the next parallel input.

Between CP7 and CP10, the number 1110_2 is input as parallel data and output as serial data.

Serial-to-Parallel Conversion

Serial input is accomplished much in the same manner as serial output. Instead of shifting the data out one bit at a time, we shift the data in one bit at a time.

To understand this conversion, you should again use figure 3-31and also the timing diagram shown in figure 3-33. In this example we will convert the number 1011_2 from serial data to parallel data.

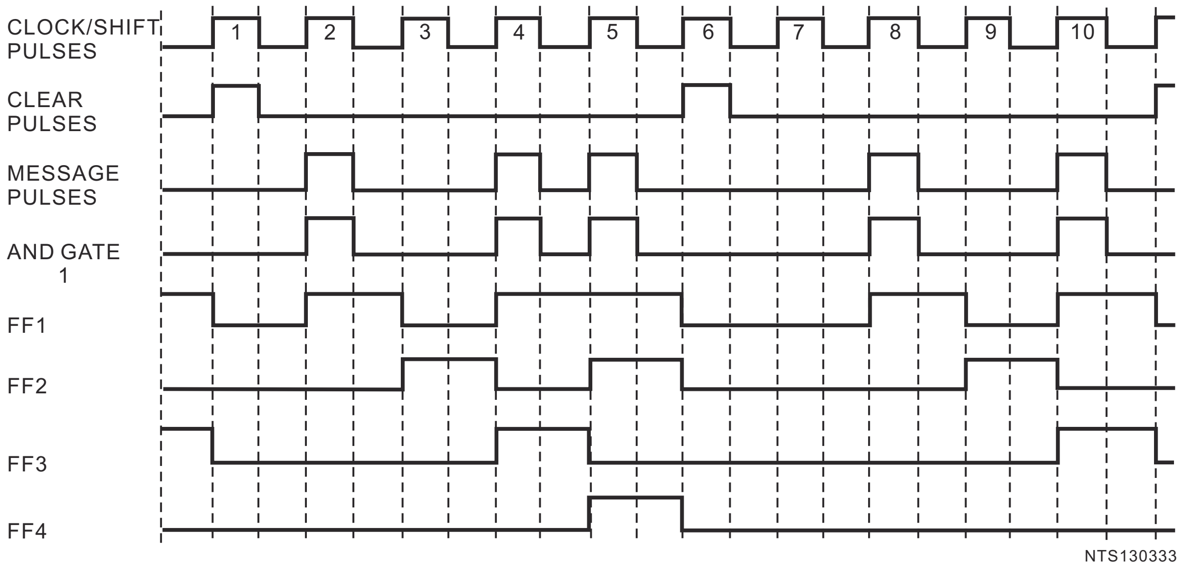

Figure 3-33. —Serial-to-parallel conversion timing diagram.

A CLEAR pulse resets all the FFs at CP1. At CP2, the most significant bit of the data is input to AND gate 1. This HIGH along with the clock pulse causes AND gate 1 to output a HIGH. The HIGH from the AND gate and the clock pulse applied to FF1 cause the FF to set. FFs 2, 3, and 4 are held reset. At this point, the MSD of the data has been shifted into the register.

The next bit of data is a 0. The output of AND gate 1 is LOW. Because of the inverter on the K input of FF1, the FF senses a HIGH at that input and resets. At the same time this is occurring, the HIGH on the J input of FF2 (from FF1) and the CLK cause FF2 to set. The two MSDs, 1 and 0, are now in the register.

CP4 causes FF3 to set and FF2 to reset. FF1 is set by the CLK pulse and the third bit of the number. The register now contains 0101_2, as a result of shifting the first three bits of data.

The remaining bit is shifted into the register by CP5. FF1 remains set, FF2 sets, FF3 resets, and FF4 sets. At this point, the serial transfer is complete. The binary word can be sampled on the parallel output lines. Once the parallel data is transferred, a CLEAR pulse resets the FFs (CP6), and the register is ready to input the next word.

Scaling Operation

Using the shift register shown in figure 3-31 for scaling a number is quite simple. The number to be scaled is loaded into the register either in serial or parallel form. Once the data is in the register, the scaling takes place in the same manner as that for shifting the data for serial output. A single clock pulse will cause each bit of data to shift one place to the left. Remember that each shift is the equivalent of increasing the value by a power of 2. The scaled data is read from the parallel outputs. Care must be taken not to over shift the data to the point that the MSDs are shifted out of the register.

Q54. Serial-to-parallel and parallel-to-serial conversions are accomplished by what type of circuit?

Q55. What type of data transfer requires the most time?

Q56. What is the main disadvantage of parallel transfer?

Q57. How many FFs would be required for an 8-bit shift register?

Q58. How many clock pulses are required to output a 4-bit number in serial form?

Q59. Two shifts to the left are equal to increasing the magnitude of a number by how much?

Q60. To increase the magnitude of a number by 2^3, you must shift the number how many times and in what direction?

LOGIC FAMILIES

Logic families are groups of logic circuits that are based on particular types of elements (resistors, transistors, and so forth). Families are identified by the manner in which the elements are connected, and, in some cases, by the types of elements used.

Logic circuits of a particular family can be interconnected without having to use additional circuitry. In other words, the output of one logic circuit can be used as the input to another logic circuit. This feature is known as compatibility. All circuits within a logic family will be compatible with the other circuits within that family.

As a technician, your responsibility will be to identify defective parts and repair or replace them as required. It will be beneficial for you to have a basic knowledge of the types of logic that are used in digital equipment.

Logic circuits are usually manufactured as integrated circuits and packaged in dual-inline packages (DIP), modified transistor outlines (TO), or flat packs. These packaging techniques are described in NEETS, Module 7, *Introduction to Solid-State Devices and Power Supplies.*

Circuitry in a package is normally shown using standard logic symbols instead of individual components such as transistors, diodes, and so forth. Figure 3-34 shows four examples of this type of packaging. The numbered blocks (1-14 and 1-16) are the pins on the package. Circuit packages are also identified by a manufacturer's part number. Similar circuits produced by different manufacturers will not carry the same identification numbers in all cases.

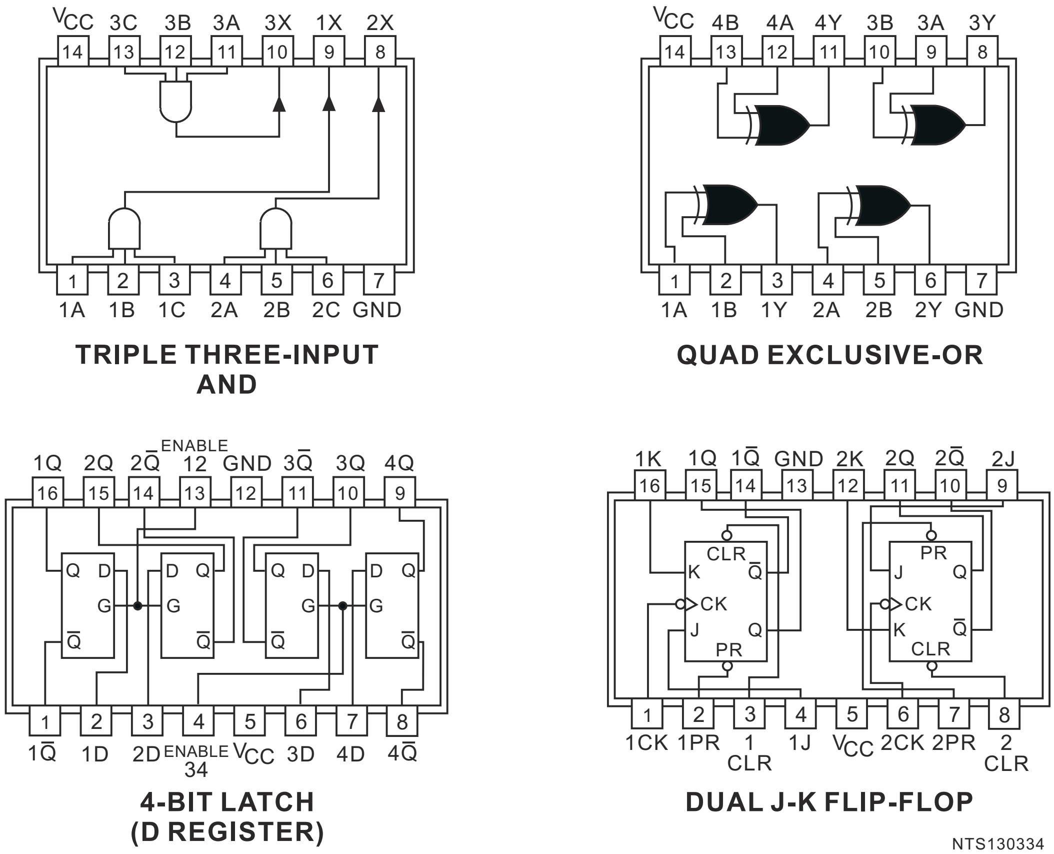

Figure 3-34. —Logic packages.

As mentioned before, logic families are identified by the elements used and the manner in which the elements are used. A brief description of some of the more common logic families follows.

RTL (RESISTOR-TRANSISTOR LOGIC)

In this type of logic, inputs are applied to resistors, and the output is produced by a transistor. RTL is normally constructed from discrete components (individual resistors and transistors). Some circuits are manufactured as integrated circuits and packaged in modified transistor outline (TO) packages, as shown in figure 3-35. An in-depth coverage of circuit packaging can be found in NEETS, Module 14, *Introduction to Microelectronics*.

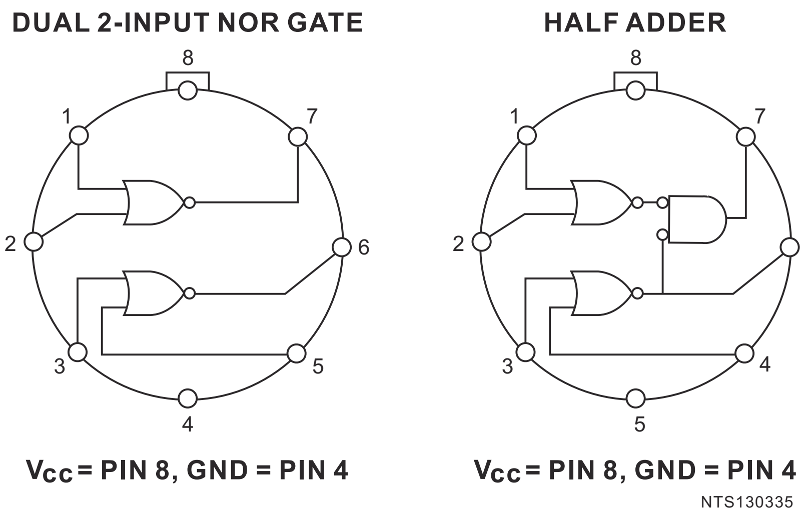

Figure 3-35. —RTL integrated circuits.

DTL (DIODE TRANSISTOR LOGIC)

Input signals are applied to diodes in this logic family. The diodes either conduct or cut off and produce the desired output from the transistor. DTL is normally found in dual-inline packages (DIP) as well as older discrete component logic.

TTL (TRANSISTOR-TRANSISTOR LOGIC)

In TTL, transistors with multiple emitters are used for the logic inputs. Additional transistors are used to produce the desired output. TTL is normally packed in DIPs and is quite common in military equipment.

CMOS (COMPLEMENTARY METAL OXIDE SEMICONDUCTORS)

The CMOS logic circuits use metal oxide semiconductors similar to field-effect transistors (FETs).

LOGIC FAMILY USE

The logic family used in a piece of equipment is determined by the design engineers. The type of logic used will be based on the requirements of the equipment and on what family best fulfills the requirements.

The use of integrated circuits enables designers to produce equipment that is very small and highly efficient when compared to other methods of construction. The block diagram shown in figure 3-36, view A, represents an 8-bit, serial-input and parallel-output shift register. This circuit is contained in a standard 14-pin DIP measuring about 0.75 inch long and 0.25 inch wide. View B shows this circuit package.

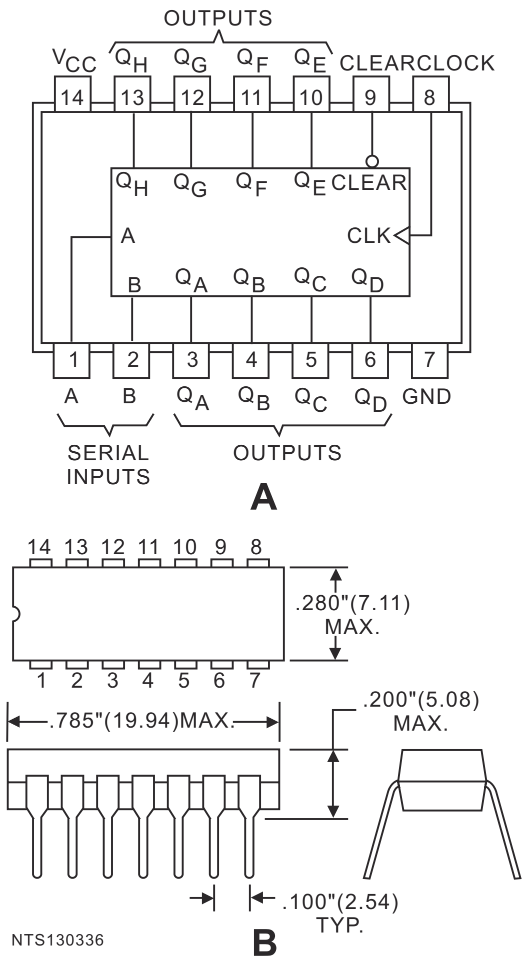

Figure 3-36. —Integrated logic circuits: A. Shift register; B. Logic package.

Q61. What are RTL, DTL, and TTL examples of?

Q62. What type of logic family uses diodes in the input?

Q63. What is the most common type of integrated circuit packaging found in military equipment?

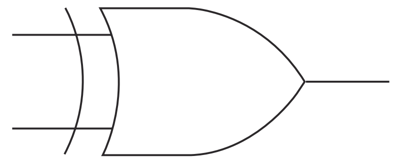
Q64. Circuits that can be interconnected without additional circuitry are known as ____________ circuits.

SUMMARY

Now that you have completed this chapter, you should have a basic understanding of the more common special logic circuits. The following is a summary of the emphasized terms and points found in the "Special Logic Circuits" chapter.

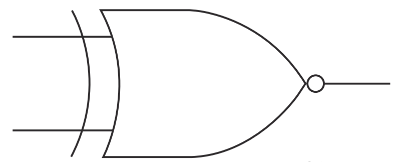
SPECIAL LOGIC CIRCUITS perform arithmetic and logic operations; input, output, store and transfer information; and provide proper timing for these operations.

EXCLUSIVE OR (X-OR) circuits produce a 1 output when ONLY one input is HIGH. Can be used as a quarter adder.



NTS130337

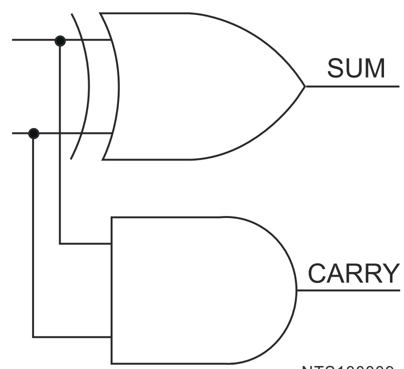
EXCLUSIVE NOR (X-NOR) circuits produce a 1 output when all inputs are 0 and when more than 1 input is 1.



NTS130338

QUARTER ADDER circuits produce the sum of two numbers but do not generate a carry.

HALF ADDER circuits produce the sum of two numbers and generate a carry.



NTS130339

FULL ADDER circuits add a carry to obtain the correct sum.

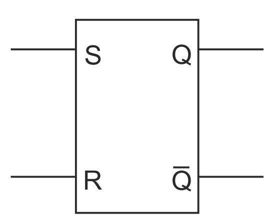
PARALLEL ADDER circuits use full adders connected in parallel to accommodate the addition of multiple-digit numbers.

STANDARD SYMBOLS depict logic circuitry with blocks, showing only inputs and outputs. One block may contain many types of gates and circuits.

SUBTRACTION in binary is accomplished by complementing and adding.

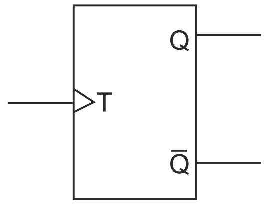
FLIP-FLOP are bistable multivibrators used for storage, timing, arithmetic operations, and transfer of information.

R-S FFs have the Q output of the FF HIGH in the set mode and LOW in the reset mode.



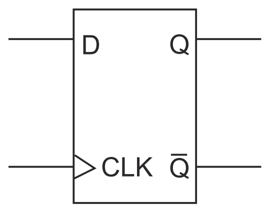
NTS130340A

T (TOGGLE) FF$_S$ change state with each pulse applied to the input. Each T FF will divide the input by 2.



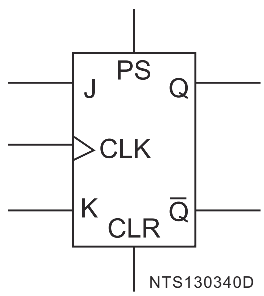
NTS130340B

D FF is used to store data at a predetermined time.



NTS130340C

J-K FF is the most versatile FF. J-Ks can perform the same functions as all the other FFs.



NTS130340D

CLOCKS are circuits that generate the timing and control signals for other operations.

COUNTERS are used to count operations, quantities, or periods of time. They can be used to divide frequencies, to address information in storage, or as temporary storage.

MODULUS of a counter is the total number of counts or stable states a counter may indicate.

UP COUNTERS count from 0 to a predetermined number.

DOWN COUNTERS count from a predetermined number to 0.

RING COUNTERS are loop counters that may be used for timing operations.

REGISTERS are used as temporary storage devices as well as for transfer of information.

PARALLEL REGISTERS receive or transfer all bits of data simultaneously.

SHIFT REGISTERS are used to perform serial-to-parallel and parallel-to-serial conversion and for scaling binary numbers.

SERIAL TRANSFER causes all bits of data to be transferred on a single line.

PARALLEL TRANSFER has each data bit on its own line.

SCALING of binary numbers means to increase or decrease the magnitude of a number by a power of 2.

LOGIC FAMILIES are composed of logic circuits based on particular types of elements.

ANSWERS TO QUESTIONS Q1. THROUGH Q64.

A1. ⊕.

A2. Low (0).

A3. One or the other of the inputs must be HIGH, but not both at the same time.

A4. Exclusive NOR (X-NOR).

A5. HIGH.

A6. The half adder generates a carry.

A7. Quarter adder.

A8. Sum equals 0 with a carry of 1.

A9. Full adder.

A10. Four.

A11. $S_1 = 1$, $S_2 = 0$ *and* $C_2 = 1$.

A12. $C_1 = 0$.

A13. X-OR gates.

A14. Four.

A15. MSD of the sum.

A16. Add 1 portion.

A17. Subtrahend.

A18. Storing information.

A19. Six.

A20. 1 and 0, or opposite states.

A21. By cross-coupling NAND or OR gates.

A22. One.

A23. To divide the input by 2.

A24. Clock and data.

A25. Up to one clock pulse.

A26. A positive-going clock pulse.

A27. J-K flip-flop.

A28. Set, or HIGH (1).

A29. When the clock pulse goes LOW.

A30. Both J and K must be HIGH.

A31. Clear (CLR) and preset (PS or PR).

A32. The flip-flop is jammed.

A33. A timing signal.

A34. An astable or free-running multivibrator.

A35. Triggers.

A36. A multiphase clock.

A37. 32.

A38. Ripple.

A39. Toggle.

A40. Synchronous.

A41. The AND gate.

A42. 1111_2, *or* 15_{10}.

A43. Four.

A44. FFs 2 and 4.

A45. Two.

A46. Three.

A47. The input, or clock pulse.

A48. One.

A49. Four.

A50. $\overline{Q}$ *output of FF 1 going LOW.*

A51. 16.

A52. Parallel.

A53. By clearing the register.

A54. Shift register.

A55. Serial.

A56. Requires more circuitry.

A57. Eight.

A58. Four.

A59. 2^2*, or four times.*

A60. Three to the left.

A61. Logic families.

A62. DTL (diode transistor logic).

A63. DIPs (dual inline packages).

A64. Compatible.

APPENDIX I

GLOSSARY

ADDEND —A number to be added to an augend.

ADDITION —A form of counting where on quantity is added to another.

AND GATE —A logic circuit in which all inputs must be HIGH to produce a HIGH output.

ASSOCIATIVE LAW —A simple equality statement A(BC) = ABC or A+(B+C) = A+B+C.

AUGEND —A number to which another number is to be added.

BASE —The number of symbols used in the particular number system.

BCD (BINARY CODED DECIMAL) —A method of using binary digits to represent the decimal digits 0 through 9.

BINARY SYSTEM —The base 2 number system using 0 and 1 as the symbols.

BOOLEAN ALGEBRA —A mathematical concept based on the assumption that most quantities have two possible conditions —TRUE and FALSE.

BOOLEAN EXPRESSION —A description of the input or output conditions of a logic gate.

BORROW —To transfer a digit (equal to the base of the number system) from the next higher order column for the purpose of subtraction.

CARRY —A carry is produced when the sum of two or more numbers in a vertical column equals or exceeds the base of the number system in use.

CLOCK —A circuit that generates timing control signals in a computer or other type of digital equipment.

COMMUTATIVE LAW —The order in which terms are written does not affect their value; AB = BA, A+B = B+A.

COMPATIBILITY —The feature of logic families that allows interconnection of circuits without the need for additional circuitry.

COMPLEMENT —Something used to complete something else.

COMPLEMENTARY LAW —A term ANDed with its complement is 0, and a term ORed with its complement is 1; $A\overline{A} = 0$, $A + \overline{A} = 1$.

CONVERSION —To change a number in one base to its equivalent in another base.

COUNTER —A device that counts.

D FLIP-FLOP —Stores the data bit (D) in conjunction with the clock input.

DECADE COUNTER —Counter from 0 to 10_{10} in base 2, then resets.

DECIMAL POINT —The radix point for the decimal system.

DECIMAL SYSTEM —A number system with a base or radix of 10.

DEMORGAN'S THEOREM —This theorem has two parts: the first states that $\overline{AB} = \overline{A} + \overline{B}$; the second states that $\overline{A + B} = \overline{A}\ \overline{B}$.

DIFFERENCE —That which is left after subtraction.

DISTRIBUTIVE LAW —(1) a term (A) ANDed with a parenthetical expression (B+C) equals that term ANDed with each term within the parenthesis: A(B+C) = AB+AC; (2) a term (A) ORed with a parenthetical expression (BC) equals that term ORed with each term within the parenthesis: A+(BC) = (A+B)(A+C).

DIVIDEND —A number to be divided.

DIVISOR —A number by which a dividend is divided.

DOUBLE NEGATIVE LAW —A term that is inverted twice is equal to the term; $\overline{\overline{A}} = A$.

DOWN COUNTER—A circuit that counts from a predetermined number down to 0.

EXCLUSIVE-NOR (X-NOR) —A logic circuit that produces a HIGH output when all inputs are LOW or all inputs are HIGH.

EXCLUSIVE-OR (X-OR) GATE —A logic circuit that produces a HIGH output when one and only one input is HIGH.

EXPONENT —A number above and to the right of a base indicating the number of time the base is multiplied by itself; $2^4 = 2 \times 2 \times 2 \times 2$.

FLIP-FLOP —A bistable multivibrator.

FRACTIONAL NUMBER —A symbol to the right of the radix point that represents a portion of a complete object.

HEXADECIMAL (HEX) SYSTEM —The base 16 number system using 0 through 9 and A, B, C, D, E, and F as symbols.

IDEMPOTENT LAW —States that a term ANDed with itself or ORed with itself is equal to the term; AA = A, A+A = A.

INVERTER —A logic gate that outputs the complement of its input.

J-K FLIP-FLOP —Can perform the functions of the RS, T, and D flip-flops.

LAW OF ABSORPTION —This law is the result of the application of several other laws. It states that A(A+B) = A or A+(AB) = A.

LAW OF COMMON IDENTITIES —The two statements $A(\overline{A}+B) = AB$ and $A+\overline{A}B = A+B$ are based on the complementary law.

LAW OF IDENTITY —States that a term TRUE in one part of an expression will be TRUE in all parts of the expression; A = A, $\overline{A} = \overline{A}$.

LAW OF INTERSECTION —A term ANDed with 1 equals that term, and a term ANDed with 0 equals 0; $A \cdot 1 = A$, $A \cdot 0 = 0$.

LAW OF UNION —A term ORed with 1 equals 1; a term ORed with 0 equals that term; A+1 = 1, A + 0 = 0.

LEAST SIGNIFICANT (LSD) —The digit which has the least effect on the value of a number.

LOGIC —The science of reasoning; the development of a reasonable or logical conclusion based on known information.

LOGIC FAMILY —A group of logic circuits based on specific types of circuit elements (DTL, TTL, CMOS, and so forth).

LOGIC GATES —Decision-making circuits in computers and other types of equipment.

LOGIC POLARITY —The polarity of a voltage used to represent the logic 1 state.

LOGIC SYMBOL —Standard symbol used to indicate a particular logic function.

MINUEND —The number from which another number is subtracted.

MIXED NUMBER —Represents one or more complete units and a portion of a single unit.

MODULUS —The number of different values that a counter can contain or display.

MOST SIGNIFICANT DIGIT (MSD) —The digit which if changed will have the greatest effect on the value of a number.

NAND GATE —An AND gate with an inverted output. The output is LOW when all inputs are HIGH, and HIGH when any or all inputs are LOW.

NEGATIVE LOGIC —The voltage representing logic state 1 is more negative that the voltage representing a logic state 0.

NEGATOR —See inverter.

NOR GATE —An OR gate with an inverted output. The output is LOW when any or all inputs are HIGH, and HIGH when all inputs are LOW.

NOT CIRCUIT —See inverter.

NUMBER —A symbol used to represent a unit or a quantity.

OCTAL SYSTEM —The base 8 number system using 0 through 7 as the symbols.

OR GATE —A logic circuit which produces a HIGH output when one or more inputs is/are HIGH.

PARALLEL DATA —Each bit of data has a separate line and all bits are moved simultaneously.

PARALLEL REGISTER —A register that receives, stores, and transfers data in a parallel mode.

POSITIONAL NOTATION —A method where the value of the number is defined by the symbol and the symbol's position.

POSITIVE LOGIC —The voltage representing logic state 1 is more positive than the voltage representing a logic state 0.

POWER OF A NUMBER —The number of times a base is multiplied by itself. The power of a base is indicated by the exponent; that is, $10^3 = 10 \times 10 \times 10$.

QUOTIENT —The result in division.

RADIX POINT —The symbol that separates whole numbers and fractional numbers.

RADIX —The total number of symbols used in a particular number system.

REGISTER —A circuit of flip-flops designed to receive, store, and transfer data.

REMAINDER —The final undivided part that is less than the divisor.

RING COUNTER —A loop in which only one flip-flop will be set at any given time; used in timing.

RIPPLE (ASYNCHRONOUS) COUNTER —A circuit that counts from 0 to a specified value. Subject to error at high frequency.

R's (RADIX) COMPLEMENT —The difference between a given number and the next higher power of the number system (1000_8 minus 254_8 equals 524_8).

R's-1 (RADIX-1) COMPLEMENT —The difference between a given number and the highest value symbol in the number system (777_8 minus 254_8 equals 524_8).

R-S FLIP-FLOP —A flip-flop with two inputs —S (set) and R (reset). The Q output is HIGH in the set mode and LOW in the reset mode.

SERIAL DATA —All data bits are transferred one bit at a time along a single conductor.

SHIFT REGISTER —A register capable of serial-to-parallel and parallel-to-serial conversion and scaling.

SHIFTING —Moving the contents of a register right or left to scale the number or to input or output serial data.

SUBSCRIPT —A number written below and to the right of a value indicating the base or radix of the number system in use (35_8).

SUBTRACTION —Taking away one number from another.

SUBTRAHEND —The quantity to be subtracted from the minuend.

SUM —The result in addition.

SYNCHRONOUS COUNTER —Performs the same function as a ripple counter but error free at high frequency.

T FLIP-FLOP —A single input flip-flop that changes state with each positive pulse or each negative pulse. Divides input frequency by two.

TRUTH TABLE —A chart showing all possible input combinations and the resultant outputs.

UNIT —A single object.

UP/DOWN COUNTER —A counter circuit that can count up or down on command.

VINCULUM —A bar over a logic statement indicating the FALSE condition of the statement.

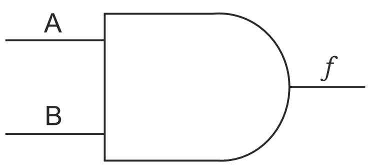
WHOLE NUMBER —A symbol that represents one or more complete objects.

ZERO —A symbol that indicates no numerical value for a position in positional notation.

APPENDIX II

LOGIC SYMBOLS

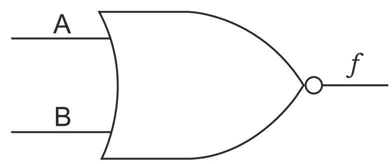
AND



A	B	f
0	0	0
0	1	0
1	0	0
1	1	1

$f = AB$

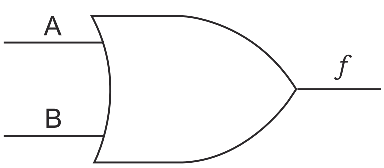
NOR



A	B	f
0	0	1
0	1	0
1	0	0
1	1	0

$f = \overline{A + B}$

OR



A	B	f
0	0	0
0	1	1
1	0	1
1	1	1

$f = A + B$

EXCLUSIVE-OR

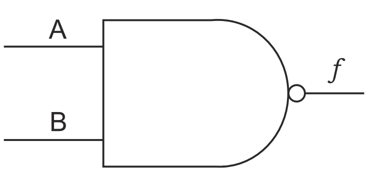
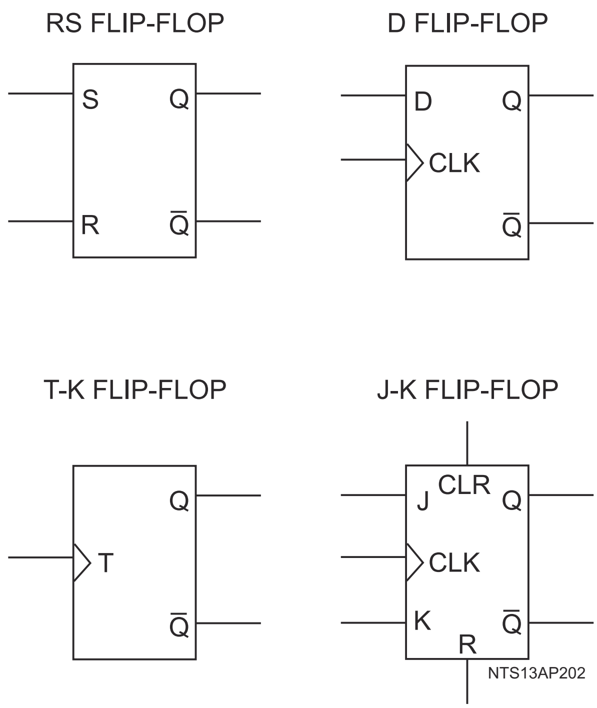
NAND



A	B	f
0	0	1
0	1	1
1	0	1
1	1	0

$f = \overline{AB}$

Logic Symbols (Cont'd)



MODULE 13

INDEX

ASSIGNMENT 1

Textbook Assignment: "Number Systems," chapter 1, pages 1-1 through 1-69.

1-1. Modern number systems are built around which of the following components?

1. Unit, number, and radix
2. Number, base, and radix
3. Position, power, and unit
4. Digit, power, and position

1-2. What term describes a single object in a modern number system?

1. Unit
2. Base
3. Digit
4. Number

1-3. What is a number?

1. A quantity of objects
2. A counting system based on symbols
3. The decimal system
4. A symbol representing a unit or a quantity

1-4. Which of the following symbols is NOT an Arabic figure?

1. C
2. 2
3. 7
4. 9

1-5. What term describes the number of symbols used in a number system?

1. Power
2. Radix
3. Exponent
4. Subscript

1-6. What is the base of a number system using all the letters of the alphabet —A=0, B=1, C=2, and so forth?

1. 29
2. 25
3. 28
4. 26

1-7. A number system uses the symbols 0 through 4. What is its base?

1. 6
2. 5
3. 3
4. 4

1-8. Using positional notation, what two factors determine the value of a number?

1. Symbol and position
2. Position and base
3. Radix and symbol
4. Unit and symbol

1-9. How many decimal units are represented by the 5 in the number 1572_{10}?

1. 100
2. 50
3. 500
4. 5000

1-10. The 1 in 1572_{10} is equal to what power of ten?

1. 10^1
2. 10^2
3. 10^3
4. 10^4

1-11. The power of a number is indicated by the

1. subscript
2. exponent
3. radical
4. radix

1-12. What is the value of 5 times 10^0?

1. 1
2. 0.5
3. 5
4. 50

1-13. Which of the following numbers is a mixed number?

1. 14.03
2. 156
3. 1,257
4. .0004

1-14. What term describes the symbol that separates the whole and fractional numbers in any number system?

1. Exponent
2. Radix point
3. Decimal point
4. Position point

1-15. What is the MSD of (a) 0.4201, (b) 13, and (c) 32.06?

1. (a) 4 (b) 1 (c) 3
2. (a) 1 (b) 3 (c) 2
3. (a) 2 (b) 1 (c) 2
4. (a) 4 (b) 3 (c) 3

1-16. What term is defined as a number to be added to a preceding number?

1. Addend
2. Augend
3. Carry
4. Sum

1-17. Identify A through D in the following example.

$$\begin{array}{rl} 1 & -\text{A} \\ 25 & -\text{B} \\ \underline{+\ 17} & -\text{C} \\ 42 & -\text{D} \end{array}$$

1. Addend, sum, carry, augend
2. Carry, augend, addend, sum
3. Augend, carry, sum, addend
4. Carry, augend, sum, addend

IN ANSWERING QUESTION 1-18, PERFORM THE INDICATED OPERATION.

1-18. Add:

$$\begin{array}{r} 326_{10} \\ \underline{+\ 192_{10}} \end{array}$$

1. 418
2. 508
3. 528
4. 518

1-19. In subtraction, the (a) is subtracted from the (b).

1. (a) Minuend (b) subtrahend
2. (a) Remainder (b) subtrahend
3. (a) Subtrahend (b) difference
4. (a) Subtrahend (b) minuend

1-20. A borrow is required in which of the following examples?

1. $\begin{array}{r} 64 \\ \underline{-\ 59} \end{array}$

2. $\begin{array}{r} 32 \\ \underline{-\ 12} \end{array}$

3. $\begin{array}{r} 59 \\ \underline{-\ 17} \end{array}$

4. $\begin{array}{r} 29 \\ \underline{-\ 11} \end{array}$

1-21. The result of subtraction is known as the

1. addend
2. quotient
3. difference
4. subtrahend

1-22. What are the (a) radix and (b) the symbols used in the binary number system?

1. (a) 1 (b) 0, 1
2. (a) 2 (b) 1, 0
3. (a) 3 (b) 0, 1, 2
4. (a) 0 (b) 1, 2

1-23. Positional notation for the binary system is based on powers of

1. 1
2. 2
3. 3
4. 0

1-24. What is the decimal equivalent of 2^3?

1. 6
2. 2
3. 8
4. 10

1-25. The decimal number 1 is equal to what power of two?

1. 2^1
2. 2^2
3. 2^3
4. 2^0

1-26. Which of the following powers of two indicates a fraction?

1. 2^1
2. 2^0
3. 2^{-2}
4. 2^2

1-27. Which digit is the MSD in the binary number 1011001?

1. The 0 farthest to the left
2. The 1 farthest to the left
3. The 0 farthest to the right
4. The 1 farthest to the right

1-28. Which of the following combinations of binary addition is INCORRECT?

1. 1 + 1 = 1 with a carry
2. 1 + 0 = 1
3. 0 + 0 = 0
4. 0 + 1 = 1

IN ANSWERING QUESTIONS 1-29 THROUGH 1-33, PERFORM THE INDICATED OPERATION.

1-29. Add:

$$\begin{array}{r} 10010_2 \\ \underline{+\quad 1010_2} \end{array}$$

1. 10000_2
2. 11100_2
3. 10101_2
4. 11010_2

1-30. Add:

$$\begin{array}{r} 11101_2 \\ \underline{+\ 01001_2} \end{array}$$

1. 11111_2
2. 100110_2
3. 111010_2
4. 100000_2

1-31. Add:

$$\begin{array}{r} 111_2 \\ \underline{+\ 001_2} \end{array}$$

1. 100_2
2. 1010_2
3. 1001_2
4. 1000_2

1-32. Add:

$$\begin{array}{r} 100_2 \\ 010_2 \\ \underline{+\ 001_2} \end{array}$$

1. 1000_2
2. 1001_2
3. 101_2
4. 111_2

1-33. Add:

$$\begin{array}{r} 11010_2 \\ 100_2 \\ \underline{+\ \ 111_2} \end{array}$$

1. 011110_2
2. 101010_2
3. 100101
4. 111001_2

1-34. Which of the following rules of binary subtraction is correct?

1. 0 – 0 = 0 with a borrow
2. 1 – 0 = 0
3. 2 – 1 = 1
4. 1 – 0 = 1

1-35. In the following example, which number is the minuend?

$$\begin{array}{r} 10110_2 \\ \underline{-\ \ 1100_2} \end{array}$$

1. 10110_2
2. 1100_2
3. 1010_2
4. 10101_2

1-36. Which of the following rules of binary subtraction requires the use of a borrow?

1. 0 – 0
2. 1 – 0
3. 1 – 1
4. 0 – 1

1-37. In binary subtraction, what is the value of a borrow when it is moved to the next lower order column?

1. 1_2
2. 2_2
3. 10_2
4. 10_{10}

IN ANSWERING QUESTIONS 1-38 THROUGH 1-40, PERFORM THE INDICATED OPERATION.

1-38. Subtract:

$$\begin{array}{r} 11111_2 \\ \underline{-\ \ 10101_2} \end{array}$$

1. 10100_2
2. 11010_2
3. 00101_2
4. 01010_2

1-39. Subtract:

$$\begin{array}{r} 10101_2 \\ \underline{-\ \ 1111_2} \end{array}$$

1. 00110_2
2. 01001_2
3. 01100_2
4. 00010_2

1-40. Subtract:

$$\begin{array}{r} 10001_2 \\ -\ \ 0110_2 \\ \hline \end{array}$$

1. 1010_2
2. 1011_2
3. 1110_2
4. 1001_2

1-41. Subtraction is accomplished by which of the following methods in a computer that can only add?

1. Binary subtraction
2. Decimal complement
3. Complementary subtraction
4. Minuend complement

1-42. What is the R's-1 complement of 633_{10}?

1. 477_{10}
2. 466_{10}
3. 366_{10}
4. 377_{10}

1-43. What is the R's-1 complement of 1011101_2?

1. 0100010_2
2. 1011110_2
3. 8988898_{10}
4. 8988899_{10}

1-44. What is the R's complement of 395_{10}?

1. 604_{10}
2. 605_{10}
3. 715_{10}
4. 714_{10}

1-45. Which of the following parts of a subtraction problem must be complemented to perform complementary subtraction?

1. Subtrahend
2. Difference
3. Remainder
4. Minuend

1-46. Which of the following examples is the correct step when using the R's complement to subtract 123_{10} from 264_{10}?

1. $\begin{array}{r} 735 \\ +\ 123 \\ \hline \end{array}$

2. $\begin{array}{r} 264 \\ +\ 876 \\ \hline \end{array}$

3. $\begin{array}{r} 264 \\ +\ 321 \\ \hline \end{array}$

4. $\begin{array}{r} 264 \\ +\ 877 \\ \hline \end{array}$

1-47. Which of the following solutions is correct when using the R's complement method of subtracting 516_{10} from 845_{10}?

1. $\begin{array}{r} 845 \\ +\ 483 \\ \hline 328 \end{array}$

2. $\begin{array}{r} 845 \\ +\ 484 \\ \hline 329 \end{array}$

3. $\begin{array}{r} 845 \\ +\ 615 \\ \hline 460 \end{array}$

4. $\begin{array}{r} 155 \\ +\ 516 \\ \hline 671 \end{array}$

1-48. Which of the following numbers is the R's-1 complement of the binary number 10101?

1. 10100_2
2. 01011_2
3. 01100_2
4. 01010_2

1-49. Perform the R's-1 complement of the following binary numbers.

(a) 1000, (b) 1101, (c) 0100

1. (a) 0111_2 (b) 0010_2 (c) 1011_2
2. (a) 0110_2 (b) 0011_2 (c) 1010_2
3. (a) 0111_2 (b) 0011_2 (c) 1011_2
4. (a) 0110_2 (b) 0010_2 (c) 1010_2

1-50. Which of the following statements regarding the forming of the R's complement of a binary number is correct?

1. Retain the MSD and complement all other digits
2. Complement all digits and subtract 1
3. Complement all digits
4. Retain the least significant 1 and complement all other digits to the left

1-51. Which of the following numbers is the R's complement of 100101_2?

1. 101010_2
2. 011011_2
3. 110110_2
4. 101001_2

IN ANSWERING QUESTIONS 1-52 AND 1-53, USE THE R'S COMPLEMENT METHOD TO SOLVE THE PROBLEMS.

1-52. Subtract:

$$\begin{array}{r} 1001_2 \\ \underline{-\ 101_2} \end{array}$$

1. 110_2
2. 010_2
3. 100_2
4. 1100_2

1-53. Subtract:

$$\begin{array}{r} 1101_2 \\ \underline{-\ 1010_2} \end{array}$$

1. 0001_2
2. 0100_2
3. 0110_2
4. 0011_2

1-54. In the previous problems, what is indicated by the carry that expands the difference by one place?

1. The answer is incorrect
2. The answer is a positive number
3. The answer is correct
4. The answer is a negative number

IN ANSWERING QUESTIONS 1-55 THROUGH 1-57, SOLVE THE SUBTRACTION PROBLEMS AND INDICATE THE SIGN OF THE DIFFERENCE.

1-55. Subtract:

$$\begin{array}{r} 10010_2 \\ \underline{-\ 10001_2} \end{array}$$

1. 00001_2 positive
2. 01111_2 negative
3. 01100_2 positive
4. 00001_2 negative

1-56. Subtract:

$$\begin{array}{r} 0001_2 \\ \underline{-\ 1111_2} \end{array}$$

1. 0010_2 negative
2. 0111_2 positive
3. 1110_2 negative
4. 1111_2 positive

1-57. Subtract:

$$\begin{array}{r} 01111_2 \\ \underline{-\ 10000_2} \end{array}$$

1. 11111_2 negative
2. 00001_2 negative
3. 01111_2 positive
4. 10000_2 positive

1-58. What is the radix of the octal number system?

1. 10_{10}
2. 0 to 7
3. 8
4. 7_8

1-59. Which of the following is NOT a valid octal number?

1. 604_8
2. 591_8
3. 743_8
4. 477_8

1-60. Which of the following equations is correct?

1. $8^0 = 8$
2. $8^1 = 1$
3. $8^4 = 8 \times 8 \times 8$
4. $8^2 = 8 \times 8$

1-61. One octal digit is represented by how many binary digits?

1. One
2. Two
3. Three
4. Four

1-62. What is the decimal value of 8^3?

1. 64_{10}
2. 128_{10}
3. 256_{10}
4. 512_{10}

1-63. Which of the following symbols is the least significant digit of the octal number 1622.374?

1. 1
2. 2
3. 6
4. 4

1-64. What is the sum of 4_8 and 4_8?

1. 10_{10}
2. 10_8
3. 7_8
4. 16_8

1-65. What is the sum of 77_8 and 3_8?

1. 127_8
2. 80_8
3. 100_8
4. 102_8

IN ANSWERING QUESTION 1-66, PERFORM THE INDICATED OPERATION.

1-66. Add:

$$\begin{array}{r} 374_8 \\ \underline{+\ \ 165_8} \end{array}$$

1. 465_8
2. 561_8
3. 437_8
4. 531_8

1-67. Find the sum of 7741_8 and 67_8.

1. 10000_8
2. 10030_8
3. 7030_8
4. 10730_8

1-68. What is the sum of 7_8, 6_8, 5_8, and 4_8?

1. 22_8
2. 17_8
3. 26_8
4. 24_8

IN ANSWERING QUESTIONS 1-69 AND 1-70, PERFORM THE INDICATED OPERATION.

1-69. Add:

$$\begin{array}{r} 2601_8 \\ +\ 5035_8 \\ \hline \end{array}$$

1. 7636_8
2. 7640_8
3. 10636_8
4. 10700_8

1-70. Add:

$$\begin{array}{r} 2345_8 \\ +\ 7654_8 \\ \hline \end{array}$$

1. 10110_8
2. 10741_8
3. 10571_8
4. 12221_8

1-71. Which, if any, of the following is a difference between subtracting octal numbers and subtracting decimal numbers?

1. The amount of the borrow
2. The octal minuend is converted to decimal
3. The octal subtrahend is converted to decimal
4. None; there is no difference

IN ANSWERING QUESTIONS 1-72 THROUGH 1-74, PERFORM THE INDICATED OPERATION.

1-72. Subtract:

$$\begin{array}{r} 646_8 \\ -\ 421_8 \\ \hline \end{array}$$

1. 125_8
2. 265_8
3. 225_8
4. 225_{10}

1-73. Subtract:

$$\begin{array}{r} 421_8 \\ -\ 267_8 \\ \hline \end{array}$$

1. 144_8
2. 232_8
3. 132_8
4. 142_8

1-74. Subtract:

$$\begin{array}{r} 3000_8 \\ -\ 777_8 \\ \hline \end{array}$$

1. 2001_8
2. 2011_8
3. 2111_8
4. 2000_8

ASSIGNMENT 2

Textbook assignment: Chapter 1, "Number Systems," page 1-30 through 1-62.

2-1. Which of the following numbers does NOT represent a hexadecimal value?

1. 2DF4
2. A32B
3. 47CE
4. 9FGF

2-2. What is the decimal value of the highest symbol in the hex system?

1. 15_{10}
2. 16_{10}
3. F_{16}
4. 10_{16}

2-3. The decimal number 256 is equal to what power of 16?

1. 16^3
2. 16^2
3. 16^4
4. 16^1

2-4. List the MSD and LSD of the hex number F24.ECB.

1. MSD = 4, LSD = E
2. MSD = 4, LSD = B
3. MSD = F, LSD = 4
4. MSD = F, LSD = B

IN ANSWERING QUESTIONS 2-5 THROUGH 2-7, PERFORM THE INDICATED OPERATION.

2-5. Find the sum.

$$\begin{array}{r} A_{16} \\ \underline{+\ 4_{16}} \end{array}$$

1. C_{16}
2. D_{16}
3. E_{16}
4. F_{16}

2-6. Add:

$$\begin{array}{r} 1E_{16} \\ \underline{+\ 19_{16}} \end{array}$$

1. 33_{16}
2. 31_{16}
3. 37_{16}
4. 47_{16}

2-7. Add:

$$\begin{array}{r} 478_{16} \\ \underline{+792_{16}} \end{array}$$

1. $C11_{16}$
2. $C0A_{16}$
3. $B00_{16}$
4. BFA_{16}

2-8. When a borrow is taken from a hex number, that number is reduced by how much?

1. 1
2. 10_{16}
3. 16_{10}
4. 10_{10}

IN ANSWERING QUESTION 2-9, FIND THE DIFFERENCE.

2-9. Subtract:

$$\begin{array}{r} 10_{16} \\ \underline{-\ 8_{16}} \end{array}$$

1. A_{16}
2. 7_{16}
3. 8_{16}
4. 9_{16}

2-10. To begin conversion of a decimal number to a different base, divide the (a) by (b).

1. (a) new base
   (b) 10
2. (a) decimal number
   (b) 2
3. (a) decimal number
   (b) the new base
4. (a) new base
   (b) the decimal equivalent

2-11. Which of the following terms describes the first remainder when converting decimal numbers to other bases?

1. MSD
2. LSD
3. Radix of the new base
4. Exponent of the new base

IN ANSWERING QUESTIONS 2-12 THROUGH 2-14, USE THE DIVISION METHOD TO CONVERT DECIMAL NUMBERS TO BINARY.

2-12. 43_{10}

1. 101011_2
2. 110101_2
3. 100011_2
4. 101101_2

2-13. 63_{10}

1. 101011_2
2. 110011_2
3. 101101_2
4. 111111_2

2-14. 130_{10}

1. 1111000_2
2. 1111010_2
3. 10000010_2
4. 10001010_2

2-15. To convert fractional decimal numbers to binary, multiply the number by (a) and extract the portion of the product to the (b) of the radix point.

1. (a) 2 (b) left
2. (a) 2 (b) right
3. (a) 10 (b) left
4. (a) 10 (b) right

IN ANSWERING QUESTIONS 2-16 THROUGH 2-19, PERFORM THE INDICATED OPERATION.

2-16. Convert 0.75_{10} to binary.

1. 0.10_2
2. 0.01_2
3. 0.11_2
4. 1.00_2

2-17. Convert 0.625_{10} to binary.

1. 0.011_2
2. 0.101_2
3. 0.110_2
4. 0.100_2

2-18. Convert 12.5_{10} to base 2.

1. 1100.10_2
2. 1010.01_2
3. 1001.10_2
4. 1101.01_2

2-19. Convert 33.34_{10} to base 2 (four places).

1. 11110.1010_2
2. 100001.1010_2
3. 100001.0101_2
4. 100010.1011_2

IN ANSWERING QUESTIONS 2-20 THROUGH 2-22, USE THE DIVISION METHOD TO CONVERT DECIMAL NUMBERS TO OCTAL.

2-20. 193_{10}

1. 62_8
2. 142_8
3. 301_8
4. 403_8

2-21. 746_{10}

1. 1352_8
2. 2531_8
3. 1476_8
4. 2312_8

2-22. 3007_{10}

1. 5000_8
2. 5677_8
3. 4771_8
4. 4115_8

IN ANSWERING QUESTIONS 2-23 THROUGH 2-25, PERFORM THE INDICATED OPERATION.

2-23. Convert 0.305_{10} to octal (four places).

1. 0.5765_8
2. 0.1471_8
3. 0.3050_8
4. 0.2341_8

2-24. Convert 78.9_{10} to octal (three places).

1. 100.417_8
2. 103.714_8
3. 116.714_8
4. 116.147_8

2-25. Convert 506.66_{10} to octal (four places).

1. 677.5063_8
2. 521.4401_8
3. 653.3774_8
4. 772.5217_8

2-26. What is the hex equivalent of 45_{10}?

1. $1F_{16}$
2. 24_{16}
3. $2A_{16}$
4. $2D_{16}$

2-27. What is the hex equivalent of 255_{10}?

1. AE_{16}
2. BC_{16}
3. CG_{16}
4. FF_{16}

IN ANSWERING QUESTIONS 2-28 THROUGH 2-30, PERFORM THE INDICATED OPERATION.

2-28. Convert 1609_{10} to hex.

1. $5A5_{16}$
2. 649_{16}
3. $C41_{16}$
4. $A95_{16}$

2-29. Convert 0.84 to hex (three places).

1. $0.D70_{16}$
2. $0.1F3_{16}$
3. $0.AAC_{16}$
4. $0.C3E_{16}$

2-30. Convert 0.109_{10} to hex (four places).

1. 0.1114_{16}
2. $0.101F_{16}$
3. $0.1BE7_{16}$
4. $0.09D4_{16}$

2-31. What is the hex equivalent of 174.95_{10}? Carry out two places.

1. $9F.C4_{16}$
2. $AE.F3_{16}$
3. $AE.9C_{16}$
4. $BA.EC_{16}$

2-32. What is the hex equivalent of 7023.869_{10}? Carry out to four places.

1. $1C5E.A9F6_{16}$
2. $1B6F.DE76_{16}$
3. $1D7C.EC87_{16}$
4. $1AA9.DB1A_{16}$

IN ANSWERING QUESTIONS 2-33 THROUGH 2-38, CONVERT THE BINARY NUMBERS TO THEIR OCTAL EQUIVALENT.

2-33. 0011010_2

1. 150_8
2. 032_8
3. 042_8
4. 062_8

2-34. 001010011100_2

1. 516_8
2. 147_8
3. 667_8
4. 1234_8

2-35. 0101011011111101_2

1. 53375_8
2. 155776_8
3. 255771_8
4. 126771_8

2-36. 0.1110101000_2

1. 0.1560_8
2. 0.1650_8
3. 0.750_8
4. 0.724_8

2-37. 1001000.00011110_2

1. 110.074_8
2. 440.036_8
3. 410.070_8
4. 220.074_8

2-38. 1111111011.11110011_2

1. 1773.746_8
2. 7751.363_8
3. 1773.633_8
4. 7751.473_8

IN ANSWERING QUESTIONS 2-39 THROUGH 2-42, CONVERT THE BINARY NUMBERS TO THEIR HEXADECIMAL EQUIVALENTS.

2-39. 101101_2

1. $B1_{16}$
2. 55_{16}
3. $1B_{16}$
4. $2D_{16}$

2-40. 111010110010_2

1. $EB2_{16}$
2. $EC4_{16}$
3. $7B2_{16}$
4. 7262_{16}

2-41. 0.0100111100_2

1. $0.4\ F_{16}$
2. $0.9\ E_{16}$
3. $0.13C_{16}$
4. 0.236_{16}

2-42. 11011100.110010101011_2

1. 670.6253_{16}
2. $9A.BAC_{16}$
3. $DC.CAB_{16}$
4. $AB.CDE_{16}$

IN ANSWERING QUESTIONS 2-43 THROUGH 2-45, CONVERT THE OCTAL NUMBERS TO THEIR BINARY EQUIVALENTS.

2-43. 571_8

1. 101111001_2
2. 1011111_2
3. 101011101_2
4. 110111010_2

2-44. 1312_8

1. 0101101010_2
2. 1011001010_2
3. 00111000101_2
4. 01010101010_2

2-45. 136.52_8

1. 1110110.101100_2
2. 11011111.101010_2
3. 01011011.010101_2
4. 01011110.101010_2

IN ANSWERING QUESTIONS 2-46 AND 2-47, PERFORM THE INDICATED OPERATIONS.

2-46. Convert 24.73_8 to hex.

1. 11.76_{16}
2. $14.EC_{16}$
3. $24.7D_{16}$
4. $20.A6_{16}$

2-47. Convert 657.13_8 to hex.

1. 328.065_{16}
2. $D37.26_{16}$
3. $1AF.2C_{16}$
4. $20A.B1_{16}$

IN ANSWERING QUESTIONS 2-48 THROUGH 2-50, CONVERT THE HEX NUMBERS TO BINARY.

2-48. $2A_{16}$

1. 01001010_2
2. 00101010_2
3. 01001100_2
4. 00011100_2

2-49. $E47_{16}$

1. 111001000111_2
2. 111101000111_2
3. 110010001110_2
4. 101010100111_2

2-50. $8C.1F_{16}$

1. 100111.00111110_2
2. 10001100.00011111_2
3. 1001100.00011110_2
4. 10011101.00011111_2

IN ANSWERING QUESTIONS 2-51 AND 2-52, CONVERT THE HEX NUMBERS TO OCTAL.

2-51. $74E_{16}$

1. 7416_8
2. 7217_8
3. 3516_8
4. 4636_8

2-52. $F1.C8_{16}$

1. 741.620_8
2. 661.304_8
3. 331.64_8
4. 361.62_8

2-53. What is the decimal equivalent of 1011_2

1. 13_{10}
2. 11_{10}
3. 9_{10}
4. 10_{10}

IN ANSWERING QUESTIONS 2-54 AND 2-55, PERFORM THE INDICATED OPERATION.

2-54. Convert 101101_2 to decimal.

1. 55_{10}
2. 29_{10}
3. 36_{10}
4. 45_{10}

2-55. Convert 1110111011_2 to decimal.

1. 773_{10}
2. 867_{10}
3. 955_{10}
4. 1673_{10}

IN ANSWERING QUESTIONS 2-56 THROUGH 2-60, CONVERT THE OCTAL NUMBERS TO THEIR DECIMAL EQUIVALENTS.

2-56. 133_8

1. 100_{10}
2. 107_{10}
3. 63_{10}
4. 91_{10}

2-57. 2737_8

1. 1899_{10}
2. 1503_{10}
3. 2105_{10}
4. 1511_{10}

2-58. 777.7_8

1. 511.875_{10}
2. 614.750_{10}
3. 614.875_{10}
4. 511.750_{10}

2-59. 1603.75_8 (three places)

1. 1219.840_{10}
2. 907.650_{10}
3. 899.953_{10}
4. 1143.150_{10}

2-60. 2000.1_8

1. 1250.25_{10}
2. 1024.125_{10}
3. 969.5_{10}
4. 1000.05_{10}

IN ANSWERING QUESTIONS 2-61 THROUGH 2-64, CONVERT THE HEX NUMBERS TO THEIR DECIMAL EQUIVALENTS.

2-61. $1B3_{16}$

1. 435_{10}
2. 1185_{10}
3. 2390_{10}
4. 4275_{10}

2-62. $10AF_{16}$

1. 4271_{10}
2. 2985_{10}
3. 3417_{10}
4. 4003_{10}

2-63. $C3.6_{16}$

1. 46.5_{10}
2. 84.4_{10}
3. 150.505_{10}
4. 195.375_{10}

2-64. $4DD.E_{16}$

1. 1245.7505_{10}
2. 1245.8750_{10}
3. 733.7505_{10}
4. 733.9375_{10}

2-65. What term describes the use of four binary digits to represent one decimal digit?

1. Decimal-coded binary
2. Octal-coded binary
3. Binary-coded decimal
4. Hexadecimal notation

2-66. How many binary digits are required to represent the decimal number 243 in BCD?

1. 12
2. 8
3. 3
4. 4

IN ANSWERING QUESTIONS 2-67 AND 2-68, PERFORM THE INDICATED OPERATION.

2-67. Convert 389_{10} to BCD.

1. $0000\ 1110\ 0101_{BCD}$
2. $0011\ 0001\ 1101_{BCD}$
3. $0011\ 1000\ 1001_{BCD}$
4. $0011\ 0100\ 0101_{BCD}$

2-68. Convert 010001010111_{BCD} to decimal.

1. 897_{10}
2. 857_{10}
3. 497_{10}
4. 457_{10}

2-69. Which of the following numbers has the highest decimal value?

1. 10011001_2
2. 11100001_2
3. $1001\ 1001_{BCD}$
4. $1000\ 0110_{BCD}$

2-70. Which of the following numbers is NOT a valid BCD number?

1. 0110
2. 1001
3. 1000
4. 1010

IN ANSWERING QUESTIONS 2-71 THROUGH 2-75, PERFORM THE INDICATED OPERATION.

2-71. Add:

$$\begin{array}{r} 0101_{BCD} \\ \underline{0010}_{BCD} \end{array}$$

1. 0111_{BCD}
2. 1001_{BCD}
3. 1010_{BCD}
4. 1000_{BCD}

2-72. Add:

$$\begin{array}{r} 1001_{BCD} \\ \underline{0111}_{BCD} \end{array}$$

1. $0001\ 0000_{BCD}$
2. $0001\ 0110_{BCD}$
3. $0111\ 0110_{BCD}$
4. $0001\ 1111_{BCD}$

2-73. Add:

$$\begin{array}{r} 1001_{BCD} \\ \underline{+100}_{BCD} \end{array}$$

1. 1101_{BCD}
2. 0011_{BCD}
3. $0001\ 0011_{BCD}$
4. $0001\ 0110_{BCD}$

2-74. Add:

$$\begin{array}{r} 0010\ \ 0011_{BCD} \\ \underline{+\ 0001\ \ 1000}_{BCD} \end{array}$$

1. $0011\ 1011_{BCD}$
2. $0011\ 0001_{BCD}$
3. $0100\ 1011_{BCD}$
4. $0100\ 0001_{BCD}$

2-75. Add:

$$\begin{array}{r} 0110\ \ 0100_{BCD} \\ \underline{+\ 1001\ \ 0010}_{BCD} \end{array}$$

1. $0000\ 1111\ 0110_{BCD}$
2. $0001\ 0101\ 1100_{BCD}$
3. $0001\ 0101\ 0110_{BCD}$
4. $0001\ 0111\ 0100_{BCD}$

ASSIGNMENT 3

Textbook assignment: Chapter 2, "Fundamental Logic Circuits," pages 2-1 through 2-36; and "Special Logic Circuits," Chapter 3, pages 3-1 through 3-3.

NOTE: UNLESS OTHERWISE INDICATED, ALL QUESTIONS AND ANSWERS REFER TO POSITIVE LOGIC.

3-1. Logic is the development of a reasonable conclusion based on known information.

1. T
2. F

3-2. Which of the following methods is used to represent the FALSE condition of the logic symbol, F?

1. (F)
2. [F]
3. $\overline{F}$
4. F

3-3. Which of the following statements describes logic polarity?

1. Negative logic is indicated by a vinculum
2. Positive logic is always represented by a positive voltage
3. A logic 1 is a positive voltage; a logic 0 is a negative voltage
4. The change in voltage polarity to represent a logic 1

3-4. Which of the following examples represents positive logic?

1. −5v equals 0, −10v equals 1
2. +5v equals 0, +10v equals 1
3. +5v equals 1, +10v equals 0
4. −5v equals 1, +5v equals 0

3-5. Of the following examples, choose the one that represents negative logic.

1. −15v equals 0, −10v equals 1
2. −10v equals 1, −15v equals 0
3. 0v equals 0, −10v equals 1
4. −5v equals 0, 0v equals 1

3-6. If the letter X represents an input to a logic device, what logic state of X must exist to activate the device or contribute to the activation of the device?

1. 0
2. 1
3. Positive logic
4. Negative logic

3-7. A chart that lists all possible input combinations and resultant output is called a

1. Truth Table
2. Decision Table
3. logic symbol listing
4. polarity magnitude listing

3-8. What is a logic gate?

1. A block diagram
2. An astable multivibrator
3. A bistable multivibrator
4. A decision-making circuit

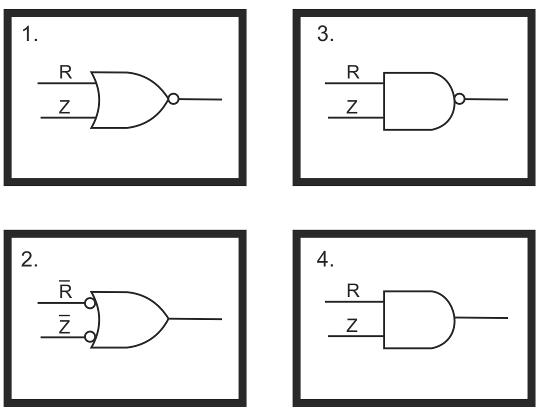
3-9. Which of the following logic gates requires all inputs to be TRUE at the same time to produce a TRUE output?

1. OR
2. NOT
3. AND
4. NAND

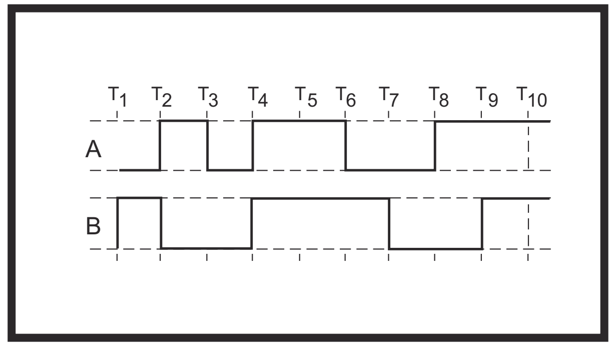
3-10. Which of the following output Boolean expressions is/are correct for an AND gate?

1. $f = AB$
2. $f = A \cdot B$
3. Both 1 and 2 above
4. $A=B$

3-11. Which of the following symbols represents the output Boolean expression RZ?



NTS13A301



NTS13A302

Figure 3A. —AND gate timing diagram.

IN ANSWERING QUESTIONS 3-12 THROUGH 3-14, REFER TO FIGURE 3A.

3-12. At which of the following times will the output of a two input AND gate go HIGH?

1. T_2, T_5, and T_8
2. T_4 only
3. T_2, T_6, and T_{10}
4. T_4 and T_9

3-13. At which of the following times will the output of the AND gate be LOW?

1. T_1 to T_4 and T_5 to T_8
2. T_1 to T_4 and T_6 to T_9
3. T_4 to T_6 and T_8 to T_{10}
4. T_1 to T_3 and T_6 to T_{10}

3-14. If input $\overline{B}$ were used instead of input B, how would the output be affected, if at all?

1. It would be HIGH from T_2 to T_4
2. It would be LOW from T_4 to T_6
3. It would be HIGH from T_2 to $T_3$and T_8 to T_9
4. It would not be affected

3-15. What is the output Boolean expression for an AND gate having F, $\overline{G}$, $\overline{K}$, and $\overline{L}$ as inputs?

1. $f = F\,\overline{G}\,\overline{K}\,\overline{L}$
2. $f = F + \overline{G}\,\overline{K}\,\overline{L}$
3. $f = \overline{F}\,G\,K\,L$
4. $f = F\,\overline{G} + \overline{K}\,\overline{L}$

THIS SPACE LEFT BLANK INTENTIONALLY.

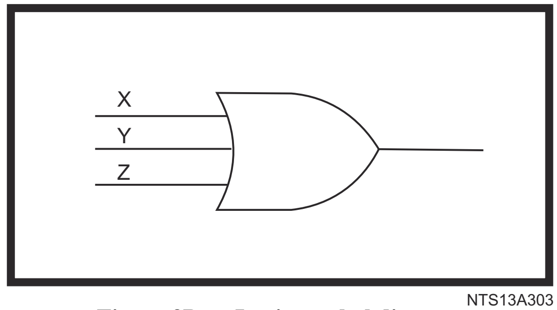


Figure 3B. —Logic symbol diagram.

IN ANSWERING QUESTIONS 3-16 THROUGH 3-18, REFER TO FIGURE 3B.

3-16. Which of the following gates is represented by the symbol in the figure?

1. AND
2. OR
3. NOR
4. X-OR

3-17. What is the output Boolean expression for the gate?

1. X, Y+Z
2. $X+Y \oplus X$
3. X+Y+Z
4. $X \oplus Y \oplus Z$

THIS SPACE LEFT BLANK INTENTIONALLY.

3-18. Which of the following Truth Tables correspond to the gate in the figure?

1.

X	Y	Z	f
0	0	0	0
0	0	1	1
0	1	0	1
0	1	1	1
1	0	0	1
1	0	1	1
1	1	0	1
1	1	1	1

2.

X	Y	Z	f
0	0	0	0
0	0	1	0
0	1	0	0
0	1	1	1
1	0	0	0
1	0	1	1
1	1	0	1
1	1	1	1

3.

0	1	1	1
1	0	0	0
1	0	1	1
1	1	0	1
1	1	1	1

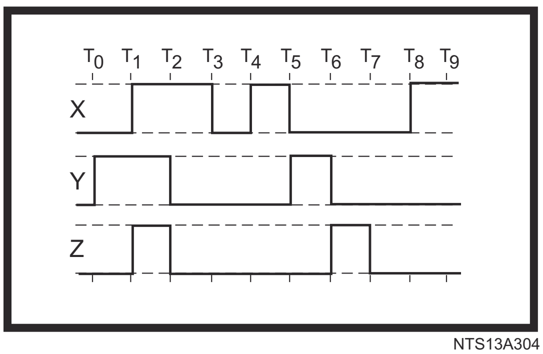

Figure 3C. — OR gate timing diagram.

IN ANSWERING QUESTIONS 3-19 THROUGH 3-21, REFER TO FIGURE 3C.

3-19. The gate will have a HIGH output at which of the following times?

1. T_0 to T_3, T_4 to T_7, and T_8 to T_9
2. T_1 to T_2 and T_4 to T_9
3. T_3 to T_4 and T_7 to T_8
4. T_1 to T_2 only

3-20. What are the input logic states between T_5 and T_6?

1. X = 1, Y = 0, Z = 0
2. X = 1, Y = 0, Z = 1
3. X = 0, Y = 1, Z = 0
4. X = 0, Y = 1, Z = 1

3-21. Between T_0 and T_6, at what times will the output of the gate be LOW?

1. T_3 to T_4
2. T_2 to T_5
3. T_3 to T_6
4. T_0 to T_1

3-22. What is the Boolean expression for an OR gate having the following inputs?

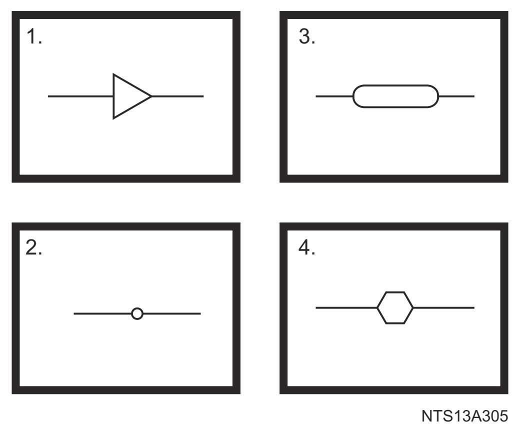
T (LOW)
$\overline{R}$ (LOW)
$\overline{P}$ (HIGH)

1. $T \overline{R} \overline{P}$
2. $\overline{T} R \overline{P}$
3. $\overline{T} + R + \overline{P}$
4. $T + \overline{R} + \overline{P}$

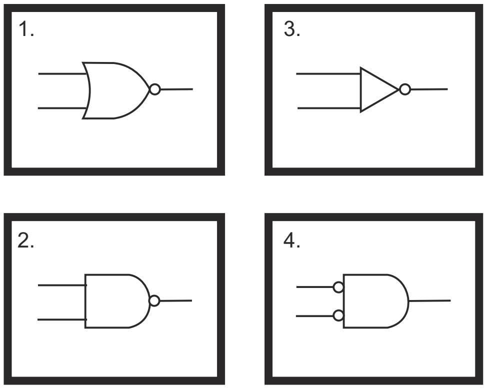
3-23. What is the purpose of an inverter?

1. To change logic polarity
2. To change voltage levels
3. To amplify the input
4. To complement the input

3-24. Which of the following symbols represents an inverter?



3-25. Which of the following is the standard logic symbol for a NAND gate?



NTS13A306

3-26. What is the output expression for an inverter with the following input?

$(R\overline{Q}) + (\overline{S}T)$

1. $(\overline{R}Q) + (S\overline{T})$
2. $R\overline{Q}\,\overline{S}T$
3. $\overline{RQST}$
4. $\overline{(R\overline{Q}) + (\overline{S}T)}$

3-27. Which of the following gates produces a HIGH output when any or all of the inputs are LOW?

1. AND
2. OR
3. NAND
4. NOR

X	Y	f
0	0	1
1	0	1
1	1	0

NTS13A307

Figure 3D. —Incomplete NAND gate Truth Table.

IN ANSWERING QUESTION 3-28, REFER TO FIGURE 3D.

3-28. Which of the following NAND gate input combinations and output function is missing?

1. X = 0, Y = 1, f = 0
2. X = 0, Y = 1, f = 1
3. X = 0, Y = 0, f = 0
4. X = 1, Y = 1, f = 1

3-29. What is the output Boolean expression for a NAND gate with inputs G, K, and $\overline{P}$?

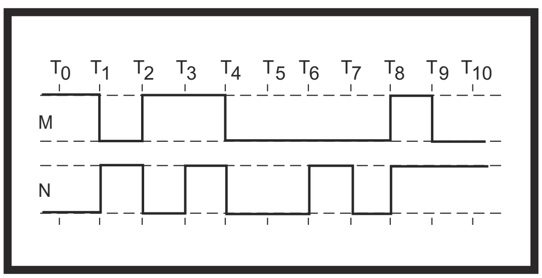
1. $\overline{GK}P$
2. $\overline{GKP}$
3. $\overline{GK\overline{P}}$
4. $\overline{G}\,\overline{K}\,\overline{P}$

3-30. The output of a NOR gate will be HIGH under which of the following conditions?

1. When all inputs are HIGH
2. When all inputs are LOW
3. When one input is HIGH
4. When one input is LOW

3-31. What is the output Boolean expression for a NOR gate with $\overline{P}$, Q, and R as inputs?

1. $\overline{\overline{P}+Q+R}$
2. $\overline{\overline{P}}+\overline{Q}+\overline{R}$
3. $P+\overline{Q}+\overline{R}$
4. $\overline{P}+Q+R$



NTS13A308

Figure 3E. —Input signal timing diagram.

IN ANSWERING QUESTIONS 3-32 THROUGH 3-34, REFER TO FIGURE 3E.

3-32. Figure 3E represents the input signals to a NOR gate. What is the output expression?

1. $M+N$
2. $\overline{M}+\overline{N}$
3. $\overline{\overline{M}+\overline{N}}$
4. $\overline{M+N}$

3-33. At which of the following times will the output be HIGH?

1. T_3 to T_4
2. T_8 to T_9
3. T_4 to T_6 and T_7 to T_8
4. T_3 to T_4 and T_8 to T_9

3-34. What should the output be between times T_3 and T_4?

1. LOW
2. HIGH

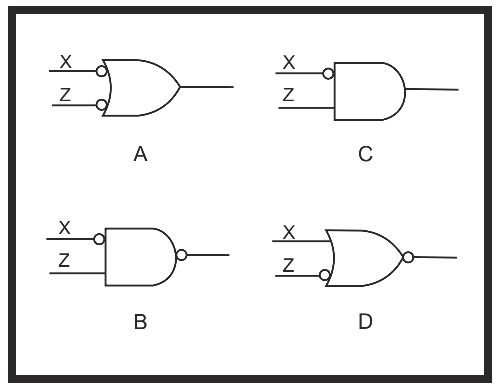


Figure 3F. —Logic gates. NTS13A309

IN ANSWERING QUESTIONS 3-35 THROUGH 3-37, REFER TO FIGURE 3F.

3-35. What is the output expression for gate D?

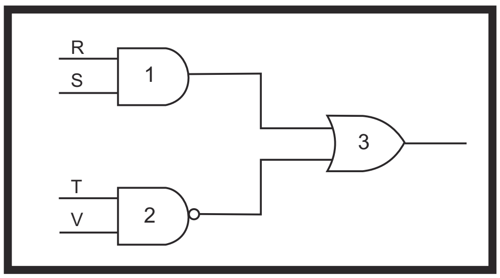
1. $\overline{X}+\overline{Z}$
2. $\overline{XZ}$
3. $\overline{\overline{X}+\overline{Z}}$
4. $\overline{X+\overline{Z}}$

3-36. The Truth Tables are identical for which two gates?

1. C and D
2. A and D
3. B and C
4. A and B

3-37. Which gate represents the output expression $\overrightarrow{\overline{X}Z}$?

1. A
2. B
3. C
4. D



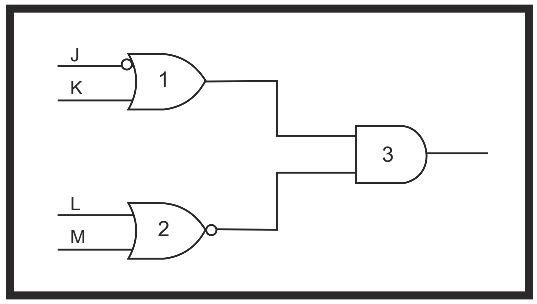
NTS13A310

Figure 3G. —Logic circuit.

IN ANSWERING QUESTION 3-38, REFER TO FIGURE 3G.

3-38. Which of the following output expressions represents the output of gate 3?

1. (RS) (TV)
2. RS + $\overline{TV}$
3. (RS) + ($\overline{TV}$)
4. ($\overline{RS}$) +(TV)



NTS13A311

Figure 3H. —Logic circuit.

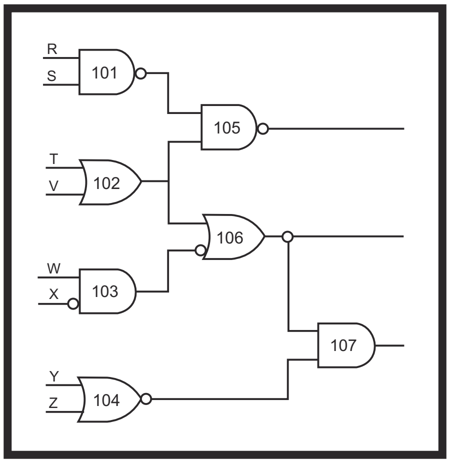
IN ANSWERING QUESTIONS 3-39 AND 3-40, REFER TO FIGURE 3H.

3-39. The output expression JK represents the output of which, if any, of the following gates?

1. 1
2. 2
3. 3
4. None of the above

3-40. What is the output expression for gate 3?

1. $\overline{J}K(\overline{L}+\overline{M})$
2. $(\overline{J}+K)\overline{(L+M)}$
3. $(\overline{J}+K)+(\overline{L}+\overline{M})$
4. $K(\overline{J}+1)(L\overline{M})$



NTS13A312

Figure 3I. —Logic circuit.

IN ANSWERING QUESTIONS 3-41 THROUGH 3-45, REFER TO FIGURE 3I.

3-41. What is the output expression for gate 105?

1. $(\overline{RS}) + (T + V)$
2. RSTV
3. $\overrightarrow{(\overline{RS})(T + V)}$
4. $(\overline{RS}) + (\overline{T + V})$

3-42. Which of the following gates provides a common output to two other gates?

1. 101
2. 102
3. 104
4. 106

3-43. Which of the following expressions represents the output of gate 106?

1. $W\overline{X}TV$
2. $W + \overline{X} + T + V$
3. $(TV) + (W\overline{X})$
4. $(T + V) + (\overline{W\overline{X}})$

3-44. Which of the following conditions will cause gate 107 output to be HIGH?

1. Gate 106 is LOW; Y and Z are HIGH
2. Gate 106 is LOW; Y is HIGH, Z is LOW
3. Gate 106 is HIGH; Y and Z are LOW
4. Gate 106 is HIGH; Y is LOW, Z is HIGH

3-45. What is the output expression for gate 107?

1. $(TV + W\overline{X})(Y + Z)$
2. $(\overrightarrow{T + V + W + \overline{X}})(YZ)$
3. $((T+V)+(\overline{W}X))(\overline{Y+Z})$
4. $(T + V)(\overline{W\overline{X}})(Y + Z)$

3-46. Boolean algebra is used primarily by which of the following groups?

1. Fabricators
2. Technicians
3. Design engineers
4. Repair personnel

3-47. Which of the following Boolean laws states, "a term that is TRUE in one part of an expression will be TRUE in all parts of the expression"?

1. Identity
2. Commutative
3. Complementary
4. Double negative

3-48. The examples AB = BA and A+B = B+A represent which of the following Boolean laws?

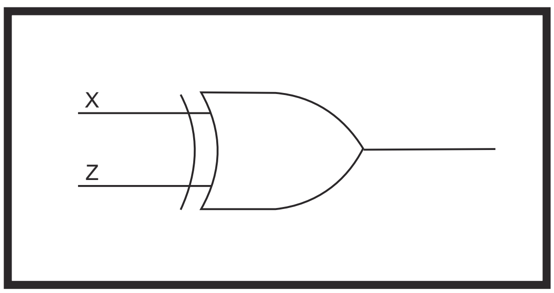
1. Associative
2. Commutative
3. Intersection
4. Union

3-49. What type of logic gate is modified to produce an exclusive OR gate?

1. AND
2. NAND
3. OR
4. NOR

3-50. Which of the following symbols represents the operation function of an exclusive OR gate?

1. Θ
2. $\oplus$
3. O
4. $\otimes$



NTS13A313

Figure 3J. —Logic gate.

IN ANSWERING QUESTIONS 3-51 AND 3-52, REFER TO FIGURE 3J.

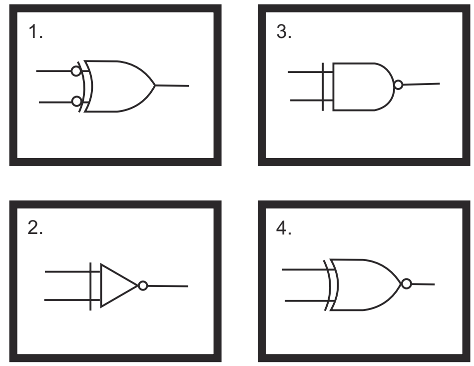
3-51. What will be the output of the gate when (a) X is HIGH and Z is LOW, and (b) X and Z are both HIGH?

1. (a) LOW (b) LOW
2. (a) LOW (b) HIGH
3. (a) HIGH (b) LOW
4. (a) HIGH (b) HIGH

3-52. What will be the output of the gate when (a) X and Z are both LOW and (b) X is LOW and Z is HIGH?

1. (a) LOW (b) LOW
2. (a) LOW (b) HIGH
3. (a) HIGH (b) LOW
4. (a) HIGH (b) HIGH

3-53. Which of the following symbols represents an exclusive NOR gate?



NTS13A314

3-54. What is the output of an exclusive NOR gate when (a) all inputs are LOW and (b) all inputs are HIGH?

1. HIGH (b) HIGH
2. LOW (b) HIGH
3. HIGH (b) LOW
4. LOW (b) LOW

3-55. What is the output expression for an exclusive NOR gate with R and T as inputs?

1. $\overline{R \oplus T}$
2. $\overline{R} + \overline{T}$
3. $\overline{R + T}$
4. $\overline{R} \oplus \overline{T}$

ASSIGNMENT 4

Textbook assignment: Chapter 4, "Special Logic Circuits," pages 3-3 through 3-67.

4-1. Which of the following circuits will add two binary digits but not produce a carry?

1. AND gate
2. Half adder
3. Quarter adder
4. Summation amplifier

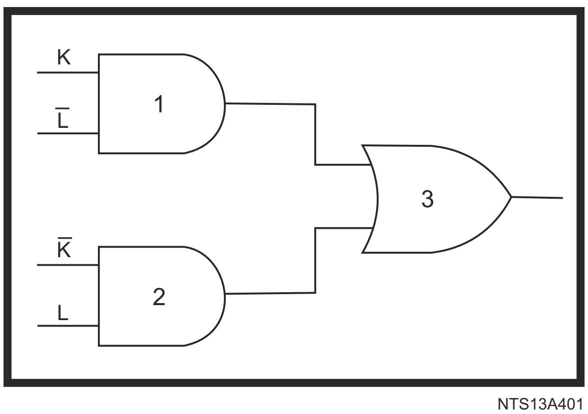


Figure 4A.—Logic circuit.

IN ANSWERING QUESTIONS 4-2 THROUGH 4-5, REFER TO FIGURE 4A.

4-2. What type of circuit is depicted in the figure?

1. Inverter amplifier
2. Half subtracter
3. Half adder
4. Quarter adder

4-3. Which of the following gates will have HIGH outputs when K is HIGH and L is LOW?

1. 1 only
2. 3 only
3. 1 and 2
4. 1 and 3

4-4. What will be the output of gate 3 when K and L are both HIGH?

1. LOW
2. HIGH

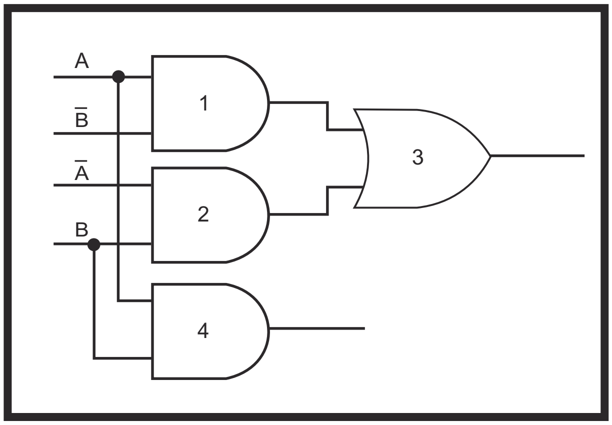
4-5. Assume that K and L are both HIGH. Which of the following statements represents the output of gate 3?

1. 1 plus 1 = 0 (No carry)
2. 1 plus 0 = 1
3. 0 plus 1 = 1
4. 0 plus 0 = 0

4-6. Which of the following gates performs the same function as a quarter adder?

1. Half adder
2. Exclusive OR
3. NOR
4. Exclusive NOR

THIS SPACE LEFT BLANK INTENTIONALLY.



NTS13A402

Figure 4B.—Logic circuit.

IN ANSWERING QUESTIONS 4-7 THROUGH 4-9, REFER TO FIGURE 4B.

4-7. Which of the following circuits is shown in the figure?

1. Quarter adder
2. Half adder
3. Full adder
4. Subtracter

4-8. Which of the following gate combinations may be replaced with an exclusive OR gate?

1. 1, 2, and 3
2. 1, 2, and 4
3. 1, 3, and 4
4. 2, 3, and 4

4-9. The output of gate 3 is the (a) and the output of gate 4 is the (b).

1. (a) Carry (b) sum
2. (a) Sum (b) difference
3. (a) Sum (b) carry
4. (a) Carry (b) difference

4-10. What is the largest sum that can be obtained from a half adder?

1. 01_2
2. 10_2
3. 11_2
4. 100_2

4-11. Which of the following statements describes the difference between a half adder and a full adder?

1. A half adder produces a carry
2. A full adder produces a carry
3. A half adder will add a carry from another circuit
4. A full adder will add a carry from another circuit

THIS SPACE LEFT BLANK INTENTIONALLY.

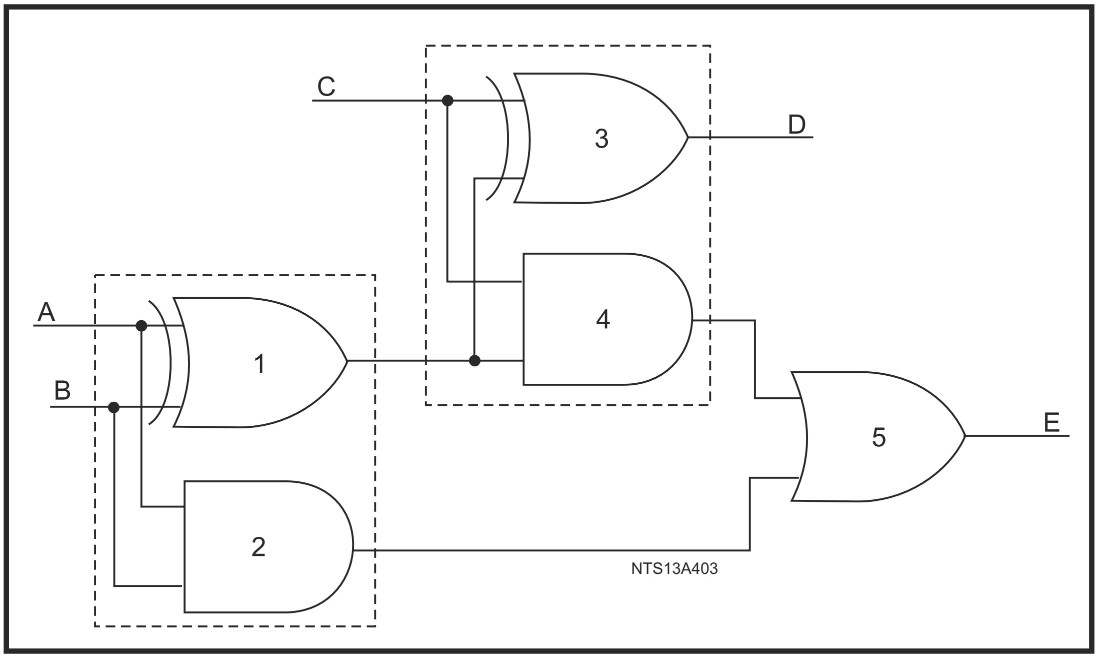


Figure 4C.—Logic circuit.

IN ANSWERING QUESTIONS 4-12 THROUGH 4-14, REFER TO FIGURE 4C.

4-12. What type of circuit is shown in the figure?

1. Full adder
2. Subtracter adder
3. Double half adder
4. Double exclusive OR

4-13. If A and B are 0 and C is 1, what will be the outputs at D and E?

1. D = 0, E = 0
2. D = 0, E = 1
3. D = 1, E = 0
4. D = 1, E = 1

4-14. Under which of the following conditions will outputs D and E both be HIGH?

1. A, B, and C are HIGH
2. A and B are HIGH, C is LOW
3. A and B are LOW, C is HIGH
4. A, B, and C are LOW

4-15. What is the largest sum that can be obtained from a full adder?

1. 10_2
2. 11_2
3. 100_2
4. 111_2

4-16. How many full adders are required to form a parallel adder capable of adding 10001_2 and 1000_2?

1. Five
2. Six
3. Three
4. Four

4-17. Which of the following statements describes the method used in computers to subtract binary numbers?

1. R's complement the minuend and add to the subtrahend
2. Add the minuend and subtrahend and complement the sum
3. R's complement the subtrahend and add to the minuend
4. Subtract the subtrahend from the minuend and complement the difference

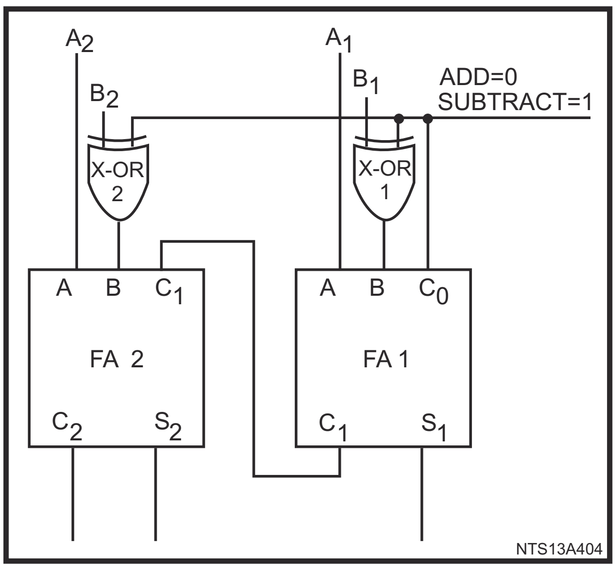

Figure 4D.—Adder/subtracter circuit.

IN ANSWERING QUESTIONS 4-18 THROUGH 4-20, REFER TO FIGURE 4D.

4-18. What type of complement is performed by X-OR gates 1 and 2?

1. R's complement
2. Minuend complement
3. R's + 1 complement
4. Difference complement

4-19. Which of the following inputs is used for the least significant digit of the minuend?

1. A_1
2. A_2
3. B_1
4. B_2

4-20. What will be the output of (a) X-OR 2 and (b) X-OR 1 in the subtract mode with a subtrahend of 10_2?

1. (a) 0 (b) 0
2. (a) 0 (b) 1
3. (a) 1 (b) 0
4. (a) 1 (b) 1

4-21. Flip-flops are what type of multivibrators?

1. Astable
2. Monostable
3. Free running
4. Bistable

4-22. Flip-flops may NOT be used for which of the following operations?

1. Temporary storage
2. Subtraction
3. Division
4. Transfer of information

4-23. When, if ever, will the outputs Q and $\overline{Q}$ of an R-S flip-flop be the same?

1. When R and S are both LOW
2. When R is LOW and S is HIGH
3. When R is HIGH and S is LOW
4. Never

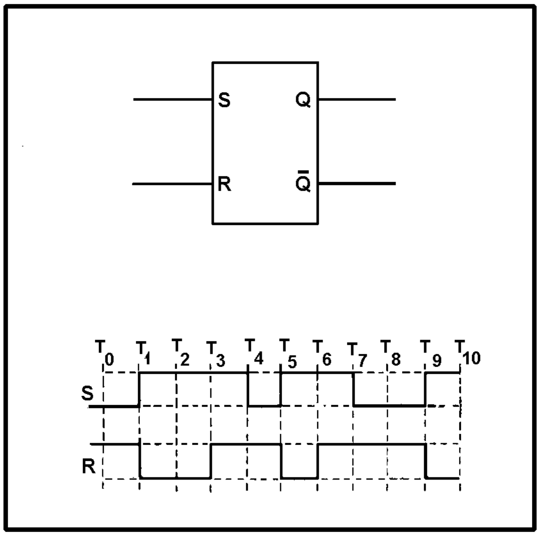

Figure 4E.—R-S flip-flop with timing diagram.

WHEN ANSWERING QUESTIONS 4-24 AND 4-25, REFER TO FIGURE 4E.

4-24. Assume the flip-flop is set at T_0. At which of the following times will the flip-flop be reset?

1. T_1 to T_3, T_5 to T_6, and T_9 to T_{10}
2. T_0 to T_1, T_3 to T_5, and T_6 to T_9
3. T_1 to T_3, T_5 to T_7, and T_9 to T_{10}
4. T_1 to T_4, T_5 to T_7, and T_9 to T_{10}

4-25. What happens to the flip-flop at T_6?

1. It sets
2. It resets
3. It sets and immediately resets
4. It remains reset

4-26. Which of the following statements describes a toggle flip-flop?

1. A monostable device
2. An astable device that changes state only on a set pulse
3. A two input bistable device
4. A bistable device with a single input

4-27. A T flip-flop is used primarily for which of the following functions?

1. To divide the input frequency by two
2. To double the input frequency
3. To amplify the input frequency
4. To invert the input frequency

4-28. What are the inputs to a D flip-flop?

1. Set and reset
2. Set and clock
3. Data and clock
4. Reset and data

4-29. What is the purpose of a D flip-flop?

1. To eliminate the output of the equipment
2. To divide the data input by the clock frequency
3. To store data until it is needed
4. To toggle the data input

4-30. An inverter on the clock input has which of the following effects on the D flip-flop?

1. The output will change on the negative-going transition of the clock pulse
2. The output will change on the positive-going transition of the clock pulse
3. The data input will change at the clock frequency
4. The output will change at the clock frequency

4-31. Which of the following statements is true concerning CLR and PR pulses to the D flip-flop?

1. CLR causes Q to go high, PR causes Q to go low
2. CLR and PR override any existing output condition
3. Other inputs override CLR and PR
4. CLR and PR have no effect on the output

4-32. Which of the following statements is correct concerning D flip-flops?

1. The output is delayed up to one clock pulse
2. Input data is delayed until it coincides with the clock
3. The clock is delayed until it coincides with the input data
4. The output is always a square wave

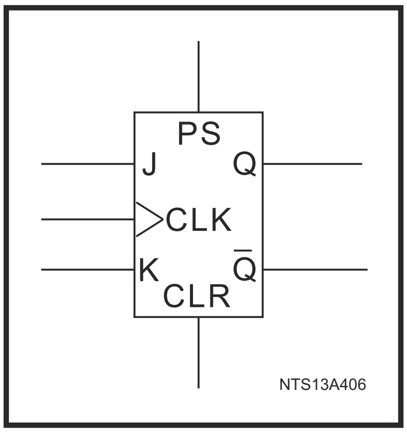

Figure 4F.—Standard symbol for a J-K flip-flop.

WHEN ANSWERING QUESTIONS 4-33 THROUGH 4-36, REFER TO FIGURE 4F.

4-33. The flip-flop shown in the figure may be used in place of which of following flip-flops?

1. R-S
2. T
3. D
4. Each of the above

4-34. With the clock applied and J and K inputs held HIGH, what is the output at Q?

1. Constant HIGH
2. Constant LOW
3. Toggle at one half the clock frequency
4. Toggle at twice the clock frequency

4-35. What will be the $\overline{Q}$ output if K is HIGH and CLK goes HIGH?

1. HIGH
2. LOW

4-36. A pulse on which of the following inputs will cause the flip-flop to set regardless of the other inputs?

1. CLK
2. CLR
3. J or K
4. PR or PS

4-37. The circuit which generates a timing signal to control operations is called a/an

1. clock
2. counter
3. oscillator
4. bistable multivibrator

4-38. Which of the following statements is true regarding astable multivibrators used as clocks?

1. As multivibrator frequency increases, stability decreases
2. Output 2 will have a higher voltage than output 1
3. The frequency stability may be increased by applying a higher frequency trigger
4. A trigger of lower frequency will stabilize the output frequency

4-39. Which of the following types of circuits will produce a stable clock when triggered by an outside source?

1. R-S flip-flop
2. Bistable multivibrator
3. One-shot multivibrator
4. D flip-flop

4-40. Which of the following types of clocks would probably be used in a complex piece of equipment with a variety of timing requirements?

1. Single triggered-monostable
2. Single free-running
3. Triggered-astable for each section of the equipment
4. Multiphase

4-41. What is the modulus of a 3-stage binary counter?

1. 7
2. 8
3. 3
4. 4

4-42. Counters may be used for which of the following purposes?

1. Counting operations, quantities and time
2. Dividing frequency
3. Addressing information in storage
4. Each of the above

THIS SPACE LEFT BLANK INTENTIONALLY

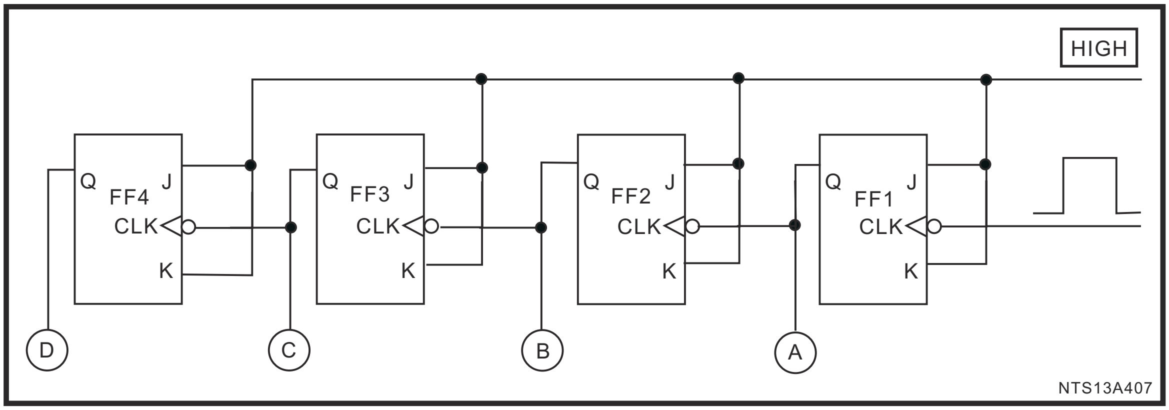

Figure 4G.—Standard symbol circuit.

WHEN ANSWERING QUESTIONS 4-43 THROUGH 4-46, REFER TO FIGURE 4G. FOR EACH QUESTION, ASSUME THAT ALL FFs ARE INITIALLY RESET.

4-43. What type of circuit is shown?

1. J-K flip-flops
2. Clock
3. Shift register
4. Ripple counter

4-44. Assume all lights are out. After 6 input pulses, which two lamps will be lit?

1. A and B
2. A and C
3. B and C
4. B and D

4-45. Assume all lamps are out. After 16 input pulses, which lamps, if any, will be lit?

1. A, B, C, and D
2. B, C, and D
3. A, B, and D
4. None

4-46. What is the main disadvantage of using this circuit with a high frequency input?

1. The circuit will burn up
2. Possible errors in the output
3. The flip-flops will act as T flip-flops
4. Above a certain frequency the circuit will count in the opposite direction

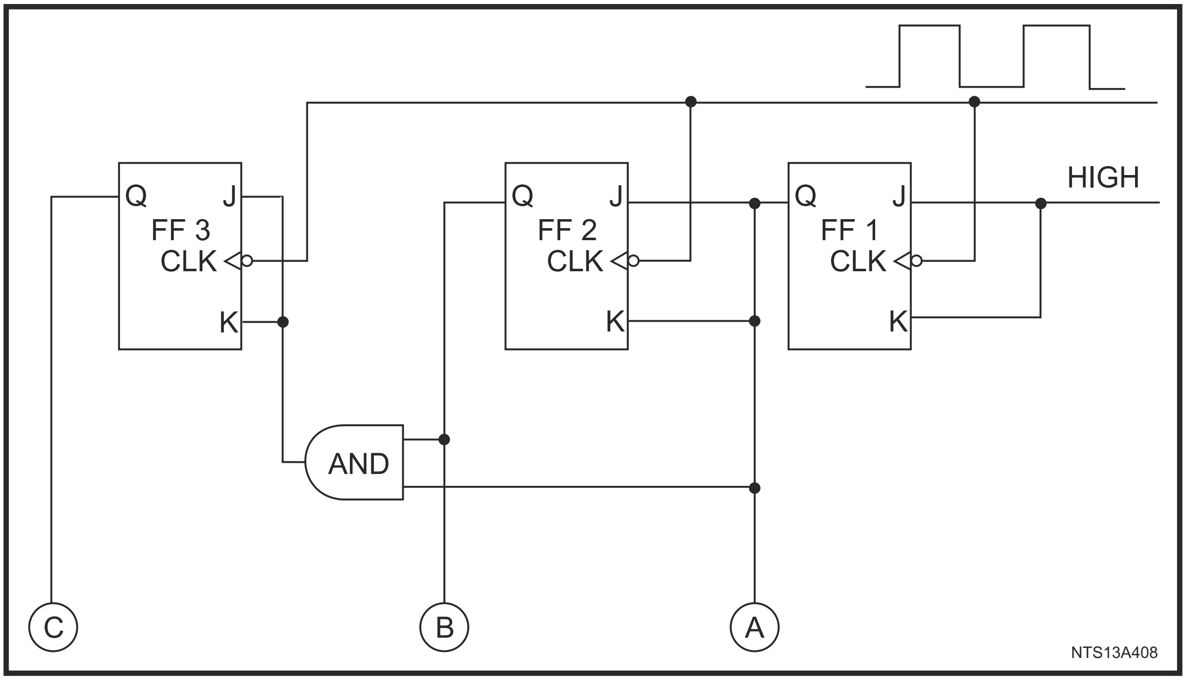

Figure 4H.—Counter circuit.

WHEN ANSWERING QUESTIONS 4-47 THROUGH 4-50, REFER TO FIGURE 4H.

4-47. What is the maximum count that this counter is capable of holding?

1. 5_8
2. 7_8
3. 3_8
4. 4_8

4-48. What type of counter is shown?

1. Ring
2. Asynchronous
3. Synchronous
4. Decade

4-49. Under which of the following conditions will the output of the AND gate be HIGH?

1. FF 1 and FF 2 are set
2. FF 1 and FF 2 are reset
3. FF 2 and FF 3 are set
4. FF 1 and FF 3 are reset

4-50. With all the FFs initially reset, the AND gate output will be HIGH after how many input pulses?

1. 3 only
2. 4 only
3. 7 only
4. 3 and 7

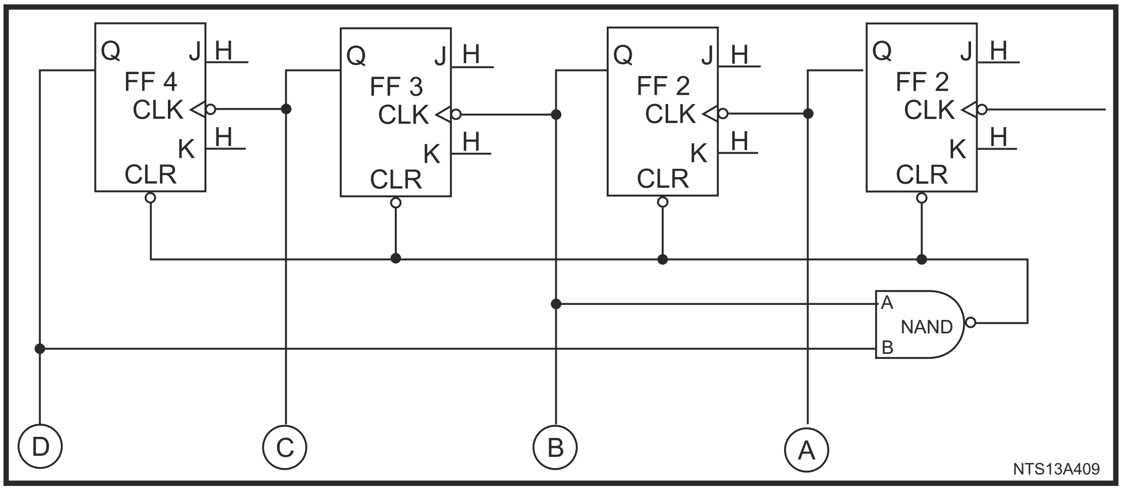

Figure 4I.—Counter circuit.

WHEN ANSWERING QUESTIONS 4-51 AND 4-52, REFER TO FIGURE 4I.

4-51. What is the maximum binary count that will be shown before all the flip-flops reset?

1. 111_2
2. 1010_2
3. 1111_2
4. 1000_2

4-52. To change the maximum count from 10_{10} to 9_{10}, which two flip-flops would be wired as NAND gate inputs?

1. FF 1 and FF 2
2. FF 2 and FF 3
3. FF 1 and FF 4
4. FF 1 and FF 3

THIS SPACE LEFT BLANK INTENTIONALLY.

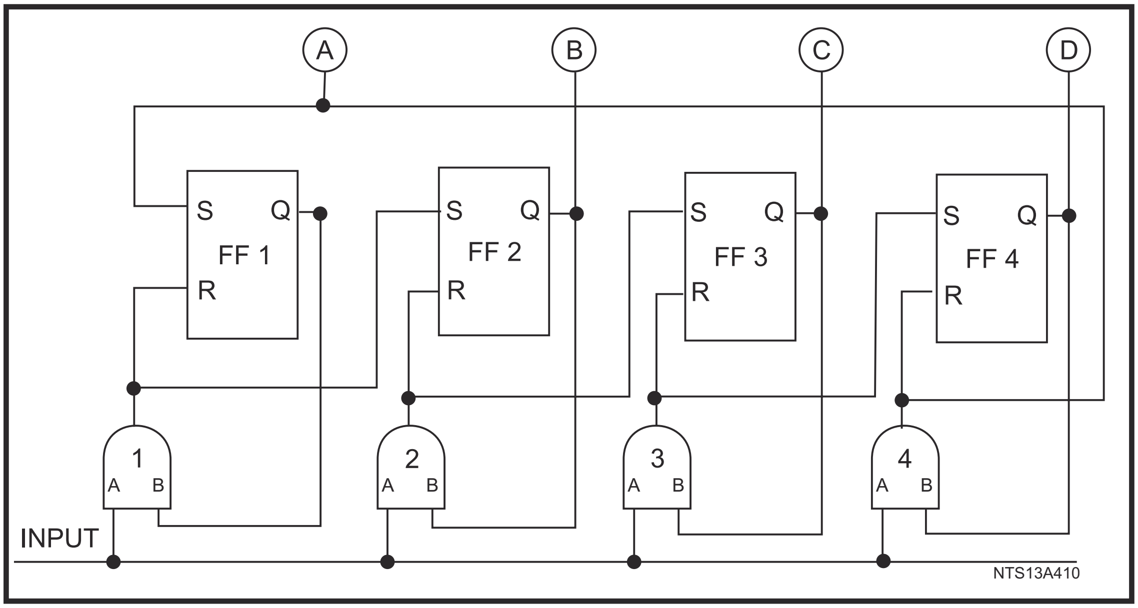

Figure 4J.—Counter circuit.

WHEN ANSWERING QUESTIONS 4-53 THROUGH 4-55, REFER TO FIGURE 4J.

4-53. Which of the following types of counters is shown in the figure?

1. Ring
2. Asynchronous
3. Synchronous
4. Decade

4-54. At any given time, how many flip-flops may be set?

1. Only one
2. Any two
3. Any three
4. All

4-55. Which of the following conditions must exist to set FF 3?

1. AND gate 1 output HIGH
2. AND gate 2 output HIGH
3. AND gate 3 output LOW
4. Clock input to AND gate 3 LOW and AND gate 4 output HIGH

THIS SPACE LEFT BLANK INTENTIONALLY

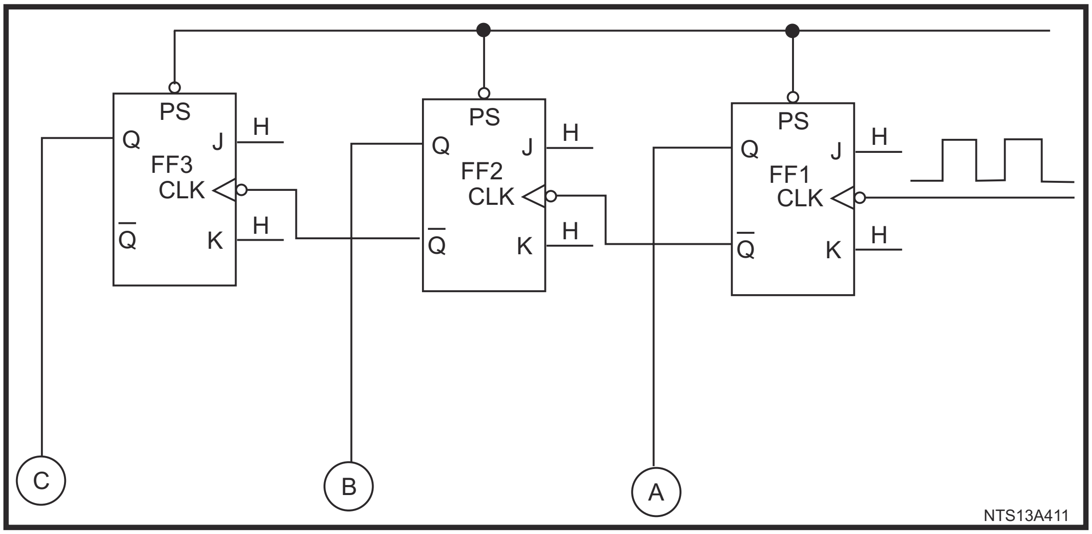

Figure 4K.—Down counter.

WHEN ANSWERING QUESTIONS 4-56 AND 4-57, REFER TO FIGURE 4K.

4-56. Assume only FF 1 and FF 3 are set. Which, if any, of the flip-flops will be set after the next clock pulse?

1. FF 2 only
2. FF 3 only
3. FF 2 and FF 3
4. None

4-57. Assume that all FFs are set, which of the following actions will take place at clock pulse 4?

1. FF 1, FF 2 and FF 3 will set
2. FF 1 will set, FF 2 and FF 3 will reset
3. FF 1, FF 2, and FF 3 will reset
4. FF 1 and FF 2 will set, FF 3 will reset

4-58. What term identifies a series of FFs designed to temporarily store information?

1. Data word
2. Counter
3. Register
4. DIP package

4-59. Which of the following statements describes parallel transfer?

1. Data is transferred one bit at a time
2. All data bits are transferred simultaneously
3. Data is received in serial form and transferred in parallel form
4. Data is transferred on a single line

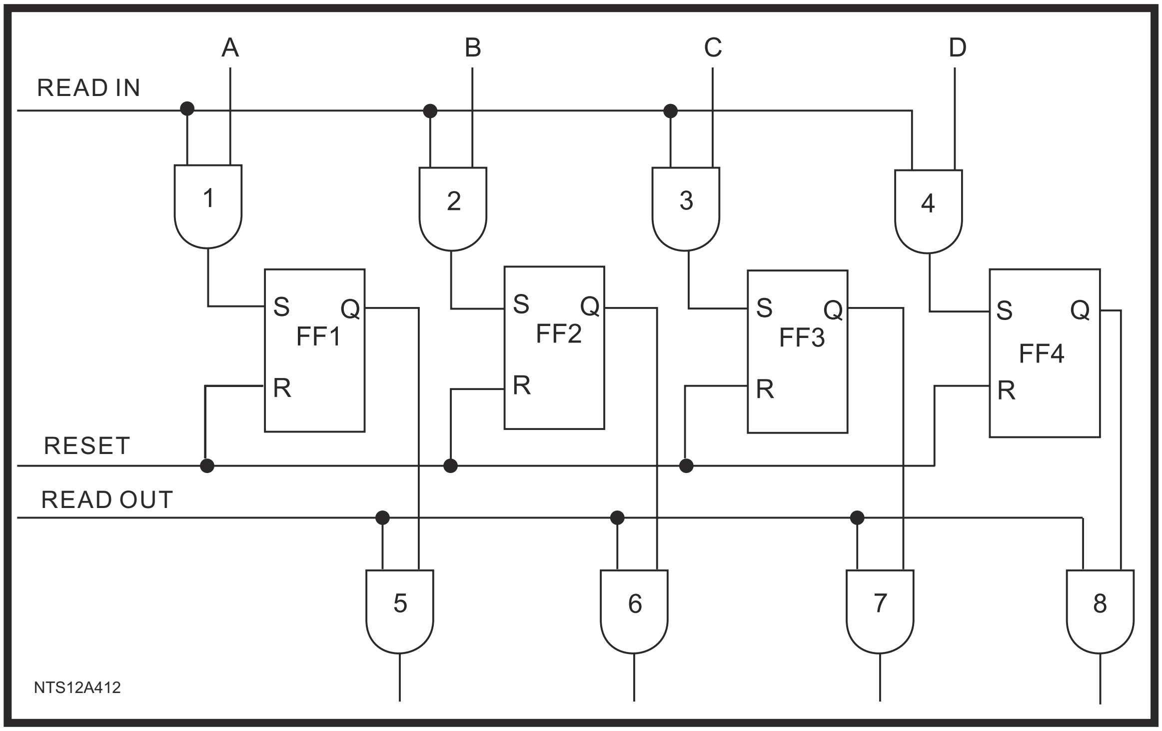

Figure 4L.—Parallel register.

WHEN ANSWERING QUESTIONS 4-60 AND 4-61, REFER TO FIGURE 4L.

4-60. Which of the following methods will clear the register of old information no longer needed?

1. A HIGH applied to the READ IN line
2. A HIGH applied to the RESET line
3. A LOW applied on the RESET and a HIGH on the READ OUT lines
4. HIGHs are applied on the A, B, C, D, and READ IN lines

4-61. Under which of the following conditions will the output of gate 7 be HIGH?

1. When FF 3 and RESET are HIGH
2. When gate 3 and FF 3 are HIGH
3. When FF 3 and READ OUT are HIGH
4. When the output of gate 3 is HIGH

THIS SPACE LEFT BLANK INTENTIONALLY

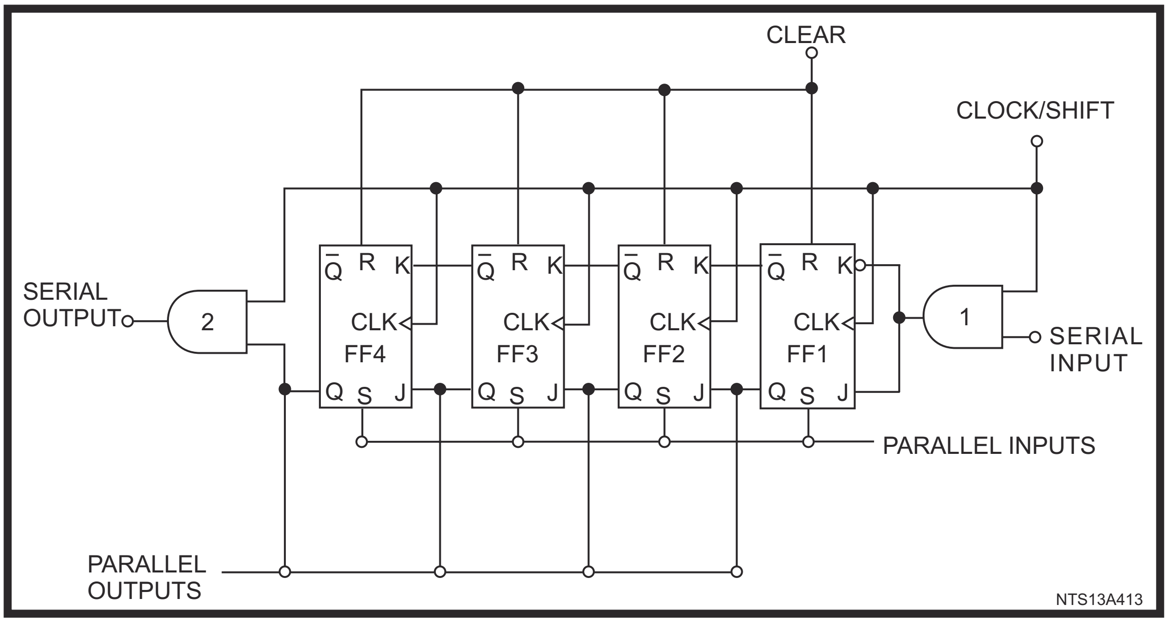

Figure 4M.—Shift register.

WHEN ANSWERING QUESTIONS 4-62 THROUGH 4-67, REFER TO FIGURE 4M.

4-62. Which of the following operations is the circuit capable of performing?

1. Serial-to-parallel conversion
2. Parallel-to-serial conversion
3. Left shifts
4. Each of the above

4-63. What is the maximum word length the register is capable of handling?

1. 6 bit
2. 5 bit
3. 3 bit
4. 4 bit

4-64. How many clock/shift pulses are required to serially input a word into the register?

1. 1
2. 5
3. 3
4. 4

4-65. To output a word in parallel form, how many output lines are required?

1. 1
2. 2
3. 4
4. 8

4-66. To increase the value of a word by one power of 2, how many shifts are required?

1. 1
2. 2
3. 3
4. 0

4-67. Which of the following operations takes the longest time?

1. Serial in, parallel out
2. Serial in, serial out
3. Parallel in, serial out
4. Parallel in, parallel out

4-68. Shifting a word in a shift register 3 places to the left is equal to multiplying the number by how much?

1. 10_{10}
2. 2_{10}
3. 8_{10}
4. 4_{10}

4-69. Logic families are identified by which of the following means?

1. Logic polarity required
2. The types of elements used
3. Size and cost of manufacture
4. Packaging (DIP, TO, flat packs)

4-70. A TTL logic circuit would use which of the following types of elements?

1. Diode-transistor
2. Resistor-transistor
3. Transistor-transistor
4. Complementary metal oxide semiconductors

PREFACE

About this course:

This is a self-study course. By studying this course, you can improve your professional/military knowledge, as well as prepare for the Navywide advancement-in-rate examination. It contains subject matter about day-to-day occupational knowledge and skill requirements and includes text, tables, and illustrations to help you understand the information. An additional important feature of this course is its reference to useful information in other publications. The well-prepared Sailor will take the time to look up the additional information.

Training series information:

This is Module 14 of a series.

History of the course:

Sep 1998: Original edition released.

Sep 2003: Administrative update released. Technical content reviewed and revised by ETC(SW) *Jack Weatherford.*

NAVSUP Logistics Tracking Number

TABLE OF CONTENTS

ASSIGNMENT QUESTIONS follow Index.

CHAPTER 1

MICROELECTRONICS

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each topic. These learning objectives serve as a preview of the information you are expected to learn in the topic. The comprehensive check questions are based on the objectives. By successfully completing the OCC-ECC, you indicate that you have met the objectives and have learned the information. The learning objectives are listed below.

Upon completion of this topic, you will be able to:

1. Outline the progress made in the history of microelectronics.
2. Describe the evolution of microelectronics from point-to-point wiring through high element density state-of-the-art microelectronics.
3. List the advantages and disadvantages of point-to-point wiring and high element density state-of-the-art microelectronics.
4. Identify printed circuit boards, diodes, transistors, and the various types of integrated circuits. Describe the fabrication techniques of these components.
5. Define the terminology used in microelectronic technology including the following terms used by the Naval Systems Commands:
    a. microelectronics
    b. microcircuit
    c. microcircuit module
    d. miniature electronics
    e. system packaging
    f. levels of packaging (0 to IV)
    g. modular assemblies
    h. cordwood modules
    i. micromodules
6. Describe typical packaging levels presently used for microelectronic systems.
7. Describe typical interconnections used in microelectronic systems.
8. Describe environmental considerations for microelectronics.

INTRODUCTION

In *NEETS, Module 6*, *Introduction to Electronic Emission, Tubes, and Power Supplies*, you learned that Thomas Edison's discovery of thermionic emission opened the door to electronic technology. Progress was slow in the beginning, but each year brought new and more amazing discoveries. The development of vacuum tubes soon led to the simple radio. Then came more complex systems of communications. Modern systems now allow us to communicate with other parts of the world via satellite. Data is now collected from space by probes without the presence of man because of microelectronic technology.

Sophisticated control systems allow us to operate equipment by remote control in hazardous situations, such as the handling of radioactive materials. We can remotely pilot aircraft from takeoff to landing. We can make course corrections to spacecraft millions of miles from Earth. Space flight, computers, and even video games would not be possible except for the advances made in microelectronics.

The most significant step in modern electronics was the development of the transistor by Bell Laboratories in 1948. This development was to solid-state electronics what the Edison Effect was to the vacuum tube. The solid-state diode and the transistor opened the door to microelectronics.

MICROELECTRONICS is defined as that area of technology associated with and applied to the realization of electronic systems made of extremely small electronic parts or elements. As discussed in topic 2 of *NEETS, Module 7*, *Introduction to Solid-State Devices and Power Supplies*, the term *microelectronics* is normally associated with integrated circuits (IC). Microelectronics is often thought to include only integrated circuits. However, many other types of circuits also fall into the microelectronics category. These will be discussed in greater detail under solid-state devices later in this topic.

During World War II, the need to reduce the size, weight, and power of military electronic systems became important because of the increased use of these systems. As systems became more complex, their size, weight, and power requirements rapidly increased. The increases finally reached a point that was unacceptable, especially in aircraft and for infantry personnel who carried equipment in combat. These unacceptable factors were the driving force in the development of smaller, lighter, and more efficient electronic circuit components. Such requirements continue to be important factors in the development of new systems, both for military and commercial markets. Military electronic systems, for example, continue to become more highly developed as their capability, reliability, and maintainability is increased. Progress in the development of military systems and steady advances in technology point to an ever-increasing need for increased technical knowledge of microelectronics in your Navy job.

Q1. What problems were evident about military electronic systems during World War II?

Q2. What discovery opened the door to solid-state electronics?

Q3. *What is microelectronics?*

EVOLUTION OF MICROELECTRONICS

The earliest electronic circuits were fairly simple. They were composed of a few tubes, transformers, resistors, capacitors, and wiring. As more was learned by designers, they began to increase both the size and complexity of circuits. Component limitations were soon identified as this technology developed.

VACUUM-TUBE EQUIPMENT

Vacuum tubes were found to have several built-in problems. Although the tubes were lightweight, associated components and chassis were quite heavy. It was not uncommon for such chassis to weigh 40 to 50 pounds. In addition, the tubes generated a lot of heat, required a warm-up time from 1 to 2 minutes, and required hefty power supply voltages of 300 volts dc and more.

No two tubes of the same type were exactly alike in output characteristics. Therefore, designers were required to produce circuits that could work with any tube of a particular type. This meant that additional components were often required to tune the circuit to the output characteristics required for the tube used.

Figure 1-1 shows a typical vacuum-tube circuit. The actual size of the transformer is approximately $4 \times 4 \times 3$ inches. Capacitors are approximately 1×3 inches. The components in the figure are very large when compared to modern microelectronics.

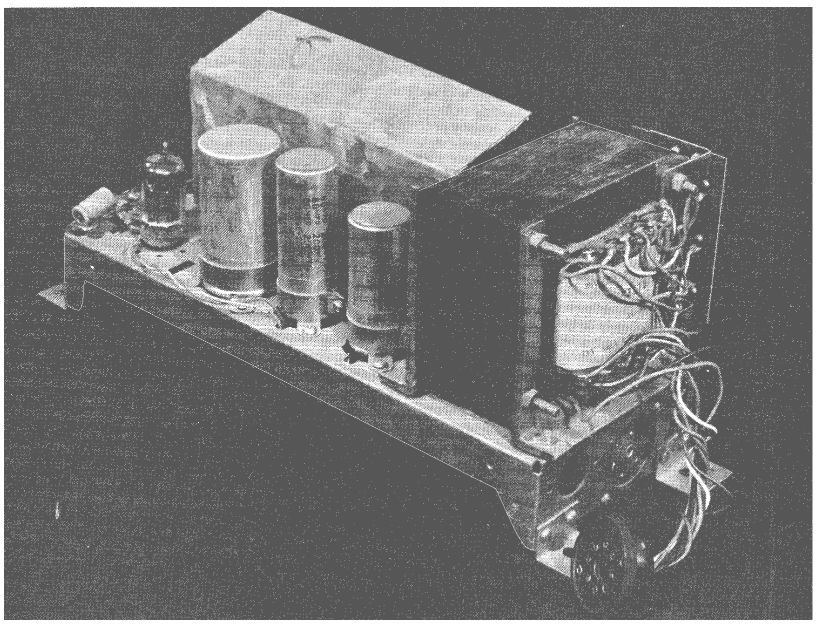

Figure 1-1.—Typical vacuum-tube circuit.

A circuit could be designed either as a complete system or as a functional part of a larger system. In complex systems, such as radar, many separate circuits were needed to accomplish the desired tasks. Multiple-function tubes, such as dual diodes, dual triodes, tetrodes, and others helped considerably to reduce the size of circuits. However, weight, heat, and power consumption continued to be problems that plagued designers.

Another major problem with vacuum-tube circuits was the method of wiring components referred to as POINT-TO-POINT WIRING. Figure 1-2 is an excellent example of point-to-point wiring. Not only did this wiring look like a rat's nest, but it often caused unwanted interactions between components. For example, it was not at all unusual to have inductive or capacitive effects between wires. Also, point-to-point wiring posed a safety hazard when troubleshooting was performed on energized circuits because of exposed wiring and test points. Point-to-point wiring was usually repaired with general-purpose test equipment and common hand tools.

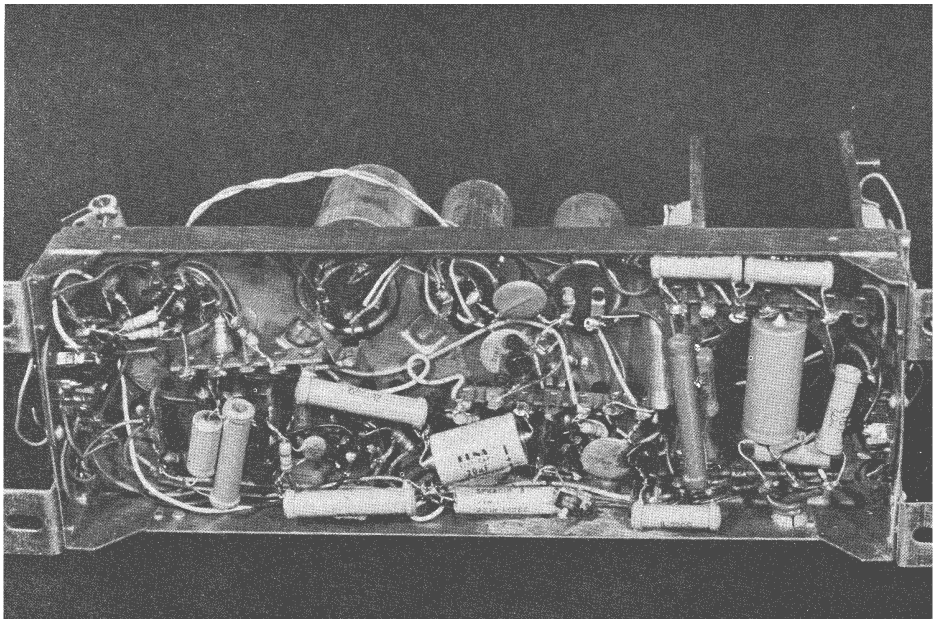

Figure 1-2.—Point-to-point wiring.

Vacuum-tube circuits proved to be reliable under many conditions. Still, the drawbacks of large size, heavy weight, and significant power consumption made them undesirable in most situations. For example, computer systems using tubes were extremely large and difficult to maintain. ENIAC, a completely electronic computer built in 1945, contained 18,000 tubes. It often required a full day just to locate and replace faulty tubes.

In some applications, we are still limited to vacuum tubes. Cathode-ray tubes used in radar, television, and oscilloscopes do not, as yet, have solid-state counterparts.

One concept that eased the technician's job was that of MODULAR PACKAGING. Instead of building a system on one large chassis, it was built of MODULES or blocks. Each module performed a necessary function of the system. Modules could easily be removed and replaced during troubleshooting and repair. For instance, a faulty power supply could be exchanged with a good one to keep the system operational. The faulty unit could then be repaired while out of the system. This is an example of how the module concept improved the efficiency of electronic systems. Even with these advantages, vacuum tube modules still had faults. Tubes and point-to-point wiring were still used and excessive size, weight, and power consumption remained as problems to be overcome.

Vacuum tubes were the basis for electronic technology for many years and some are still with us. Still, emphasis in vacuum-tube technology is rapidly becoming a thing of the past. The emphasis of technology is in the field of microelectronics.

Q4. What discovery proved to be the foundation for the development of the vacuum tube?

Q5. Name the components which greatly increase the weight of vacuum-tube circuitry.

Q6. What are the disadvantages of point-to-point wiring?

Q7. What is a major advantage of modular construction?

Q8. When designing vacuum-tube circuits, you must take what characteristics of tubes into consideration?

SOLID-STATE DEVICES

Now would be a good time for you to review the first few pages of *NEETS, Module 7, Introduction to Solid-State Devices and Power Supplies*, as a refresher for solid-state devices.

The transition from vacuum tubes to solid-state devices took place rapidly. As new types of transistors and diodes were created, they were adapted to circuits. The reductions in size, weight, and power use were impressive. Circuits that earlier weighed as much as 50 pounds were reduced in weight to just a few ounces by replacing bulky components with the much lighter solid-state devices.

The earliest solid-state circuits still relied on point-to-point wiring which caused many of the disadvantages mentioned earlier. A metal chassis, similar to the type used with tubes, was required to provide physical support for the components. The solid-state chassis was still considerably smaller and lighter than the older, tube chassis. Still greater improvements in component mounting methods were yet to come.

One of the most significant developments in circuit packaging has been the PRINTED CIRCUIT BOARD (pcb), as shown in figure 1-3. The pcb is usually an epoxy board on which the circuit leads have been added by the PHOTOETCHING process. This process is similar to photography in that copper-clad boards are exposed to controlled light in the desired circuit pattern and then etched to remove the unwanted copper. This process leaves copper strips (LANDS) that are used to connect the components. In general, printed circuit boards eliminate both the heavy, metal chassis and the point-to-point wiring.

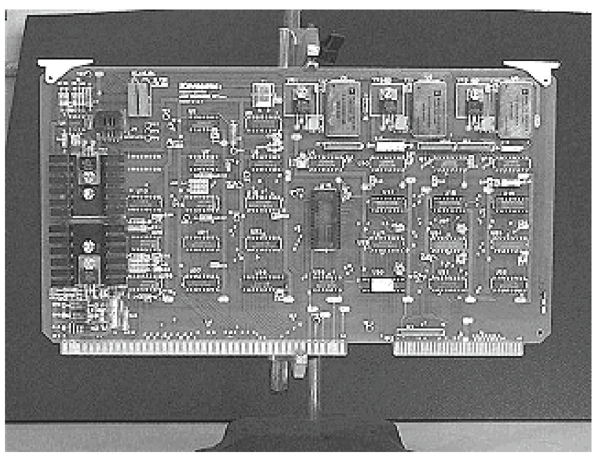

Figure 1-3.—Printed circuit board (pcb).

Although printed circuit boards represent a major improvement over tube technology, they are not without fault. For example, the number of components on each board is limited by the sizes and shapes of components. Also, while vacuum tubes are easily removed for testing or replacement, pcb components are soldered into place and are not as easily removed.

Normally, each pcb contains a single circuit or a subassembly of a system. All printed circuit boards within the system are routinely interconnected through CABLING HARNESSES (groups of wiring or ribbons of wiring). You may be confronted with problems in faulty harness connections that affect system reliability. Such problems are often caused by wiring errors, because of the large numbers of wires in a harness, and by damage to those wires and connectors.

Another mounting form that has been used to increase the number of components in a given space is the CORDWOOD MODULE, as shown in figure 1-4. You can see that the components are placed perpendicular to the end plates. The components are packed very closely together, appearing to be stacked like cordwood for a fireplace. The end plates are usually small printed circuit boards, but may be insulators and solid wire, as shown in the figure. Cordwood modules may or may not be ENCAPSULATED (totally imbedded in solid material) but in either case they are difficult to repair.

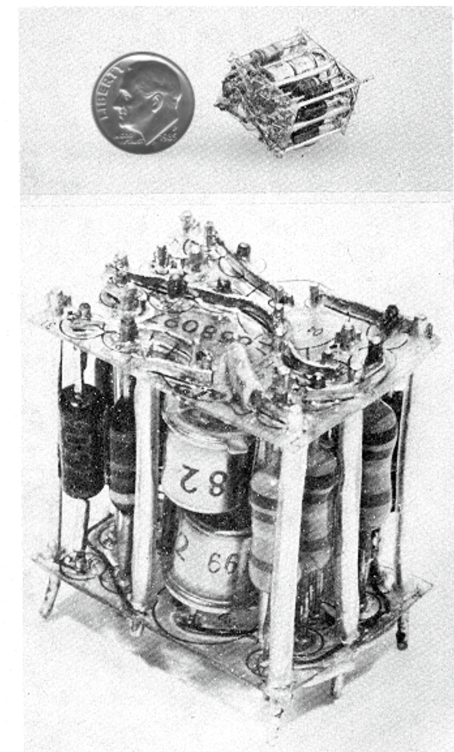

Figure 1-4.—Cordwood module.

Q9. List the major advantages of printed circuit boards.

Q10. What is the major disadvantage of printed circuit boards?

Q11. The ability to place more components in a given space is an advantage of the **_______**.

INTEGRATED CIRCUITS

Many advertisements for electronic equipment refer to integrated circuits or solid-state technology. You know the meaning of the term *solid-state*, but what is an INTEGRATED CIRCUIT? The accepted Navy definition for an integrated circuit is that it consists of elements inseparably associated and formed on or within a single SUBSTRATE (mounting surface). In other words, the circuit components and all interconnections are formed as a unit. You will be concerned with three types of integrated circuits: MONOLITHIC, FILM, and HYBRID.

MONOLITHIC INTEGRATED CIRCUITS are those that are formed completely within a semiconductor substrate. These integrated circuits are commonly referred to as SILICON CHIPS.

FILM INTEGRATED CIRCUITS are broken down into two categories, THIN FILM and THICK FILM. Film components are made of either conductive or nonconductive material that is deposited in desired patterns on a ceramic or glass substrate. Film can only be used as passive circuit components, such as resistors and capacitors. Transistors and/or diodes are added to the substrate to complete the circuit. Differences in thin and thick film will be discussed later in this topic.

HYBRID INTEGRATED CIRCUITS combine two or more integrated circuit types or combine one or more integrated circuit types and DISCRETE (separate) components. Figure 1-5 is an example of a hybrid integrated circuit consisting of silicon chips and film circuitry. The two small squares are chips and the irregularly shaped gray areas are film components.

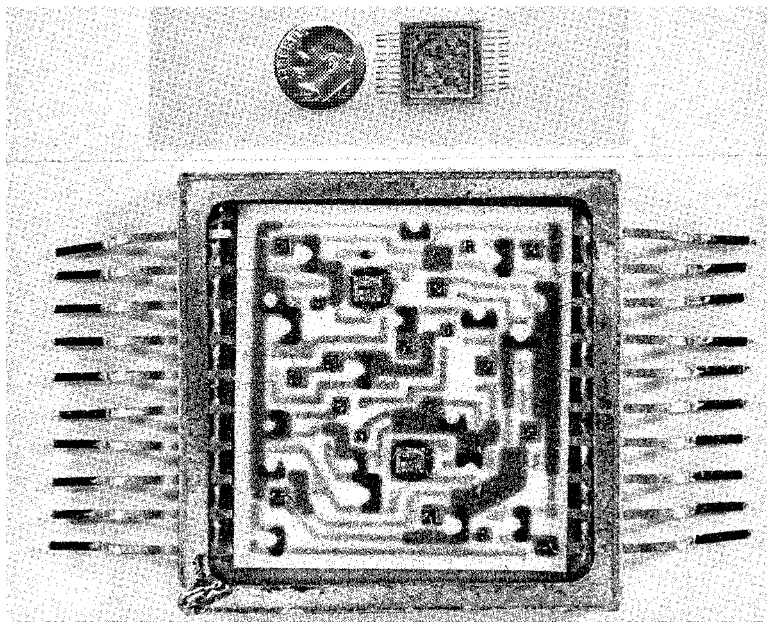

Figure 1-5.—Hybrid integrated circuit.

STATE-OF-THE-ART MICROELECTRONICS

Microelectronic technology today includes thin film, thick film, hybrid, and integrated circuits and combinations of these. Such circuits are applied in DIGITAL, SWITCHING, and LINEAR (analog) circuits. Because of the current trend of producing a number of circuits on a single chip, you may look for further increases in the packaging density of electronic circuits. At the same time you may expect a reduction in the size, weight, and number of connections in individual systems. Improvements in reliability and system capability are also to be expected.

Thus, even as existing capabilities are being improved, new areas of microelectronic use are being explored. To predict where all this use of technology will lead is impossible. However, as the demand for increasingly effective electronic systems continues, improvements will continue to be made in state-of-the-art microelectronics to meet the demands.

LARGE-SCALE INTEGRATION (lsi) and VERY LARGE-SCALE INTEGRATION (vlsi) are the results of improvements in microelectronics production technology. Figure 1-6 is representative of lsi. As shown in the figure, the entire SUBSTRATE WAFER (slice of semiconductor or insulator material) is used instead of one that has been separated into individual circuits. In lsi and vlsi, a variety of circuits can be implanted on a wafer resulting in further size and weight reduction. ICs in modern computers, such as home computers, may contain the entire memory and processing circuits on a single substrate.

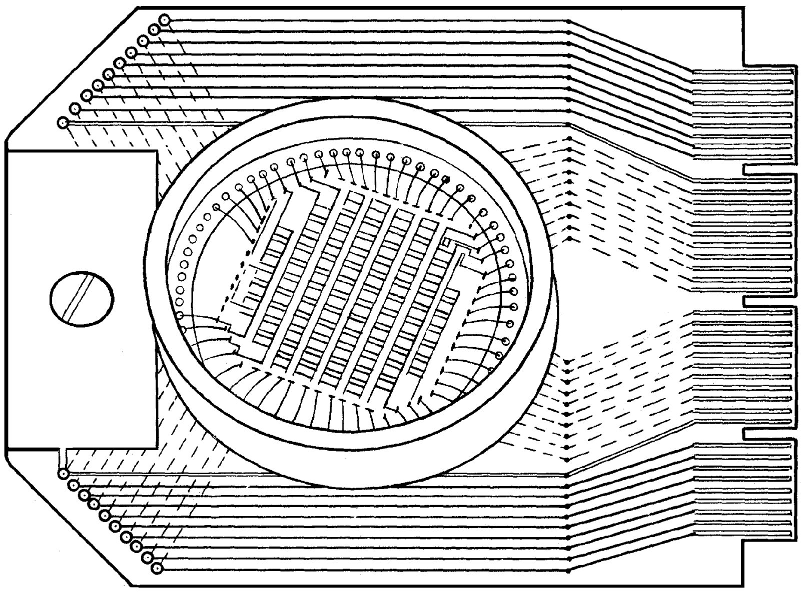

Figure 1-6.—Large-scale integration device (lsi).

Large-scale integration is generally applied to integrated circuits consisting of from 1,000 to 2,000 logic gates or from 1,000 to 64,000 bits of memory. A logic gate, as you should recall from *NEETS, Module 13, Introduction to Number Systems, Boolean Algebra, and Logic Circuits*, is an electronic switching network consisting of combinations of transistors, diodes, and resistors. Very large-scale integration is used in integrated circuits containing over 2,000 logic gates or greater than 64,000 bits of memory.

Q12. Define integrated circuit.

Q13. What are the three major types of integrated circuits?

Q14. How do monolithic ICs differ from film ICs?

Q15. What is a hybrid IC?

Q16. How many logic gates could be contained in lsi?

FABRICATION OF MICROELECTRONIC DEVICES

The purpose of this section is to give you a simplified overview of the manufacture of microelectronic devices. The process is far more complex than will be described here. Still, you will be able to see that microelectronics is not magic, but a highly developed technology.

Development of a microelectronic device begins with a demand from industry or as the result of research. A device that is needed by industry may be a simple diode network or a complex circuit consisting of thousands of components. No matter how complex the device, the basic steps of production are similar. Each type of device requires circuit design, component arrangement, preparation of a substrate, and the depositing of proper materials on the substrate.

The first consideration in the development of a new device is to determine what the device is to accomplish. Once this has been decided, engineers can design the device. During the design phase, the engineers will determine the numbers and types of components and the interconnections, needed to complete the planned circuit.

COMPONENT ARRANGEMENT

Planning the component arrangement for a microelectronic device is a very critical phase of production. Care must be taken to ensure the most efficient use of space available. With simple devices, this can be accomplished by hand. In other words, the engineers can prepare drawings of component placement. However, a computer is used to prepare the layout for complex devices. The computer is able to store the characteristics of thousands of components and can provide a printout of the most efficient component placement. Component placement is then transferred to extremely large drawings. During this step, care is taken to maintain the patterns as they will appear on the substrate. Figure 1-7 shows a fairly simple IC MASK PATTERN. If this pattern were being prepared for production, it would be drawn several hundred times the size shown and then photographed. The photo would then be reduced in size until it was the actual desired size. At that time, the pattern would be used to produce several hundred patterns that would be used on one substrate. Figure 1-8 illustrates how the patterns would be distributed to act as a WAFER MASK for manufacturing.

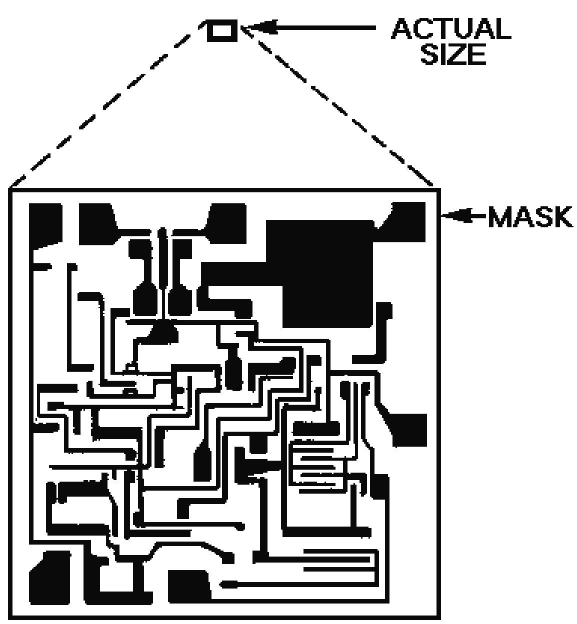

Figure 1-7.—IC mask pattern.

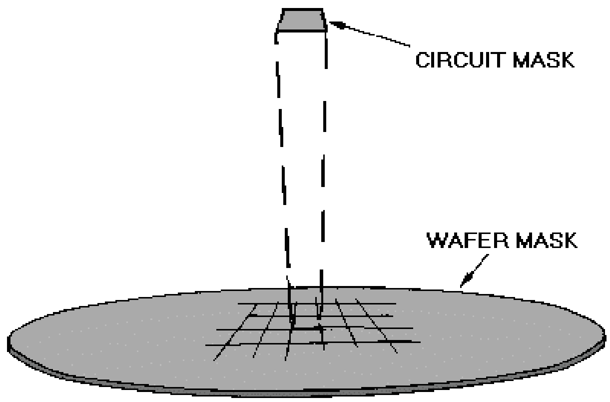

Figure 1-8.—Wafer mask distribution.

A wafer mask is a device used to deposit materials on a substrate. It allows material to be deposited in certain areas, but not in others. By changing the pattern of the mask, we can change the component arrangement of the circuit. Several different masks may be used to produce a simple microelectronic device. When used in proper sequence, conductor, semiconductor, or insulator materials may be applied to the substrate to form transistors, resistors, capacitors, and interconnecting leads.

SUBSTRATE PRODUCTION

As was mentioned earlier in this topic, microelectronic devices are produced on a substrate. This substrate will be of either insulator or semiconductor material, depending on the type of device. Film and hybrid ICs are normally constructed on a glass or ceramic substrate. Ceramic is usually the preferred material because of its durability.

Substrates used in monolithic ICs are of semiconductor material, usually silicon. In this type of IC, the substrate can be an active part of the IC. Glass or ceramic substrates are used only to provide support for the components.

Semiconductor substrates are produced by ARTIFICIALLY GROWING cylindrical CRYSTALS of pure silicon or germanium. Crystals are "grown" on a SEED CRYSTAL from molten material by slowly lifting and cooling the material repeatedly. This process takes place under rigidly controlled atmospheric and temperature conditions.

Figure 1-9 shows a typical CRYSTAL FURNACE. The seed crystal is lowered until it comes in contact with the molten material-silicon in this case. It is then rotated and raised very slowly. The seed crystal is at a lower temperature than the molten material. When the molten material is in contact with the seed, it solidifies around the seed as the seed is lifted. This process continues until the grown crystal is of the desired length. A typical crystal is about 2 inches in diameter and 10 to 12 inches long. Larger diameter crystals can be grown to meet the needs of the industry. The purity of the material is strictly controlled to maintain specific semiconductor properties. Depending on the need, n or p impurities are added to produce the desired characteristics. Several other methods of growing crystals exist, but the basic concept of crystal production is the same.

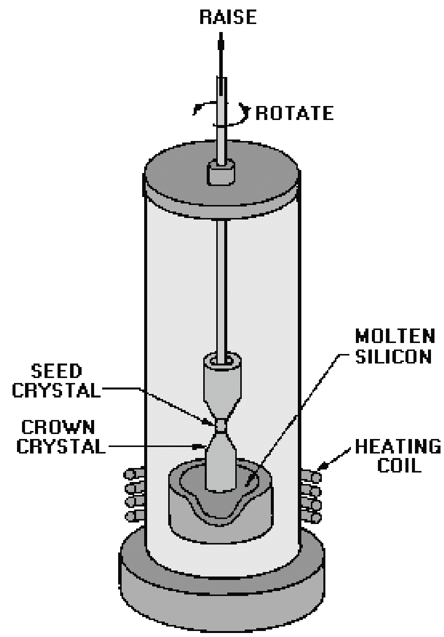

Figure 1-9.—Crystal furnace.

The cylinder of semiconductor material that is grown is sliced into thicknesses of .010 to .020 inch in the first step of preparation, as shown in figure 1-10. These wafers are ground and polished to remove any irregularities and to provide the smoothest surface possible. Although both sides are polished, only the side that will receive the components must have a perfect finish.

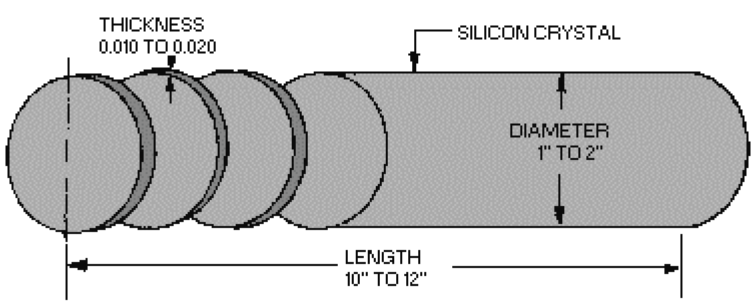

Figure 1-10.—Silicon crystal and wafers.

Q17. What are the basic steps in manufacturing an IC?

Q18. Computer-aided layout is used to prepare _______ devices.

Q19. What purpose do masks serve?

Q20. What type of substrates are used for film and hybrid ICs?

Q21. Describe the preparation of a silicon substrate.

FABRICATION OF IC DEVICES

Fabrication of monolithic ICs is the most complex aspect of microelectronic devices we will discuss. Therefore, in this introductory module, we will try to simplify this process as much as possible. Even though the discussion is very basic, the intent is still to increase your appreciation of the progress in microelectronics. You should, as a result of this discussion, come to realize that advances in manufacturing techniques are so rapid that staying abreast of them is extremely difficult.

Monolithic Fabrication.

Two types of monolithic fabrication will be discussed. These are the DIFFUSION METHOD and the EPITAXIAL METHOD.

DIFFUSION METHOD.—The DIFFUSION process begins with the highly polished silicon wafer being placed in an oven (figure 1-11). The oven contains a concentration impurity made up of impurity atoms which yield the desired electrical characteristics. The concentration of impurity atoms is diffused into the wafer and is controlled by controlling the temperature of the oven and the time that the silicon wafer is allowed to remain in the oven. This is called DOPING. When the wafer has been uniformly doped, the fabrication of semiconductor devices may begin. Several hundred circuits are produced simultaneously on the wafer.

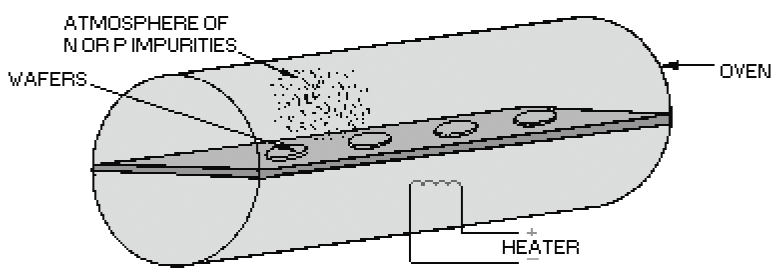

Figure 1-11.—Wafers in a diffusion oven.

The steps in the fabrication process described here, and illustrated in figure 1-12, would produce an npn, planar-diffused transistor. But, with slight variations, the technique may also be applied to the production of a complete circuit, including diodes, resistors, and capacitors. The steps are performed in the following order:

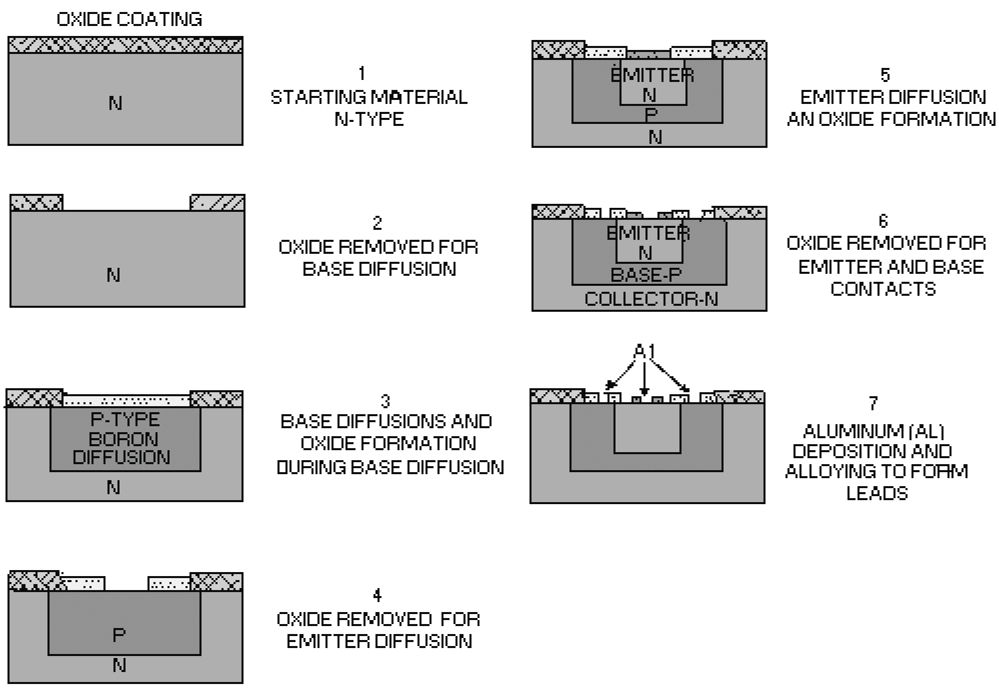

Figure 1-12.—Planar-diffused transistor.

1. An oxide coating is thermally grown over the n-type silicon starting material.

2. By means of the photolithographic process, a window is opened through the oxide layer. This is done through the use of masks, as discussed earlier.

3. The base of the transistor is formed by placing the wafer in a diffusion furnace containing a p-type impurity, such as boron. By controlling the temperature of the oven and the length of time that the wafer is in the oven, you can control the amount of boron diffused through the window (the boron will actually spread slightly beyond the window opening). A new oxide layer is then allowed to form over the area exposed by the window.

4. A new window, using a different mask much smaller than the first, is opened through the new oxide layer.

5. An n-type impurity, such as phosphorous, is diffused through the new window to form the emitter portion of the transistor. Again, the diffused material will spread slightly beyond the window opening. Still another oxide layer is then allowed to form over the window.

6. By means of precision-masking techniques, very small windows (about 0.005 inch in diameter) are opened in both the base and emitter regions of the transistor to provide access for electrical currents.

7. Aluminum is then deposited in these windows and alloyed to form the leads of the transistor or the IC.

(Note that the pn junctions are covered throughout the fabrication process by an oxide layer that prevents contamination.)

EPITAXIAL METHOD.—The EPITAXIAL process involves depositing a very thin layer of silicon to form a uniformly doped crystalline region (epitaxial layer) on the substrate. Components are produced by diffusing appropriate materials into the epitaxial layer in the same way as the planar-diffusion method. When planar-diffusion and epitaxial techniques are combined, the component characteristics are improved because of the uniformity of doping in the epitaxial layer. A cross section of a typical planar-epitaxial transistor is shown in figure 1-13. Note that the component parts do not penetrate the substrate as they did in the planar-diffused transistor.

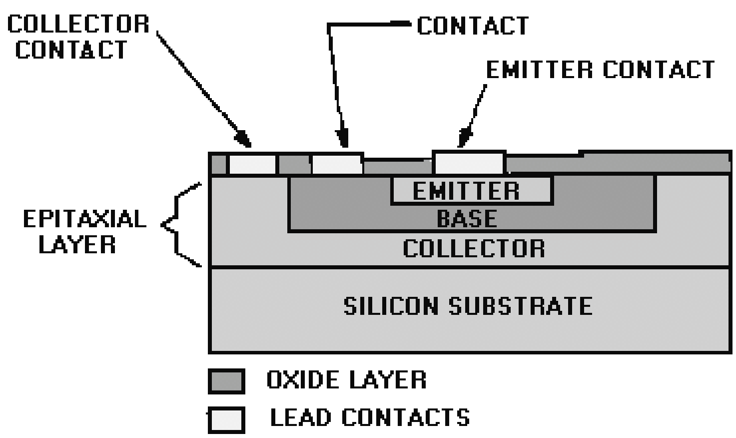

Figure 1-13.—Planar-epitaxial transistor.

ISOLATION.—Because of the closeness of components in ICs, ISOLATION from each other becomes a very important factor. Isolation is the prevention of unwanted interaction or leakage between components. This leakage could cause improper operation of a circuit.

Techniques are being developed to improve isolation. The most prominent is the use of silicon oxide, which is an excellent insulator. Some manufacturers are experimenting with single-crystal silicon grown on an insulating substrate. Other processes are also used which are far too complex to go into here. With progress in isolation techniques, the reliability and efficiency of ICs will increase rapidly.

Thin Film

Thin film is the term used to describe a technique for depositing passive circuit elements on an insulating substrate with coating to a thickness of 0.0001 centimeter. Many methods of thin-film deposition exist, but two of the most widely used are VACUUM EVAPORATION and CATHODE SPUTTERING.

VACUUM EVAPORATION.—Vacuum evaporation is a method used to deposit many types of materials in a highly evacuated chamber in which the material is heated by electricity, as shown in figure 1-14. The material is radiated in straight lines in all directions from the source and is shadowed by any objects in its path.

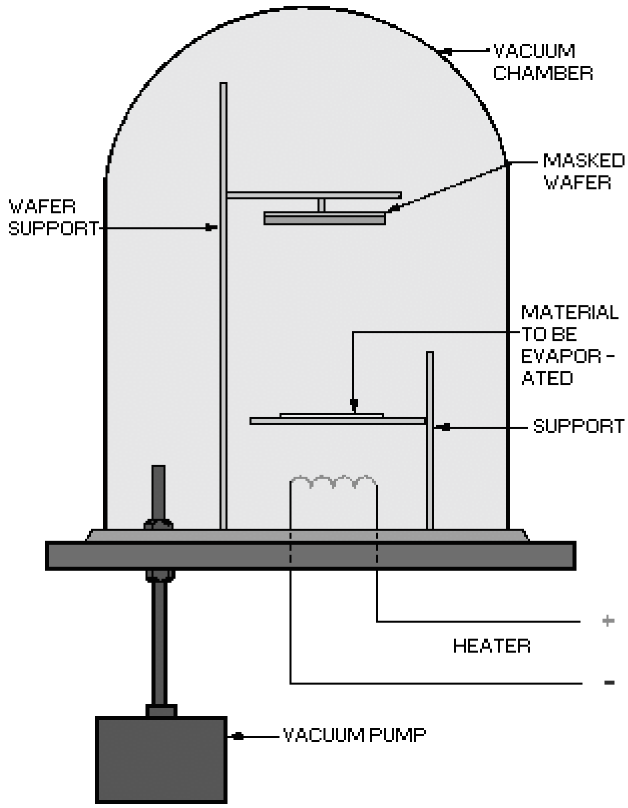

Figure 1-14.—Vacuum evaporation oven.

The wafers, with appropriate masks (figure 1-15), are placed above and at some distance from the material being evaporated. When the process is completed, the vacuum is released and the masks are removed from the wafers. This process leaves a thin, uniform film of the deposition material on all parts of the wafers exposed by the open portions of the mask. This process is also used to deposit interconnections (leads) between components of an IC.

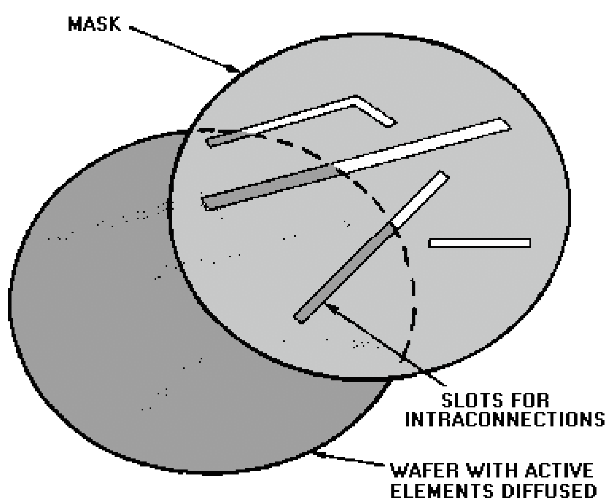

Figure 1-15.—Evaporation mask.

The vacuum evaporation technique is most suitable for deposition of highly reactive materials, such as aluminum, that are difficult to work with in air. The method is clean and allows a better contact between the layer of deposited material and the surface upon which it has been deposited. In addition, because evaporation beams travel in straight lines, very precise patterns may be produced.

CATHODE-SPUTTERING.—A typical cathode-sputtering system is illustrated in figure 1-16. This process is also performed in a vacuum. A potential of 2 to 5 kilovolts is applied between the anode and cathode (source material). This produces a GLOW DISCHARGE in the space between the electrodes. The rate at which atoms are SPUTTERED off the source material depends on the number of ions that strike it and the number of atoms ejected for each ion bombardment. The ejected atoms are deposited uniformly over all objects within the chamber. When the sputtering cycle is completed, the vacuum in the chamber is released and the wafers are removed. The masks are then removed from the wafers, leaving a deposit that forms the passive elements of the circuit, as shown in figure 1-17.

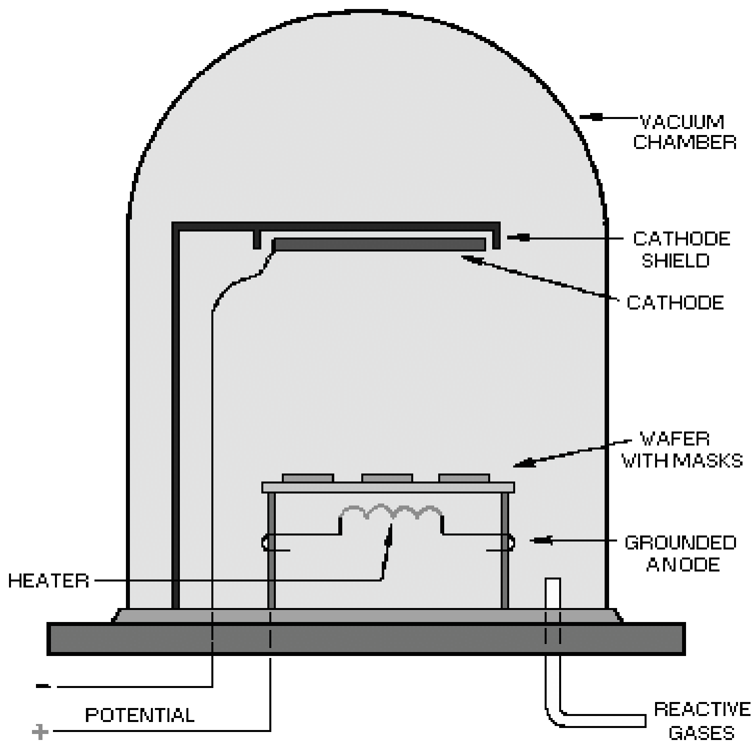

Figure 1-16.—Cathode-sputtering system.

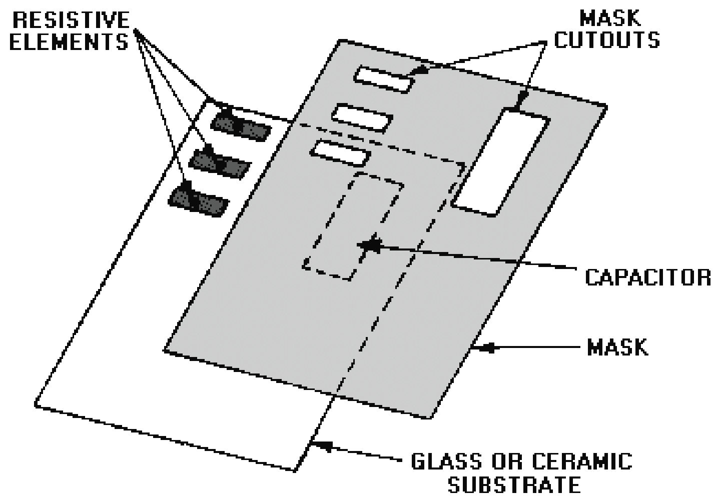

Figure 1-17.—Cathode-sputtering mask.

Finely polished glass, glazed ceramic, and oxidized silicon have been used as substrate materials for thin films. A number of materials, including nichrome, a compound of silicon oxide and chromium cermets, tantalum, and titanium, have been used for thin-film resistors. Nichrome is the most widely used.

The process for producing thin-film capacitors involves deposition of a bottom electrode, a dielectric, and finally a top electrode. The most commonly used dielectric materials are silicon monoxide and silicon dioxide.

Thick Film

Thick films are produced by screening patterns of conducting and insulating materials on ceramic substrates. A thick film is a film of material with a thickness that is at least 10 times greater than the mean free path of an electron in that material, or approximately 0.001 centimeter. The technique is used to produce only passive elements, such as resistors and capacitors.

PROCEDURES.—One procedure used in fabricating a thick film is to produce a series of stencils called SCREENS. The screens are placed on the substrate and appropriate conducting or insulating materials are wiped across the screen. Once the conducting or insulating material has been applied, the screens are removed and the formulations are fired at temperatures above 600 degrees Celsius. This process forms alloys that are permanently bonded to the insulating substrate. To a limited extent, the characteristics of the film can be controlled by the firing temperature and length of firing time.

RESISTORS.—Thick-film resistance values can be held to a tolerance of ±10 percent. Closer tolerances are obtained by trimming each resistor after fabrication. Hundreds of different cermet formulations are used to produce a wide range of component parameters. For example, the material used for a 10-ohm-per-square resistor is quite different from that used for a 100-kilohm-per-square resistor.

CAPACITORS AND RESISTOR-CAPACITOR NETWORKS.—Capacitors are formed by a sequence of screenings and firings. Capacitors, in this case, consist of a bottom plate, intraconnections, a dielectric, and a top plate. For resistor-capacitor networks, the next step would be to deposit the resistor material through the screen. The final step is screening and firing of a glass enclosure to seal the unit.

Hybrid Microcircuit

A hybrid microcircuit is one that is fabricated by combining two or more circuit types, such as film and semiconductor circuits, or a combination of one or more circuit types and discrete elements. The primary advantage of hybrid microcircuits is design flexibility; that is, hybrid microcircuits can be designed to provide wide use in specialized applications, such as low-volume and high-frequency circuits.

Several elements and circuits are available for hybrid applications. These include discrete components that are electrically and mechanically compatible with ICs. Such components may be used to perform functions that are supplementary to those of ICs. They can be handled, tested, and assembled with essentially the same technology and tools. A hybrid IC showing an enlarged chip is shown in figure 1-18.

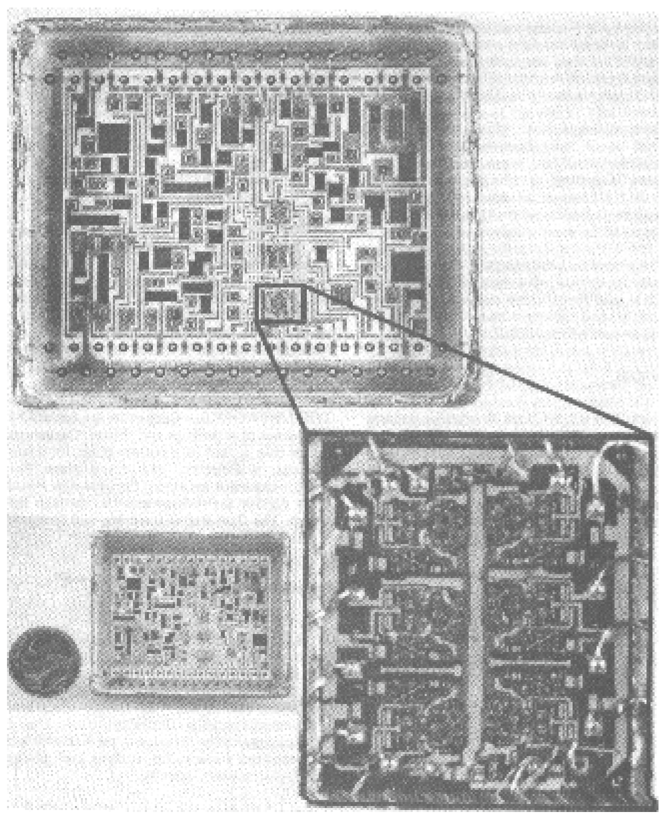

Figure 1-18.—Hybrid IC showing an enlarged chip.

Complete circuits are available in the form of UNCASED CHIPS (UNENCAPSULATED IC DICE). These chips are usually identical to those sold as part of the manufacturer's regular production line. They must be properly packaged and connected by the user if a high-quality final assembly is to be obtained. The circuits are usually sealed in a package to protect them from mechanical and environmental stresses. One-mil (0.001-inch), gold-wire leads are connected to the appropriate pins which are brought out of the package to allow external connections.

Q22. Name the two types of monolithic IC construction discussed.

Q23. How do the two types of monolithic IC construction differ?

Q24. What is isolation?

Q25. What methods are used to deposit thin-film components on a substrate?

Q26. How are thick-film components produced?

Q27. What is a hybrid IC?

Q28. What is the primary advantage of hybrid circuits?

PACKAGING TECHNIQUES

Once the IC has been produced, it requires a housing that will protect it from damage. This damage could result from moisture, dirt, heat, radiation, or other sources. The housing protects the device and aids in its handling and connection into the system in which the IC is used. The three most common types of packages are the modified TRANSISTOR-OUTLINE (TO) PACKAGE, the FLAT PACK, and the DUAL INLINE PACKAGE (DIP).

Transitor-Outline Package

Transistor-Outline Package. The transistor-outline (TO) package was developed from early experience with transistors. It was a reliable package that only required increasing the number of leads to make it useful for ICs. Leads normally number between 2 and 12, with 10 being the most common for IC applications. Figure 1-19 is an exploded view of a TO-5 package. Once the IC has been attached to the header, bonding wires are used to attach the IC to the leads. The cover provides the necessary protection for the device. Figure 1-20 is an enlarged photo of an actual TO-5 with the cover removed. You can easily see that the handling of an IC without packaging would be difficult for a technician.

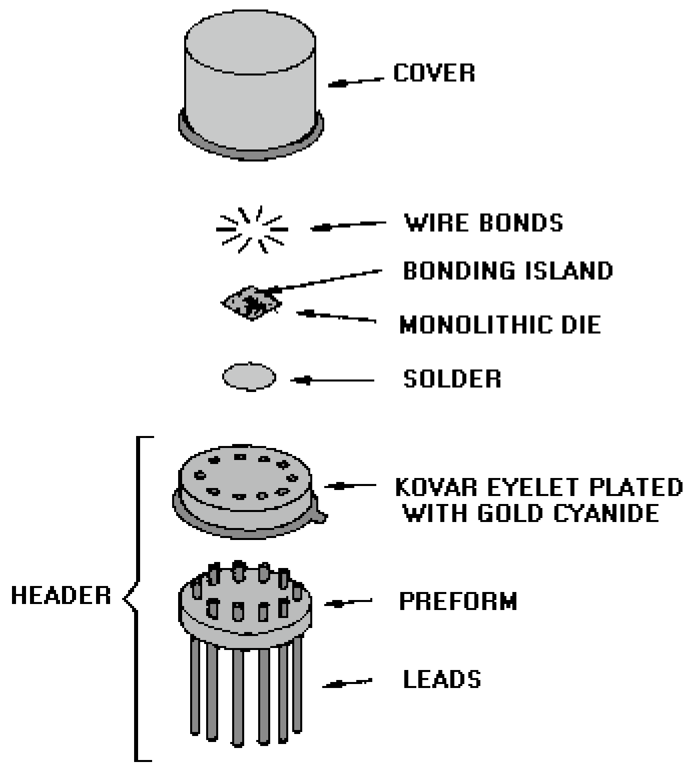

Figure 1-19.—Exploded TO-5.

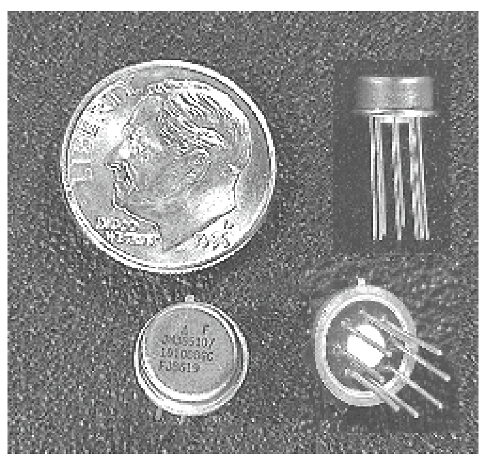

Figure 1-20.—TO-5 package.

The modified TO-5 package (figure 1-21) can be either plugged into [view (A)] or embedded in [view (B)] a board. The embedding method is preferred. Whether the package is plugged in or embedded, the interconnection area of the package leads must have sufficient clearance on both sides of the board. The plug-in method does not provide sufficient clearance between pads to route additional circuitry. When the packages are embedded, sufficient space exists between the pads [because of the increased diameter of the interconnection pattern, shown at the right in view (B)] for additional conductors.

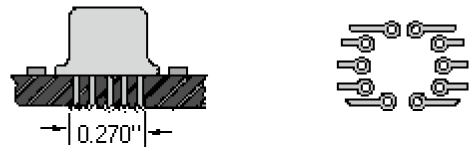

Figure 1-21A.—TO-5 mounting PLUG-IN MOUNTING

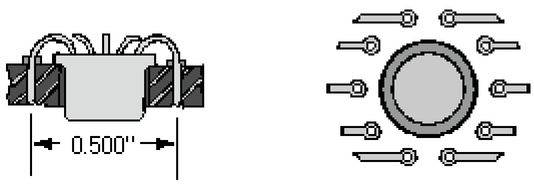

Figure 1-21B.—TO-5 mounting EMBEDDED CAN(LEADS PLUGGED IN)

Flat Pack

Many types of IC flat packs are being produced in various sizes and materials. These packages are available in square, rectangular, oval, and circular configurations with 10 to 60 external leads.

They may be made of metal, ceramic, epoxy, glass, or combinations of those materials. Only the ceramic flat pack will be discussed here. It is representative of all flat packs with respect to general package requirements (see figure 1-22).

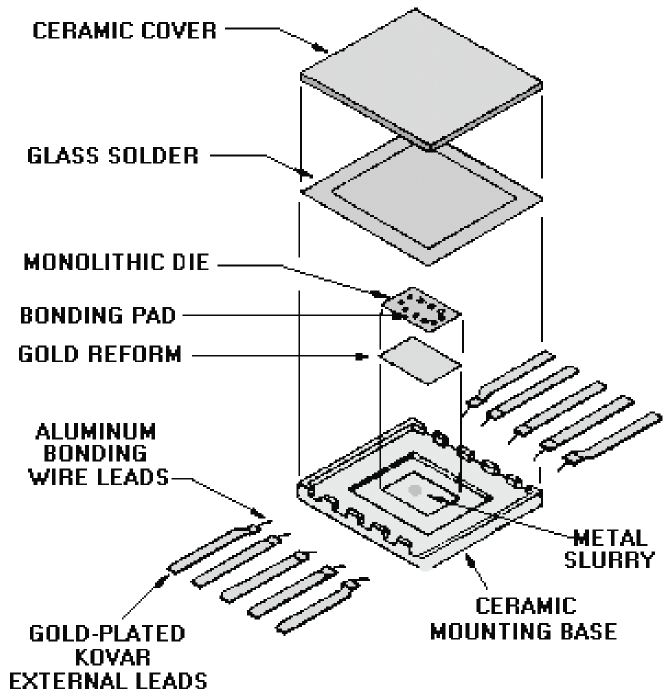

Figure 1-22.—Enlarged flat pack exploded view.

After the external leads are sealed to the mounting base, the rectangular area on the inside bottom of the base is treated with metal slurry to provide a surface suitable for bonding the monolithic die to the base. The lead and the metalized area in the bottom of the package are plated with gold. The die is then attached by gold-silicon bonding.

The die-bonding step is followed by bonding gold or aluminum wires between the bonding islands on the IC die and on the inner portions of the package leads. Next, a glass-soldered preformed frame is placed on top of the mounting base. One surface of the ceramic cover is coated with Pyroceram glass, and the cover is placed on top of the mounting base. The entire assembly is placed in an oven at 450 degrees Celsius. This causes the glass solder and Pyroceram to fuse and seal the cover to the mounting base. A ceramic flat pack is shown in figure 1-23. It has been opened so that you can see the chip and bonding wires.

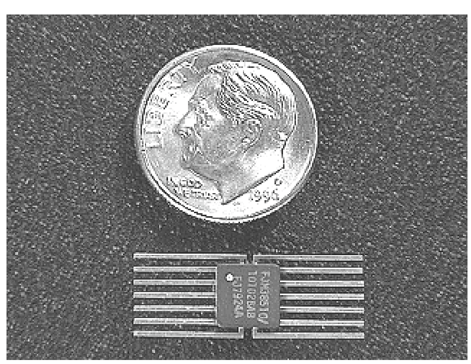

Figure 1-23.—Typical flat pack.

Dual Inline Package

The dual inline package (DIP) was designed primarily to overcome the difficulties associated with handling and inserting packages into mounting boards. DIPs are easily inserted by hand or machine and require no spreaders, spacers, insulators, or lead-forming tools. Standard hand tools and soldering irons can be used to field-service the devices. Plastic DIPs are finding wide use in commercial applications, and a number of military systems are incorporating ceramic DIPS.

The progressive stages in the assembly of a ceramic DIP are illustrated in figure 1-24, views (A) through (E). The integrated-circuit die is sandwiched between the two ceramic elements, as shown in view (A). The element on the left of view (A) is the bottom half of the sandwich and will hold the integrated-circuit die. The ceramic section on the right is the top of the sandwich. The large well in view (B) protects the IC die from mechanical stress during sealing operations. Each of the ceramic elements is coated with glass which has a low melting temperature for subsequent joining and sealing. View (B) shows the Kovar lead frame stamped and bent into its final shape. The excess material is intended to preserve pin alignment. The holes at each end are for the keying jig used in the final sealing operation. The lower half of the ceramic package is inserted into the lead frame shown in view (C). The die is mounted in the well and leads are attached. The top ceramic elements are bonded to the bottom element shown in view (D) and the excess material is removed from the package. View (E) is the final product.

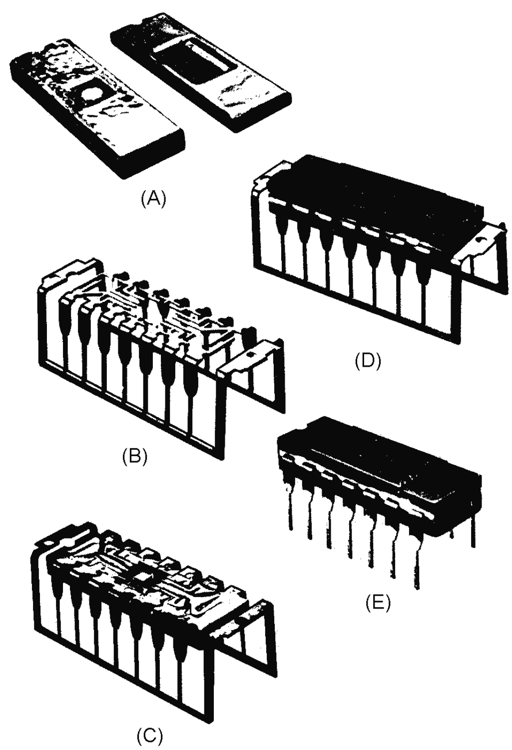

Figure 1-24.—DIP packaging steps.

Ceramic DIPs are processed individually while plastic DIPs are processed in quantities of two or more (in chain fashion). After processing, the packages are sawed apart. The plastic package also uses a Kovar lead frame, but the leads are not bent until the package is completed. Because molded plastic is used to encapsulate the IC die, no void will exist between the cover and die, as is the case with ceramic packaging.

At present, ceramic DIPs are the most common of the two package types to be found in Navy microelectronic systems. Figure 1-25 shows a DIP which has been opened.

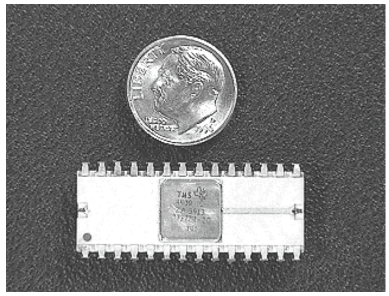

Figure 1-25.—Dual inline package (DIP).

RECENT DEVELOPMENTS IN PACKAGING

Considerable effort has been devoted to eliminating the fine wires used to connect ICs to Kovar leads. The omission of these wires reduces the cost of integrated circuits by eliminating the costs associated with the bonding process. Further, omission of the wires improves reliability by eliminating a common cause of circuit failure.

A promising packaging technique is the face-down (FLIP-CHIP) mounting method by which conductive patterns are evaporated inside the package before the die is attached. These patterns connect the external leads to bonding pads on the inside surface of the die. The pads are then bonded to appropriate pedestals on the package that correspond to those of the bonding pads on the die (figure 1-26).

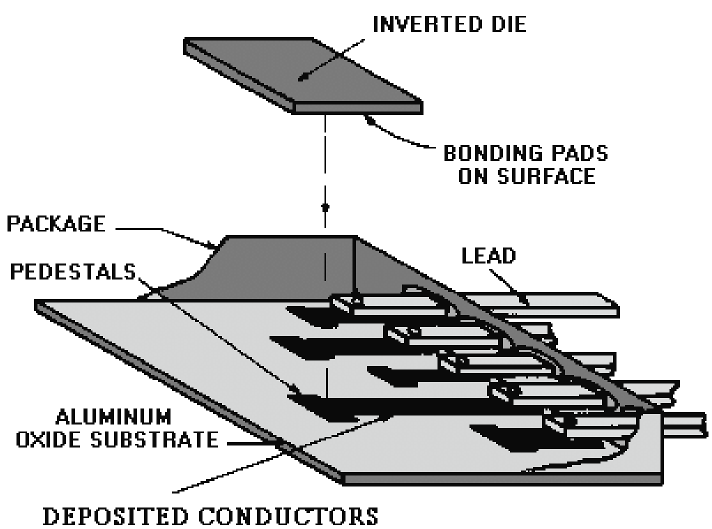

Figure 1-26.—Flip-chip package.

The BEAM-LEAD technique is a process developed to batch-fabricate (fabricate many at once) semiconductor circuit elements and integrated circuits with electrodes extended beyond the edges of the wafer, as shown in figure 1-27. This type of structure imposes no electrical difficulty, and parasitic capacitance (under 0.05 picofarad per lead) is equivalent to that of a wire-bonded and brazed-chip assembly. In addition, the electrodes may be tapered to allow for lower inductance, impedance matching, and better heat conductance. The beam-lead technique is easily accomplished and does not have the disadvantages of chip brazing and wire bonding. The feasibility of this technique has been demonstrated in a variety of digital, linear, and thin-film circuits.

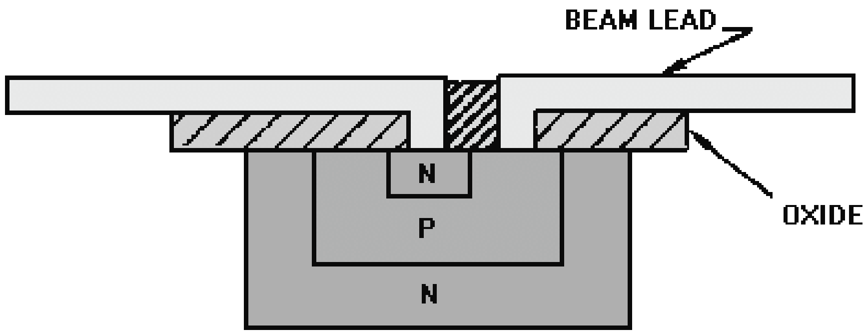

Figure 1-27.—Beam-lead technique.

Another advance in packaging is that of increasing the size of DIPs. General-purpose DIPs have from 4 to 16 pins. Because of lsi and vlsi, manufacturers are producing DIPs with up to 64 pins. Although size is increased considerably, all the advantages of the DIP are retained. DIPs are normally designed to a particular specification set by the user.

Q29. What is the purpose of the IC package?

Q30. What are the three most common types of packages?

Q31. What two methods of manufacture are being used to eliminate bonding wires?

EQUIVALENT CIRCUITS

At the beginning of this topic, we discussed many applications of microelectronics. You should understand that these applications cover all areas of modern electronics technology. Microelectronic ICs are produced that can be used in many of these varying circuit applications to satisfy the needs of modern technology. This section will introduce you to some of these applications and will show you some EQUIVALENT CIRCUIT comparisons of discrete components and integrated circuits.

J-K FLIP-FLOP AND IC SIZES

Integrated circuits can be produced that combine all the elements of a complete electronic circuit. This can be done with either a single chip of silicon or a single chip of silicon in combination with film components. The importance of this new production method in the evolution of microelectronics can be demonstrated by comparing a conventional J-K flip-flop circuit incorporating solid-state discrete devices and the same type of circuit employing integrated circuitry. (A J-K flip-flop is a circuit used primarily in computers.)

You should recall from *NEETS, Module 13*, *Introduction to Number Systems, Boolean Algebra, and Logic Circuits*, that a basic flip-flop is a device having two stable states and two input terminals (or types of input signals), each of which corresponds to one of the two states. The flip-flop remains in one state until caused to change to the other state by application of an input voltage pulse.

A J-K flip-flop differs from the basic flip-flop because it has a third input terminal. A clock pulse, or trigger, is usually applied to this input to ensure proper timing in the circuit. An input signal must occur at the same time as the clock pulse to change the state of the flip-flop. The conventional J-K flip-flop circuit in figure 1-28 requires approximately 40 discrete components, 200 connections, and 300 processing operations. Each of these 300 operations (seals and connections) represents a possible source of failure. If all the elements of this circuit are integrated into one chip of silicon, the number of connections drops to approximately 14. This is because all circuit elements are intraconnected inside the package and the 300 processing operations are reduced to approximately 30. Figure 1-29 represents a size comparison of a discrete J-K circuit and an integrated circuit of the same type.

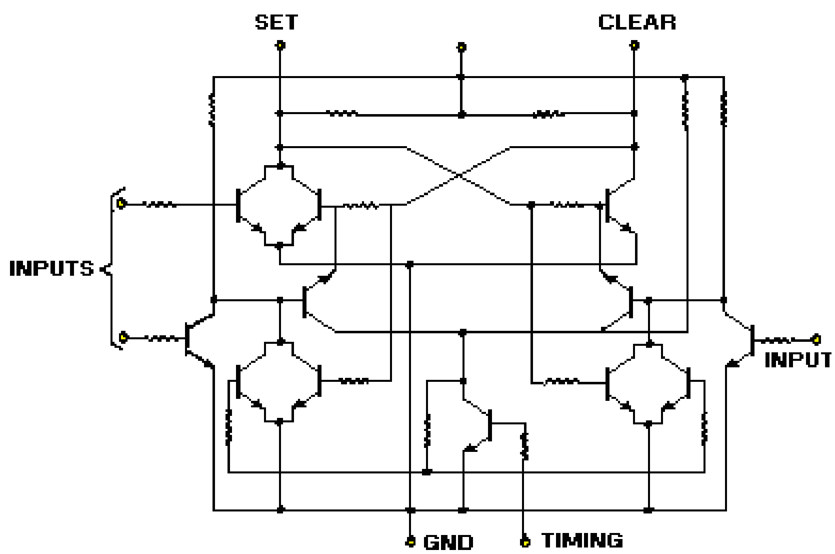

Figure 1-28.—Schematic diagram of a J-K flip-flop.

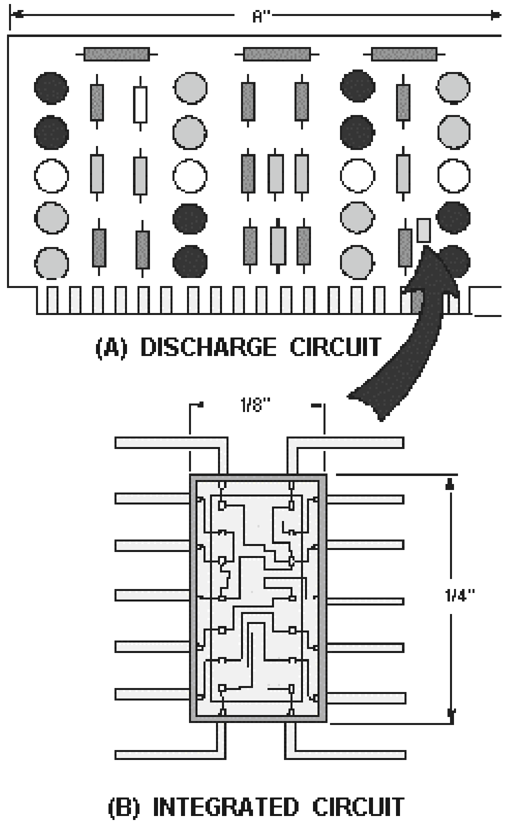

Figure 1-29.—J-K flip-flop discrete component and an IC.

IC PACKAGE LEAD IDENTIFICATION (NUMBERING)

When you look at an IC package you should notice that the IC could be connected incorrectly into a circuit. Such improper replacement of a component would likely result in damage to the equipment. For this reason, each IC has a REFERENCE MARK to align the component for placement. The dual inline package (both plastic and ceramic) and the flat pack have a notch, dot, or impression on the package. When the package is viewed from the top, pin 1 will be the first pin in the *counterclockwise* direction next to the reference mark. Pin 1 may also be marked directly by a hole or notch or by a tab on it (in this case pin 1 is the counting reference). When the package is viewed from the top, all other pins are numbered consecutively in a *counterclockwise* direction from pin 1, as shown in figure 1-30, views (A) and (B).

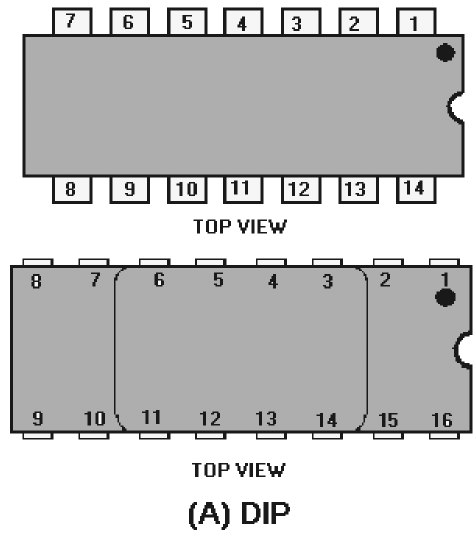

Figure 1-30A.—DIP and flat-pack lead numbering. DIP

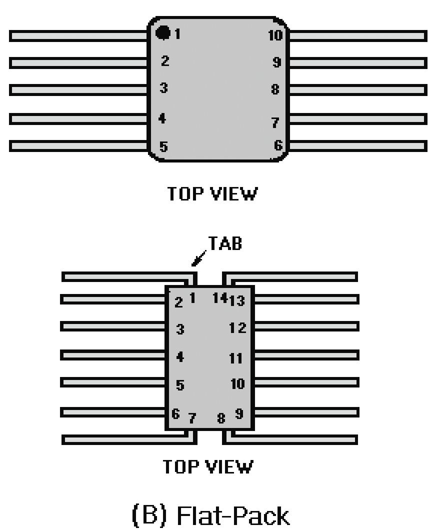

Figure 1-30B.—DIP and flat-pack lead numbering. Flat-Pack

The TO-5 can has a tab for the reference mark. When numbering the leads, you must view the TO-5 can from the *bottom*. Pin 1 will be the first pin in a *clockwise* direction from the tab. All other pins will be numbered consecutively in a clockwise direction from pin 1, as shown in figure 1-31.

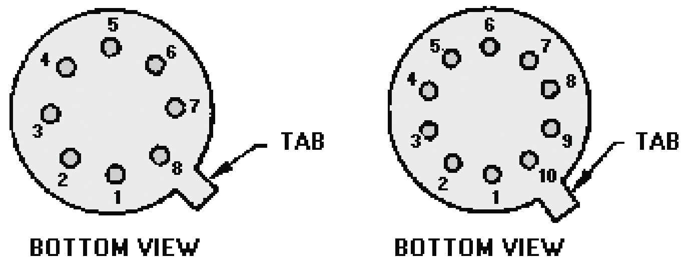

Figure 1-31.—Lead numbering for a TO-5.

IC IDENTIFICATION

As mentioned earlier, integrated circuits are designed and manufactured for hundreds of different uses. Logic circuits, clock circuits, amplifiers, television games, transmitters, receivers, and musical instruments are just a few of these applications.

In schematic drawings, ICs are usually represented by one of the schematic symbols shown in figure 1-32. The IC is identified *according to its use* by the numbers printed on or near the symbol. That series of numbers and letters is also stamped on the case of the device and can be used along with the data sheet, as shown in the data sheet in figure 1-33, by circuit designers and maintenance personnel. This data sheet is provided by the manufacturer. It provides a schematic diagram and describes the type of device, its electrical characteristics, and typical applications. The data sheet may also show the pin configurations with all pins labeled. If the pin configurations are not shown, there may be a schematic diagram showing pin functions. Some data sheets give both pin configurations and schematic diagrams, as shown in figure 1-34. This figure illustrates a manufacturer's data sheet with all of the pin functions shown.

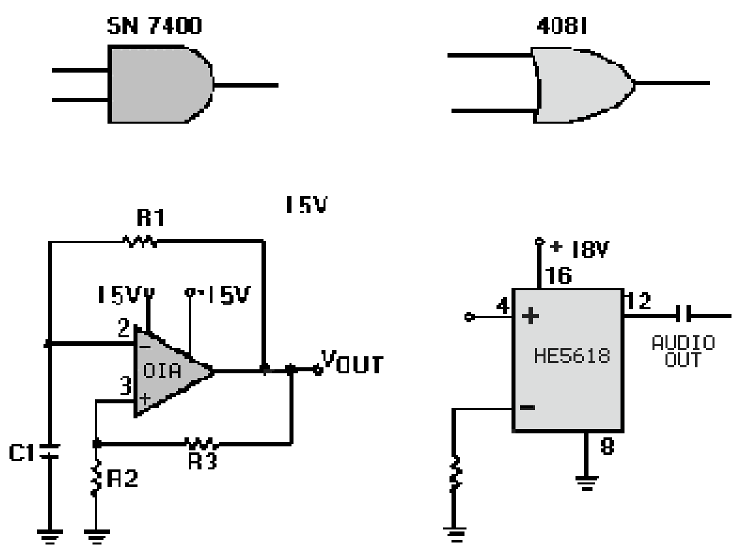

Figure 1-32.—Some schematic symbols for ICs.

LH101 LH201 OPERATIONAL AMPLIFIER

FOR AMPLIFIERS, VOLTAGE COMPARATORS, LOW DRIFT SAMPLE-AND-HOLD

Features

- Low Offsets and Temperature Drift
- Internal 30 pF Capacitor for Frequency Compensation
- Operation from ±5 to ±20 Volt Power Supplies
- Low Current Drain, 1.8 mA at ±20 Volts Typical
- Continuous Short-Circuit Protection
- No Latch Up When Common Mode Range Is Exceeded
- Same Pin Configuration as 709 Amplifier

Description

The LH101/LH201 is stable for all feedback configurations, even with capacitive loads, with no external compensation capacitors. Low power dissipation permits high voltage operation across the full temperature range.

Figure 1-33.—Manufacturer's Data Sheet.

FEATURES

- MONOLITHIC CONSTRUCTION
- INITIAL ACCURACY +10V ± 0.010V
- OUTPUT VOLTAGE ERROR, TOTAL ±1/4 LSB
- LOW NOISE $20\mu V_{p-p}$
- WIDE INPUT RANGE 12V TO 30V
- LOW POWER DISSIPATION 30mW
- OUTPUT SHORT CIRCUIT PROTECTION
- ADJUSTABLE OUTPUT

APPLICATIONS

- AN ECONOMICAL EXTERNAL REFERENCE FOR: HI-5608; DAC 08; AD1408; AD559
- VOLTAGE REGULATOR REFERENCE
- PORTABLE BATTERY OPERATED EQUIPMENT
- NEGATIVE 10V REFERENCE

DESCRIPTION

HA-1608 is a monolithic +10V adjustable voltage reference featuring accuracy and temperature stability specifications detailed exclusively for 8 bit data conversion systems. A stable +10V output is provided by a reference zener and buffer amplifier coupled with laser trimmed feedback and zener bias resistors. Long term stability is ensured through integration of all reference components into a monolithic design. Flexibility of HA-1608 is provided through an external trim control which allows the user to adjust the output voltage for binary or BCD applications without affecting overall performance.

These devices provide a total output voltage error of ± 1/4 LSB for 8 bit D/A or A/D converters. Low standby power (0.3mW) makes HA-1608 a natural selection for portable battery operated equipment, comparator references, and reference stacking circuits. These devices can also be used on -10V references.

HA-1608 is packaged in 8 pin metal cans (TO-99) and 8 pin DIPs. The pinout is arranged for convenient replacement of other less accurate regulators in applications demanding minimal change with temperature and time. HA-1608-2 is specified for -55°C to +125°C operation while the HA-1608-5 operates from 0°C to +75°C.

MICROELECTRONIC SYSTEM DESIGN CONCEPTS

You should understand the terminology used in microelectronics to become an effective and knowledgeable technician. You should be familiar with packaging concepts from a maintenance standpoint and be able to recognize the different types of assemblies. You should also know the electrical and environmental factors that can affect microelectronic circuits. In the next section of this topic we will define and discuss each of these areas.

TERMINOLOGY

As in any special electronics field, microelectronics terms and definitions are used to clarify communications. This is done so that everyone involved in microelectronics work has the same knowledge of the field. You can imagine how much trouble you would have remembering 10 or more different names and definitions for a resistor. If standardization didn't exist for the new terminology, you would have far more trouble understanding microelectronics. To standardize terminology in microelectronics, the Navy has adopted several definitions with which you should become familiar. These definitions will be presented in this section.

Microelectronics

Microelectronics is that area of electronics technology associated with electronics systems built from extremely small electronic parts or elements. Most of today's computers, weapons systems, navigation systems, communications systems, and radar systems make extensive use of microelectronics technology.

Microcircuit

A microcircuit is not what the old-time technician would recognize as an electronic circuit. The old-timer would no longer see the familiar discrete parts (individual resistors, capacitors, inductors, transistors, and so forth). Microelectronic circuits, as discussed earlier, are complete circuits mounted on a substrate (integrated circuit). The process of fabricating microelectronic circuits is essentially one of building discrete component characteristics either into or onto a single substrate. This is far different from soldering resistors, capacitors, transistors, inductors, and other discrete components into place with wires and lugs. The component characteristics built into microcircuits are referred to as ELEMENTS, rather than discrete components. Microcircuits have a high number of these elements per substrate compared to a circuit with discrete components of the same relative size. As a matter of fact, microelectronic circuits often contain thousands of times the number of discrete components. The term *HIGH EQUIVALENT CIRCUIT DENSITYS* is a description of this element-to-discrete part relationship. For example, suppose you have a circuit with 1,000 discrete components mounted on a chassis which is 8 × 10 × 2 inches. The equivalent circuit in microelectronics might be built into or onto a single substrate which is only 3/8 × 1 × 1/4 inch. The 1,000 elements of the microcircuit would be very close to each other (high density) by comparison to the distance between discrete components mounted on the large chassis. The elements within the substrate are interconnected on the single substrate itself to perform an electronic function. A microcircuit does not have any discrete components mounted on it as do printed circuit boards, circuit card assemblies, and modules composed exclusively of discrete component parts.

Microcircuit Module

Microcircuits may be used in combination with discrete components. An assembly of microcircuits or a combination of microcircuits and discrete conventional electronic components that performs one or more distinct functions is a microcircuit module. The module is constructed as an independently packaged, replaceable unit. Examples of microcircuit modules are printed circuit boards and circuit card assemblies. Figure 1-35 is a photograph of a typical microcircuit module.

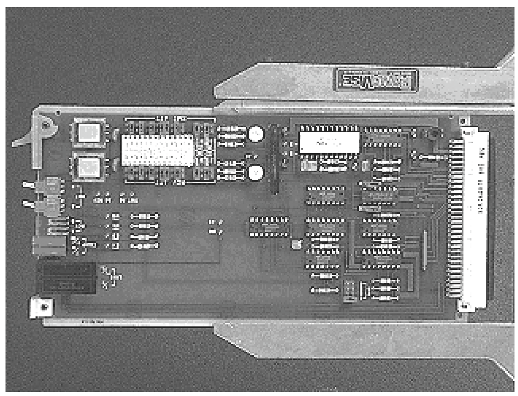

Figure 1-35.—Microcircuit module.

Miniature Electronics

Miniature electronics includes miniature electronic components and packages. Some examples are printed circuit boards, printed wiring boards, circuit card assemblies, and modules composed *exclusively* of discrete electronic parts and components (excluding microelectronic packages) mounted on boards, assemblies, or modules. MOTHER BOARDS, large printed circuit boards with plug-in modules, are considered miniature electronics. Cordwood modules also fall into this category. Miniature motors, synchros, switches, relays, timers, and so forth, are also classified as miniature electronics.

Recall that microelectronic components contain integrated circuits. Miniature electronics contain discrete elements or parts. You will notice that printed circuit boards and circuit card assemblies are mentioned in more than one definition. To identify the class (microminiature or miniature) of the unit, you must first determine the types of components used.

Q36. Standardized terms improve what action between individuals?

Q37. Microcircuit refers to any component containing what types of elements?

Q38. Components made up exclusively of discrete elements are classified as what type of electronics?

SYSTEM PACKAGING

When a new electronics system is developed, several areas of planning require special attention. An area of great concern is that of ensuring that the system performs properly. The designer must take into account all environmental and electrical factors that may affect the system. This includes temperature, humidity, vibration, and electrical interference. The design factor that has the greatest impact on you, as the technician, is the MAINTAINABILITY of the system. The designer must take into account how well you will be able to locate problems, identify the faulty components, and make the necessary repairs. If a system cannot be maintained easily, then it is not an efficient system. PACKAGING, the method of enclosing and mounting components, is of primary importance in system maintainability.

Levels of Packaging

For the benefit of the technician, system packaging is usually broken down to five levels (0 to IV). These levels are shown in figure 1-36.

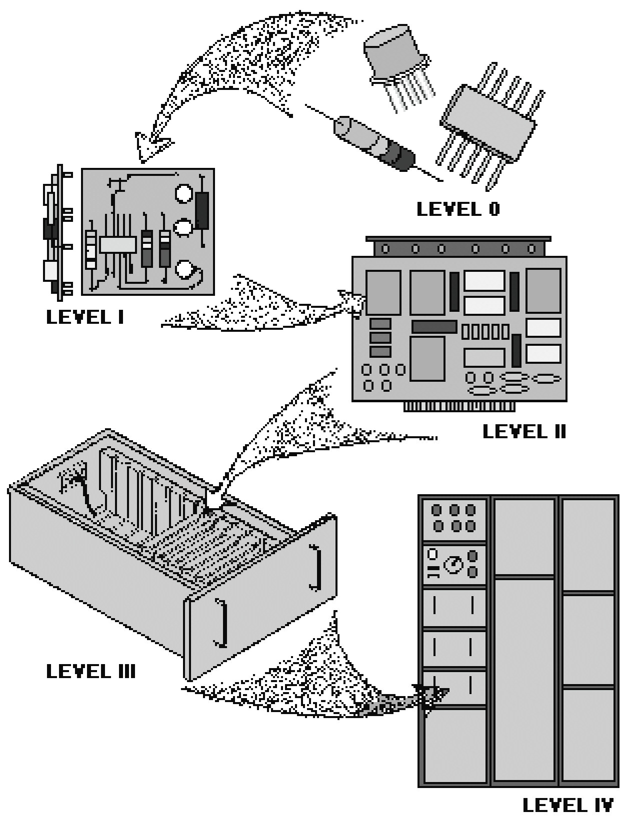

Figure 1-36.—Packaging levels.

LEVEL 0.—Level 0 packaging identifies nonrepairable parts, such as integrated circuits, transistors, resistors, and so forth. This is the lowest level at which you can perform maintenance. You are limited to simply replacing the faulty element or part. Depending on the type of part, repair might be as simple as plugging in a new relay. If the faulty part is an IC, special training and equipment will be required to accomplish the repair. This will be discussed in topic 2.

LEVEL I.—This level is normally associated with small modules or submodules that are attached to circuit cards or mother boards. The analog-to-digital (A/D) converter module is a device that converts a signal that is a function of a continuous variable (like a sine wave) into a representative number sequence in digital form. The A/D converter in figure 1-37 is a typical level I component. At this level of maintenance you can replace the faulty module with a good one. The faulty module can then be repaired at a later time or discarded. This concept significantly reduces the time equipment is inoperable.

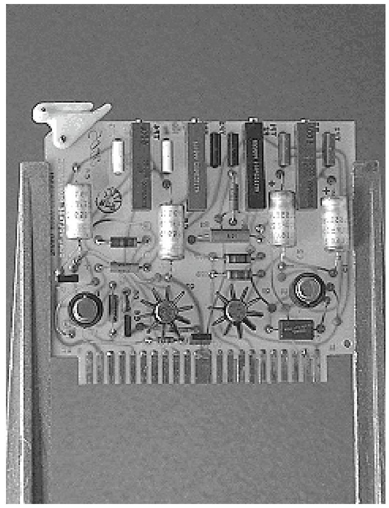

Figure 1-37.—Printed circuit board (pcb).

LEVEL II.—Level II packaging is composed of large printed circuit boards and/or cards (mother boards). Typical units of this level are shown in figures 1-37 and 1-38. In figure 1-38 the card measures 15×5.25 inches. The large dual inline packages (DIPs) are 2.25 inches x 0.75 inch. Other DIPs on the pcb are much smaller. Interconnections are shown between DIPs. You should also be able to locate a few discrete components. Repair consists of removing the faulty DIP or discrete component from the pcb and replacing it with a new part. Then the pcb is placed back into service. The removed part may be a level 0 or I part and would be handled as described in those sections. In some cases, the entire pcb should be replaced.

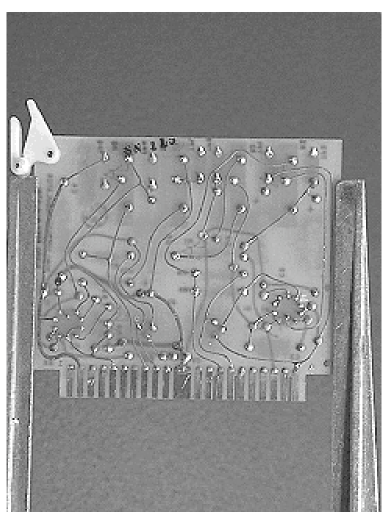

Figure 1-38.—Printed circuit board (pcb).

LEVEL III.—Drawers or pull-out chassis are level III units, as shown in figure 1-36. These are designed for accessibility and ease of maintenance. Normally, circuit cards associated with a particular subsystem will be grouped together in a drawer. This not only makes for an orderly arrangement of subsystems but also eliminates many long wiring harnesses. Defective cards are removed from such drawers and defective components are repaired as described in level II.

LEVEL IV.—Level IV is the highest level of packaging. It includes the cabinets, racks, and wiring harnesses necessary to interconnect all of the other levels. Other pieces of equipment of the same system classified as level IV, such as radar antennas, are broken down into levels 0 to III in the same manner.

During component troubleshooting procedures, you progress from level IV to III to II and on to level 0 where you identify the faulty component. As you become more familiar with a system, you should be able to go right to the drawer or module causing the problem.

Q39. Resistors, capacitors, transistors, and the like, are what level of packaging?

Q40. Modules or submodules attached to a mother board are what packaging level?

Q41. What is the packaging level of a pcb?

INTERCONNECTIONS IN PRINTED CIRCUIT BOARDS

As electronic systems become more complex, interconnections between components also becomes more complex. As more components are added to a given space, the requirements for interconnections become extremely complicated. The selection of conductor materials, insulator materials, and component physical size can greatly affect the performance of the circuit. Poor choices of these materials can contribute to poor signals, circuit noise, and unwanted electrical interaction between components. The three most common methods of interconnection are the conventional pcb, the multilayer pcb, and the modular assembly. Each of these will be discussed in the following sections.

Conventional Printed Circuit Board

Printed circuit boards were discussed earlier in topic 1. You should recall that a conventional pcb consists of glass-epoxy insulating base on which the interconnecting pattern has been etched. The board may be single- or double-sided, depending on the number of components mounted on it. Figures 1-37 and 1-38 are examples of conventional printed circuit boards.

Multilayer Printed Circuit Board.

The multilayer printed circuit board is emerging as the solution is interconnection problems associated with high-density packaging. Multilayer boards are used to:

- reduce weight
- conserve space in interconnecting circuit modules
- eliminate costly and complicated wiring harnesses
- provide shielding for a large number of conductors
- provide uniformity in conductor impedance for high-speed switching systems

- allow greater wiring density on boards

Figure 1-39 illustrates how individual boards are mated to form the multilayer unit. Although all multilayer boards are similarly constructed, various methods can be used to interconnect the circuitry from layer to layer. Three proven processes are the clearance-hole, plated-through hole, and layer build-up methods.

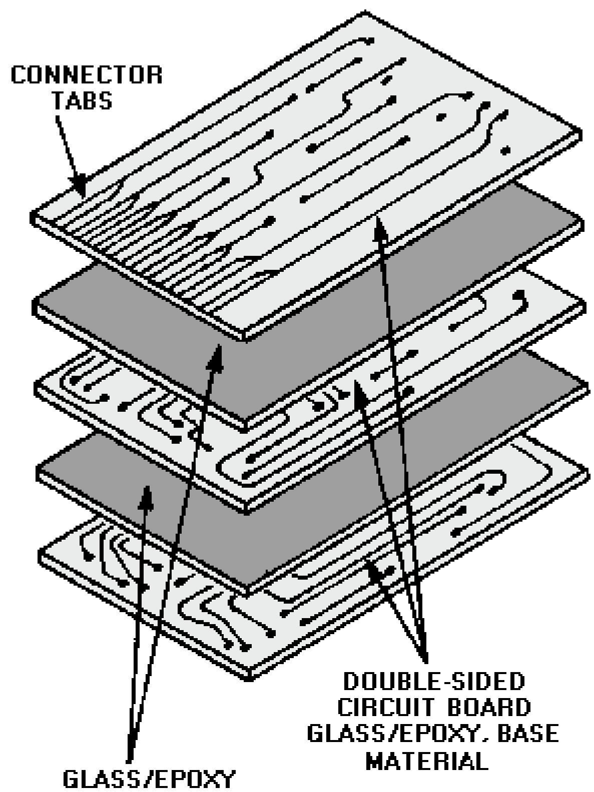

Figure 1-39.—Multilayer pcb.

CLEARANCE-HOLE METHOD.—In the CLEARANCE-HOLE method, a hole is drilled in the copper island (terminating end) of the appropriate conductor on the top layer. This provides access to a conductor on the second layer as shown by hole A in figure 1-40. The clearance hole is filled with solder to complete the connection. Usually, the hole is drilled through the entire assembly at the connection site. This small hole is necessary for the SOLDER-FLOW PROCESS used with this interconnection method.

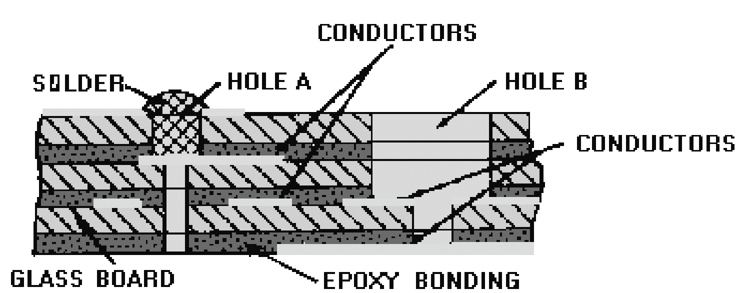

Figure 1-40.—Clearance-hole interconnection.

Conductors, located several layers below the top, are connected by using a STEPPED-DOWN HOLE PROCESS. Before assembly of a three-level board, a clearance hole is drilled down to the first layer to be interconnected. The first layer to be interconnected is predrilled with a hole smaller than those drilled in layers 1 and 2; succeeding layers to be connected have progressively smaller clearance holes. After assembly, the exposed portion of the conductors are interconnected by filling the stepped-down holes with solder, as shown by hole B in figure 1-40. The larger the number of interconnections required at one point, the larger must be the diameter of the clearance holes on the top layer. Large clearance holes on the top layer allow less space for components and reduce packaging density.

PLATED-THROUGH-HOLE METHOD.—The PLATED-THROUGH-HOLE method of interconnecting conductors is illustrated in figure 1-41. The first step is to assemble temporarily all the layers into their final form. Holes, corresponding to required connections, are drilled through the entire assembly and then the unit is disassembled. The internal walls of those holes to be interconnected are plated with metal which is 0.001 inch thick. This, in effect, connects the conductor on the board surface through the hole itself. This process is identical to that used for standard printed circuit boards. The boards are then reassembled and permanently bonded together with heat and pressure. All the holes are plated through with metal.

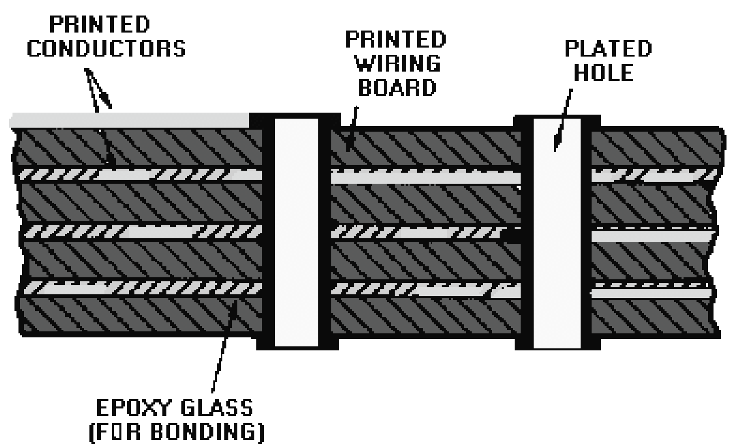

Figure 1-41.—Plated through-hole interconnection.

LAYER BUILD-UP METHOD.—With the LAYER BUILD-UP method, conductors and insulation layers are alternately deposited on a backing material, as shown in figure 1-42. This method produces copper interconnections between layers and minimizes the thermal expansion effects of dissimilar materials. However, reworking the internal connections in built-up layers is usually difficult, if not impossible.

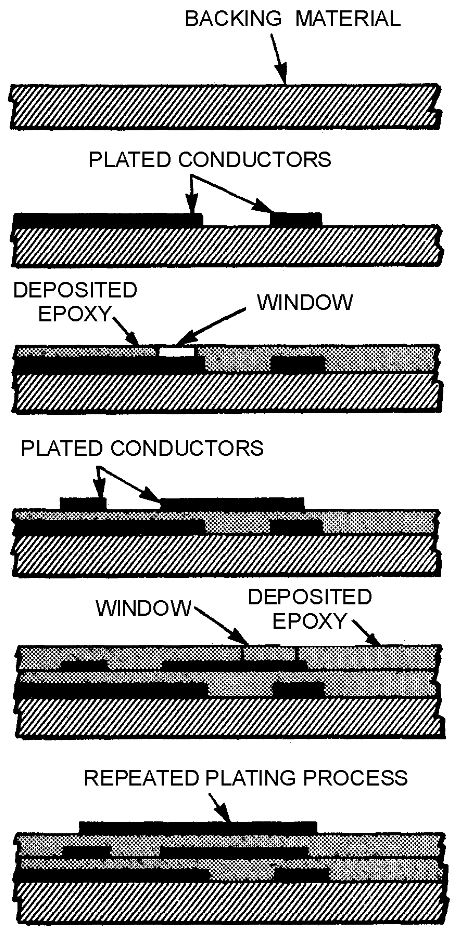

Figure 1-42.—Layer build-up technique.

Advantages and Disadvantages of Printed Circuit Boards

Some of the advantages and disadvantages of printed circuit boards were discussed earlier in this topic. They are strong, lightweight, and eliminate point-to-point wiring. Multilayer printed circuit boards allow more components per card. Entire circuits or even subsystems may be placed on the same card. However, these cards do have some drawbacks. For example, all components are wired into place, repair of cards requires special training and/or special equipment, and some cards cannot be economically repaired because of their complexity (these are referred to as THROWAWAYS).

Modular Assemblies

The MODULAR-ASSEMBLY (nonrepairable item) approach was devised to achieve ultra-high density packaging. The evolution of this concept, from discrete components to microelectronics, has progressed through various stages. These stages began with cordwood assemblies and functional blocks and led to complete subsystems in a single package. Examples of these configurations are shown in figure 1-43, view (A), view (B), and view (C).

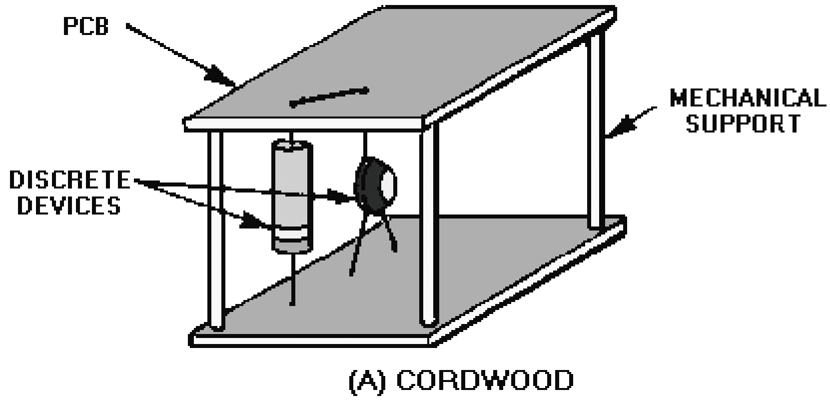

Figure 1-43A.—Evolution of modular assemblies. CORDWOOD.

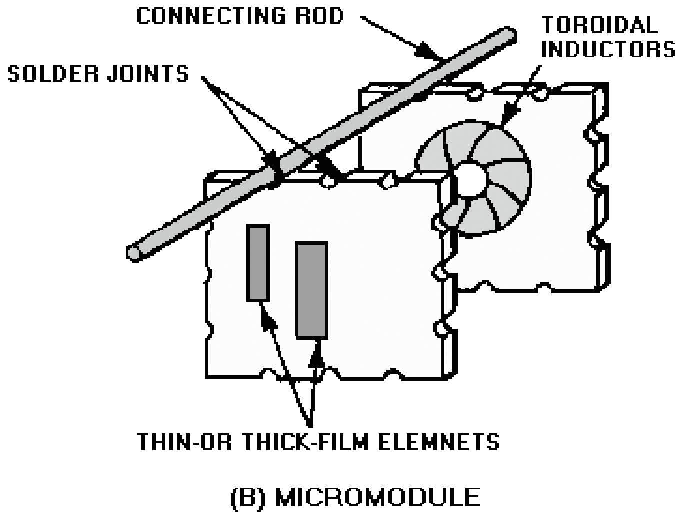

Figure 1-43B.—Evolution of modular assemblies. MICROMODULE.

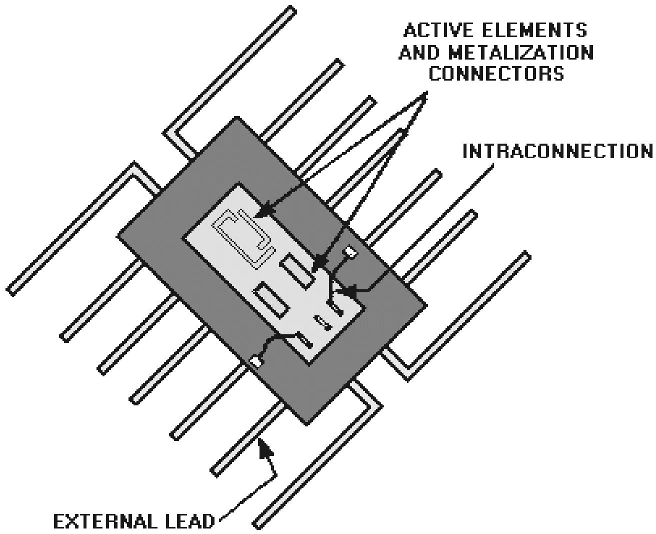

Figure 1-43C.—Evolution of modular assemblies. INTEGRATED-CIRCUIT.

Cordwood Modules

The cordwood assembly, shown in view (A) of figure 1-43, was designed and fabricated in various forms and sizes, depending on user requirements. This design was used to reduce the physical size and increase the component density and complexity of circuits through the use of discrete devices. However, the use of the technique was somewhat limited by the size of available discrete components used.

Micromodules

The next generation assembly was the micromodule. Designers tried to achieve maximum density in this design by using discrete components, thick- and thin-film technologies, and the insulator substrate principle. The method used in this construction technique allowed for the efficient use of space and also provided the mechanical strength necessary to withstand shock and vibration.

Semiconductor technology was then improved further with the introduction of the integrated circuit. The flat-pack IC form, shown in view (C), emphasizes the density and complexity that exists with this technique. This technology provides the means of reducing the size of circuits. It also allows the reduction of the size of systems through the advent of the lsi circuits that are now available and vlsi circuits that are being developed by various IC manufacturers.

Continuation of this trend toward microminiaturization will result in system forms that will require maintenance personnel to be specially trained in maintenance techniques to perform testing, fault isolation, and repair of systems containing complex miniature and microminiature circuits.

Q42. What are the three most common methods of interconnections?

Q43. Name the three methods of interconnecting components in multilayer printed circuit boards.

Q44. What is one of the major disadvantages of multilayer printed circuit boards?

Q45. What was the earliest form of micromodule?

ENVIRONMENTAL CONSIDERATIONS

The environmental requirements of each system design are defined in the PROCUREMENT SPECIFICATION. Typical environmental requirements for an IC, for example, are shown in table 1-1. After these system requirements have been established, components, applications, and packaging forms are considered. This then leads to the most effective system form.

Table 1-1.—Environmental Requirements

Temperature Operating Nonoperating	–28º C to +65º C –62º C to +75º C (MIL-E-16400E)
Humidity	95 percent plus condensation (MIL-E-16400E)
Shock	250 to 600 g (MIL-S-901C)
Vibration	5 to 15 Hz, 0.060 DA 16 to 25 Hz, 0.040 DA 26 to 33 Hz, 0.020 DA Resonance test in three mutual perpendicular planes. (MIL-STD-167)
RF Interference	30 Hz to 40 GHz

In the example in table 1-1, the environmental requirements are set forth as MILITARY STANDARDS for performance. The actual standard for a particular factor is in parentheses. To meet each of these standards, the equipment or component must perform adequately within the test guidelines. For example, to pass the shock test, the component must withstand a shock of 250 to 600 $_{Gs}$ (force of gravity). During vibration testing, the component must withstand vibrations of 5 to 15 cycles per second for 0.06 day, or about 1 1/2 hours; 16 to 25 cycles for 1 hour; and 26 to 33 cycles for 1/2 hour. Rf interference between 30 hertz and 40 gigahertz must not affect the performance of the component. Temperature and humidity factors are self-explanatory.

When selecting the most useful packaging technique, the system designer must consider not only the environmental and electrical performance requirements of the system, but the maintainability aspects as well. The system design will, therefore, reflect performance requirements of maintenance and repair personnel.

ELECTRICAL CONSIDERATIONS

The electrical characteristics of a component can sometimes be adversely affected when it is placed in a given system. This effect can show up as signal distortion, an improper timing sequence, a frequency shift, or numerous other types of unwanted interactions. Techniques designed to minimize the effects of system packaging on component performance are incorporated into system design by planners. These techniques should not be altered during your maintenance. Two of the techniques used by planners are discussed in the following sections.

Ground Planes and Shielding.

At packaging levels I and II, COPPER PLANES with voids, where feed-through is required, can be placed anywhere within the multilayer board. These planes tend to minimize interference between circuits and from external sources.

At other system levels, CROSS TALK (one signal interfering with another), rf generation within the system, and external interference are suppressed through the use of various techniques. These techniques are shown in figure 1-44. As shown in the figure, rf shielding is used on the mating surfaces of the package, cabling is shielded, and heat sinks are provided.

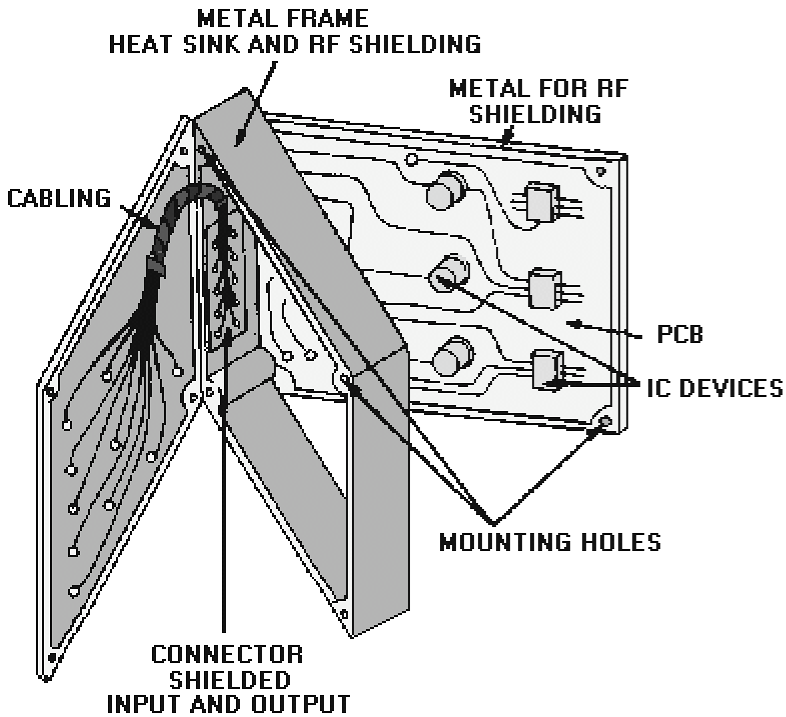

Figure 1-44.—Ground planes and shielding.

Interconnection and Intraconnections

To meet the high-frequency characteristics and propagation timing required by present and future systems, the device package must not have excessive distributed capacitance and/or inductance. This type of packaging is accomplished in the design of systems using ICs and other microelectronic devices by using shorter leads internal to the package and by careful spacing of complex circuits on printed circuit boards. To take advantage of the inherent speed of the integrated circuit, you must keep the signal propagation time between circuits to a minimum. The signal is delayed approximately 1 nanosecond per foot, so reducing the distance between circuits as much as possible is necessary. This requires the use of structures, such as high-density digital systems with an emphasis on large-scale integration, for systems in the future. Also, maintenance personnel should be especially concerned with the spacing of circuits, lead dress, and surface cleanliness. These factors affect the performance of high-speed digital and analog circuits.

Q46. In what publication are environmental requirements for equipment defined?

Q47. In what publication would you find guidelines for performance of military electronic parts?

Q48. Who is responsible for meeting environmental and electrical requirements of a system?

Q49. What methods are used to prevent unwanted component interaction?

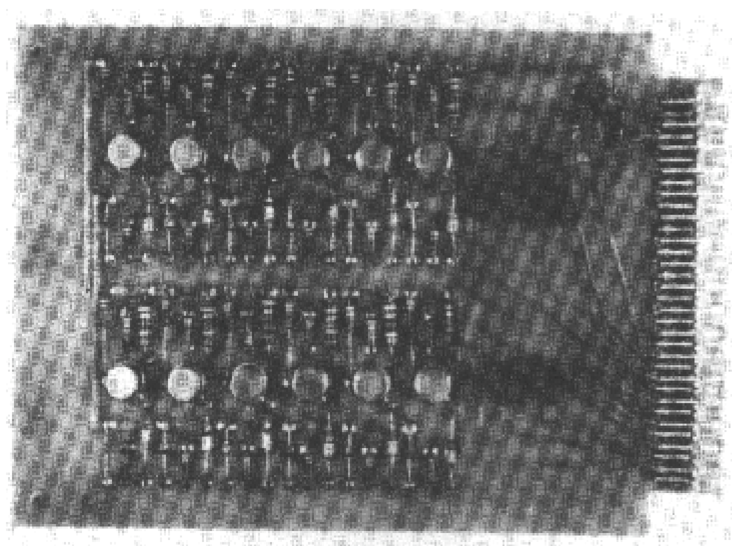
SUMMARY

This topic has presented information on the development and manufacture of microelectronic devices. The information that follows summarizes the important points of this topic.

VACUUM-TUBE CIRCUITS in most modern military equipment are unacceptable because of size, weight, and power use.

Discovery of the transistor in 1948 marked the beginning of **MICROELECTRONICS**.

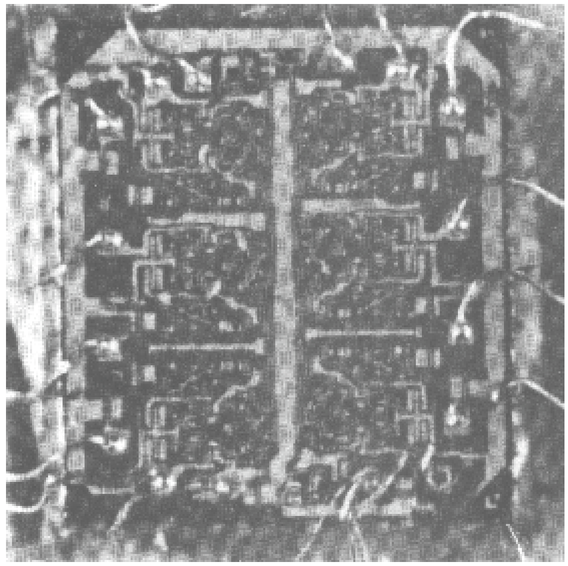
The **PRINTED CIRCUIT BOARD (pcb)** reduces weight and eliminates point-to-point wiring.



The **INTEGRATED CIRCUITS (IC)** consist of elements inseparably associated and formed on or within a single SUBSTRATE.

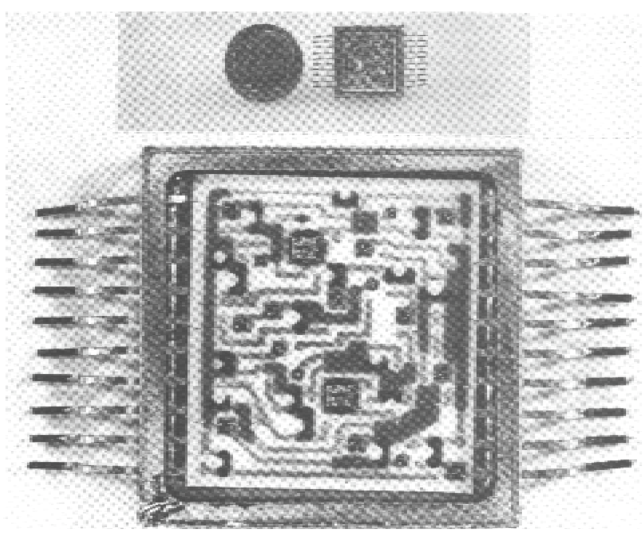
ICs are classified as three types: **MONOLITHIC, FILM**, and **HYBRID**.

The **MONOLITHIC IC**, called a chip or die, contains both active and passive elements.



FILM COMPONENTS are passive elements, either resistors or capacitors.

HYBRID ICs are combinations of monolithic and film or of film and discrete components, or any combination thereof. They allow flexibility in circuits.

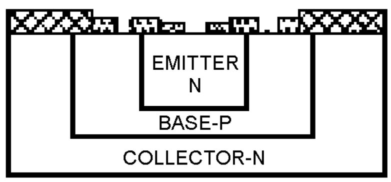


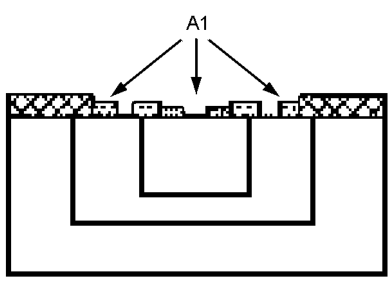
Rapid development has resulted in increased reliability and availability, reduced cost, and higher element density.

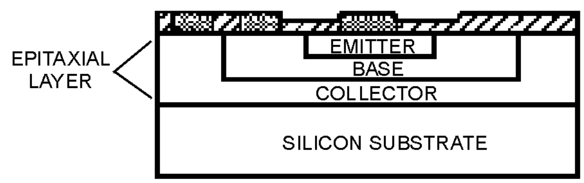
LARGE-SCALE (lsi) and **VERY LARGE-SCALE INTEGRATION (vlsi)** allow thousands of elements in a single chip.

MONOLITHIC ICs are produced by the diffusion or epitaxial methods.

DIFFUSED elements penetrate the substrate, **EPITAXIAL** do not.





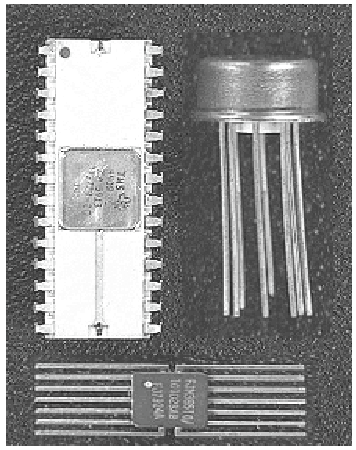


ISOLATION is a production method to prevent unwanted interaction between elements within a chip.

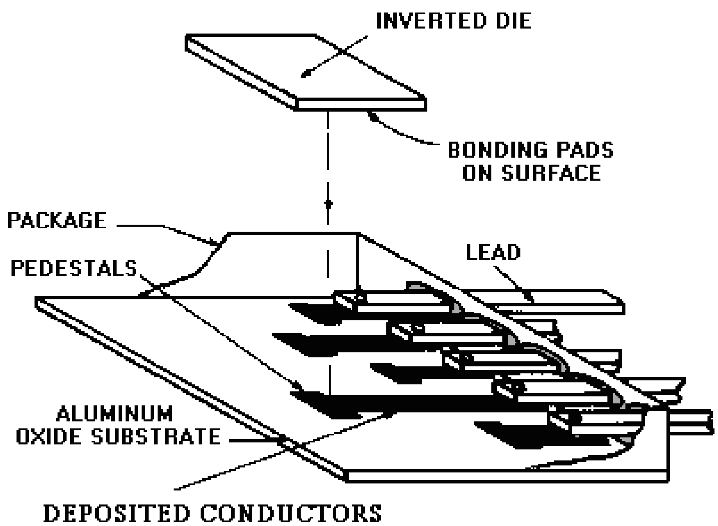
THIN-FILM ELEMENTS are produced through **EVAPORATION** or **CATHODE SPUTTERING** techniques.

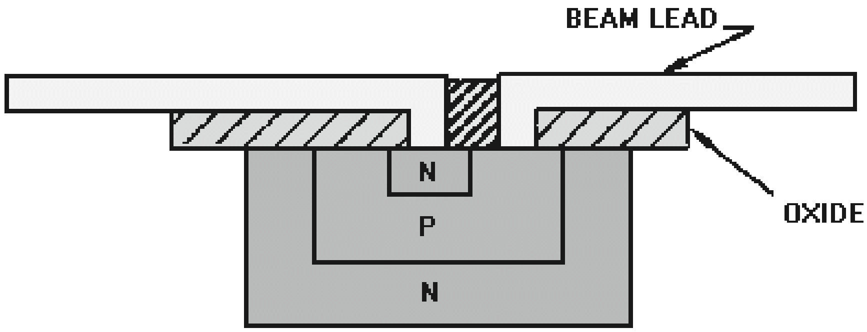
THICK-FILM ELEMENTS are screened onto the substrate.

The most common types of packages for **ICs** are **TO**, **FLAT PACK**, and **DUAL INLINE**.



FLIP CHIPS and **BEAM-LEAD CHIPS** are techniques being developed to eliminate bonding wires and to improve packaging.

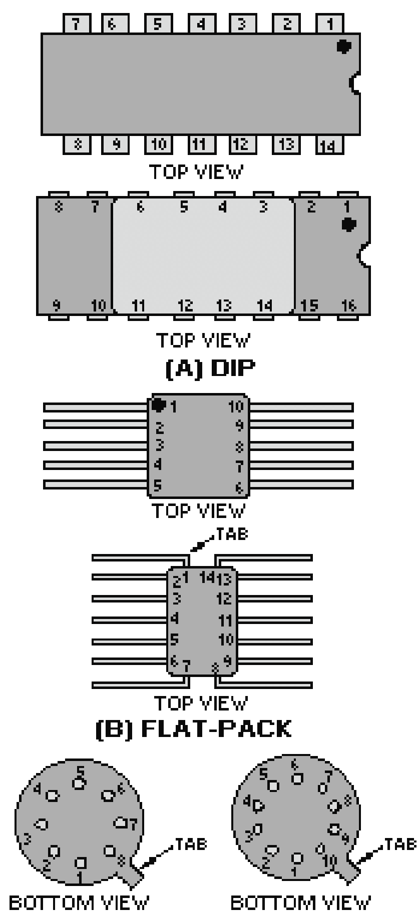




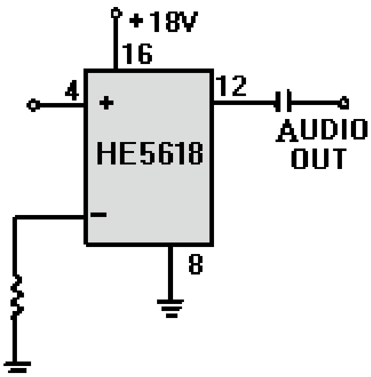
Large **DIPs** are being used to package lsi and vlsi. They can be produced with up to 64 pins and are designed to fulfill a specific need.

Viewed from the tops, **DIPS** and **FLAT-PACK LEADS** are numbered counterclockwise from the reference mark.

Viewed from the bottom, **TO-5 LEADS** are numbered clockwise from the tab.



Numbers and letters on schematics and **ICs** identify the **TYPE OF IC**.

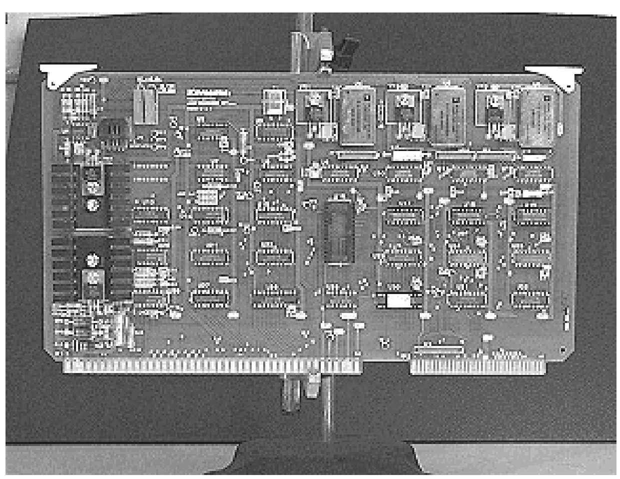


Knowledge of **TERMINOLOGY** used in microelectronics and of packaging concepts will aid you in becoming an effective technician.

STANDARD TERMINOLOGY has been adopted by the Navy to ease communication.

MICROELECTRONICS is that area of technology associated with electronic systems designed with extremely small parts or elements.

A **MICROCIRCUIT** is a small circuit which is considered as a single part composed of elements on or within a single substrate.



A **MICROCIRCUIT MODULE** is an assembly of microcircuits or a combination of microcircuits and discrete components packaged as a replaceable unit.

MINIATURE ELECTRONICS are card assemblies and modules composed exclusively of discrete electronic components.

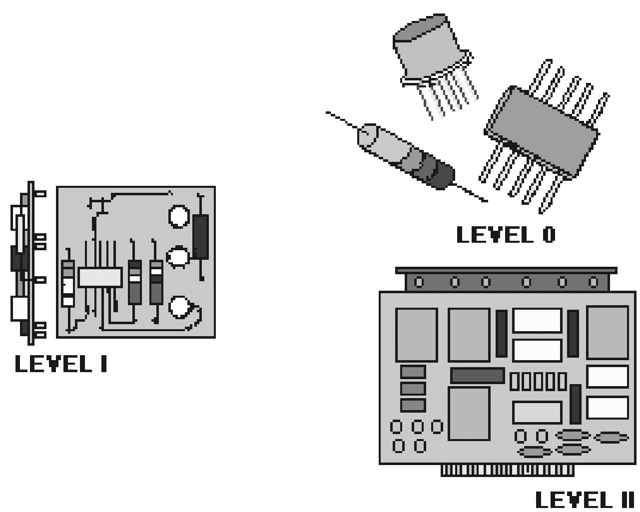
SYSTEM PACKAGING refers to the design of a system, taking into account environmental and electronic characteristics, access, and maintainability.

PACKAGING LEVELS 0 to IV are used to identify assemblies within a system. Packaging levels are as follows:

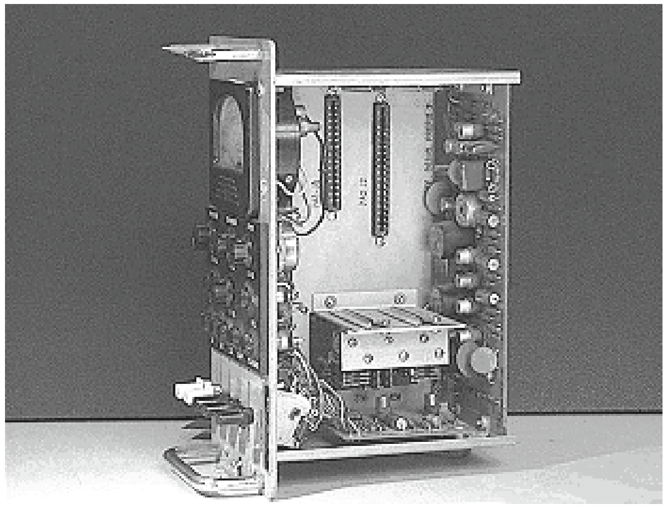
LEVEL 0-Nonrepairable parts (resistors, diodes, etc.)

LEVEL I -Submodules attached to circuit cards.

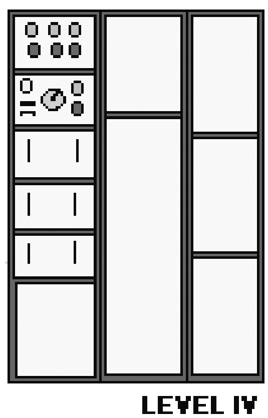
LEVEL II -Circuit cards and **MOTHER BOARDS**.



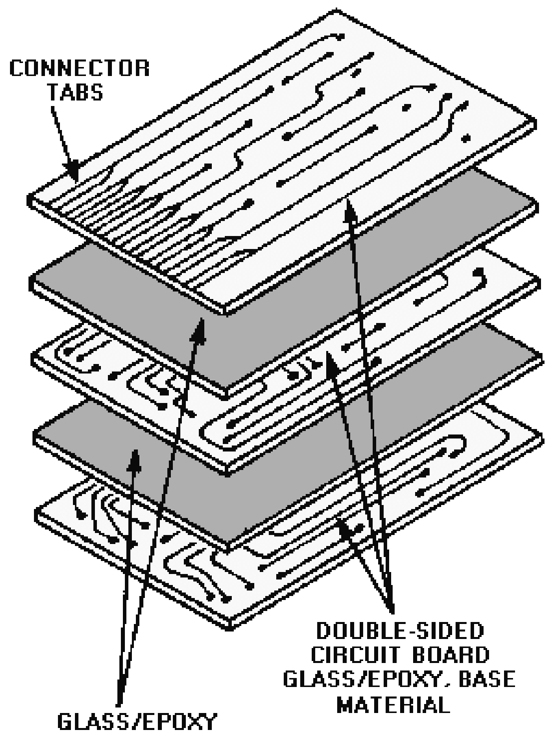
LEVEL III - Drawers.



LEVEL IV - Cabinets.



The most common **METHODS OF INTERCONNECTION** are the conventional pcb, the multilayer pcb, and modular assemblies.

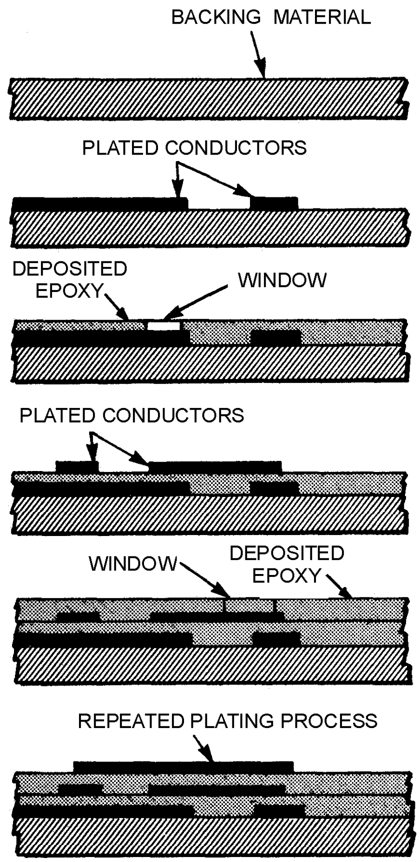


Three methods of interconnecting circuitry in multilayer printed circuit boards are the **CLEARANCE-HOLE**, the **PLATED-THROUGH-HOLE**, and **LAYER BUILD-UP**.

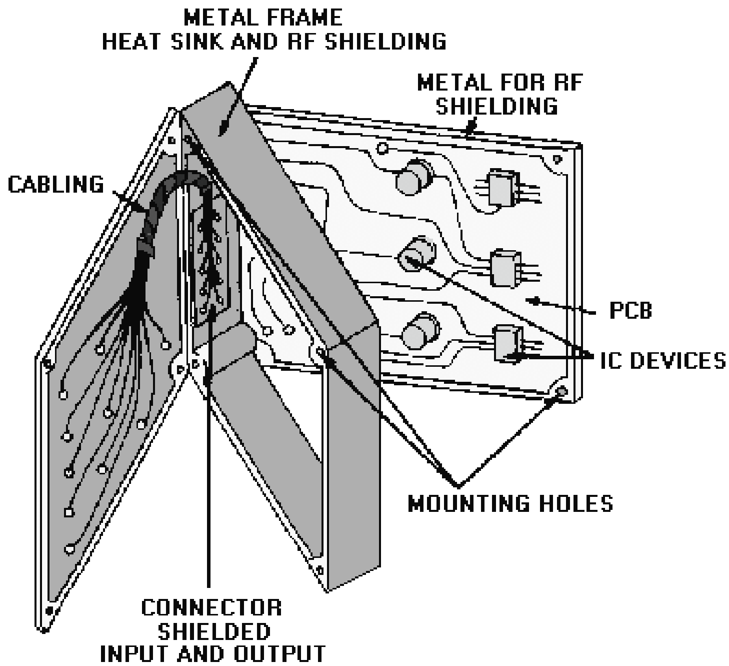
MODULAR ASSEMBLIES were devised to achieve high circuit density.

Modular assemblies have progressed from **CORDWOOD MODULES** through **MICROMODULES**. Micromodules consist of film components and discrete components to integrated and hybrid circuitry.

ENVIRONMENTAL FACTORS to be considered are temperature, humidity, shock, vibration, and rf interference.



ELECTRICAL FACTORS are overcome by using shielding and ground planes and by careful placement of components.



ANSWERS TO QUESTIONS Q1. THROUGH Q50.

A1. *Size, weight, and power consumption.*

A2. *The transistor and solid-state diode.*

A3. *Technology of electronic systems made of extremely small electronic parts or elements.*

A4. *The Edison Effect.*

A5. *Transformers, capacitors, and resistors.*

A6. *"Rat's nest" appearance and unwanted interaction, such as capacitive and inductive effects.*

A7. *Rapid repair of systems and improved efficiency.*

A8. *Differences in performance of tubes of the same type.*

A9. *Eliminate heavy chassis and point-to-point wiring.*

CHAPTER 2

MINIATURE/MICROMINIATURE (2M) REPAIR PROGRAM AND HIGH-RELIABILITY SOLDERING

LEARNING OBJECTIVES

Upon completion of this topic, the student will be able to:

1. State the purpose and need for training and certification of 2M repair technicians.
2. Explain the maintenance levels at which maintenance is performed.
3. Identify the specialized and general test equipment used in fault isolation.
4. Recognize the specialized types of tools used and the importance of repair facilities.
5. Explain the principles of high-reliability soldering.

INTRODUCTION

As mentioned in topic 1, advances in the field of microelectronics are impressive. With every step forward in production development, a corresponding step forward must be made in maintenance and repair techniques.

This topic will teach you how the Navy is coping with the new technology and how personnel are trained to carry out the maintenance and repair of complex equipment. The program discussed in this topic is up to date at this time, but as industry advances, so must the capabilities of the technician.

MINIATURE AND MICROMINIATURE (2M) ELECTRONIC REPAIR PROGRAM

Training requirements for miniature and microminiature repair personnel were developed under guidelines established by the Chief of Naval Operations. The Naval Sea Systems Command (NAVSEA) developed a program which provides for the proper training in miniature and microminiature repair. This program, NAVSEA Miniature/Microminiature (2M) Electronic Repair, authorizes and provides proper tools and equipment and establishes a personnel certification program to maintain quality repair.

The Naval Air Systems Command has developed a similar program specifically for the aviation community. The two programs are patterned after the National Aeronautics and Space Administration (NASA) high-reliability soldering studies and have few differences other than the administrative chain of command. For purposes of this topic, we will use the NAVSEA manual for reference.

The 2M program covers all phases of miniature and microminiature repair. It establishes the training curriculum for repair personnel, outlines standards of workmanship, and provides guidelines for specific repairs to equipment, including the types of tools to use. This part of the program ensures high-reliability repairs by qualified technicians.

Upon satisfactory completion of a 2M training course, a technician will be CERTIFIED to perform repairs. The CERTIFICATION is issued at the level at which the technician qualifies and specifies what type of repairs the technician is permitted to perform. The two levels of qualification for technicians are MINIATURE COMPONENT REPAIR and MICROMINIATURE COMPONENT REPAIR. Miniature component repair is limited to discrete components and single- and double-sided printed circuit boards, including removal and installation of most integrated circuit devices. Microminiature component repair consists of repairs to highly complex, densely packaged, multilayer printed circuit boards. Sophisticated repair equipment is used that may include a binocular microscope.

To ensure that a technician is maintaining the required qualification level, periodic evaluations are conducted. By inspecting and evaluating the technician's work, certification teams ensure that the minimum standards for the technician's level of qualification are met. If the standards are met, the technician is recertified; if not, the certification is withheld pending retraining and requalification. This portion of the program ensures the high-quality, high-reliability repairs needed to meet operational requirements.

Q1. Training requirements for (2M) repair personnel were developed under guidelines established by what organization?

Q2. What agencies provide training, tools, equipment, and certification of the 2M system?

Q3. To perform microminiature component repair, a 2M technician must be currently certified in what area?

Q4. Multilayer printed circuit board repair is the responsibility of what 2M repair technician?

LEVELS OF MAINTENANCE

Effective maintenance and repair of microelectronic devices require one of three levels of maintenance. Level-of-repair designations called SOURCE, MAINTENANCE, and RECOVERABILITY CODES (SM&R) have been developed and are assigned by the Chief of Naval Material. These codes are D for DEPOT LEVEL, I for INTERMEDIATE LEVEL, and O for ORGANIZATIONAL LEVEL.

DEPOT-LEVEL MAINTENANCE.

SM&R Code D maintenance is the responsibility of maintenance activities designated by the systems command (NAVSEA, NAVAIR, NAVELEX). This code augments stocks of serviceable material. It also supports codes I and O activities by providing more extensive shop facilities and equipment and more highly skilled technicians. Code D maintenance includes repair, modification, alteration, modernization, and overhaul as well as reclamation or reconstruction of parts, assemblies, subassemblies, and components. Finally, it includes emergency manufacture of nonavailable parts. Code D maintenance also provides technical assistance to user activities and to code I maintenance organizations. Code D maintenance is performed in shops, located in shipyards and shore-based facilities, including contractor maintenance organizations.

INTERMEDIATE-LEVEL MAINTENANCE

SM&R Code I maintenance, performed at mobile shops, tenders on shore-based repair facilities (SIMAS) provides *direct* support to user organizations. Code I maintenance includes calibration, repair, or replacement of damaged or unserviceable parts, components, or assemblies, and emergency manufacture of nonavailable parts. It also provides technical assistance to ships and stations.

ORGANIZATIONAL-LEVEL MAINTENANCE

SM&R Code O maintenance is the responsibility of the activity who owns the equipment. Code O maintenance consists of inspecting, servicing, lubricating, adjusting, and replacing parts, minor assemblies, and subassemblies.

An INTEGRATED LOGISTICS SUPPORT PLAN (ILSP) determines the maintenance level for electronic assemblies, modules, and boards for each equipment assigned to an activity. The ILSP codes the items according to the normal maintenance capabilities of that activity. This results in two additional repair-level categories - NORMAL and EMERGENCY.

Normal Repairs

Generally, 2M repairs are performed at the level set forth in the maintenance plan and specified by the appropriate SM&R coding for each board or module. Therefore, normal repairs include all repairs except organizational-level repair of D- and I-coded items and intermediate-level repair of D-coded items.

Emergent/Emergency Repairs

In the NAVSEA 2M Electronic Repair Program, emergent/emergency repairs are those arising unexpectedly. They may require prompt repair action to restore a system or piece of equipment to operating condition where normal repairs are not authorized. These Code O repairs on boards or modules are normally SM&R-coded for Code D repairs. Emergent/emergency 2M repairs may be performed only to meet an urgent operational commitment as directed by the operational commander.

SOURCE, MAINTENANCE, AND RECOVERABILITY (SM&R) CODES

The Allowance Parts List (APL) is a technical document prepared by the Navy for specific equipment/system support. This document lists the repair parts requirements for a ship having the exact equipment/component. To determine the availability of repair parts, the 2M technician must be familiar with these documents. SM&R codes, found in APLs, determine where repair parts can be obtained, who is authorized to make the repair, and at what maintenance level the item may be recovered or condemned.

Q5. What are the three levels of maintenance?

Q6. Maintenance performed by the user activity is what maintenance level?

TEST EQUIPMENT

Microelectronic developments have had a great impact on the test equipment, tools, and facilities necessary to maintain systems using this technology. This section discusses, in general terms, the importance of these developments.

Early electronic systems could be completely checked-out with general-purpose electronic test equipment (GPETE), such as multimeters, oscilloscopes, and signal generators. Using this equipment to test the microelectronics components individually in one of today's very complex electronic systems would be extremely difficult if not impossible. Therefore, improvements in system testing procedures have been necessary.

One such improvement in system testing is the design of a method that can test systems at various *functional levels*. This allows groups of components to be tested as a whole and reduces the time required to test components individually. One advantage of this method is that complete test plans can be written to provide the best sequencing of tests for wave shape or voltage outputs for each functional level. This method of testing has led to the development of special test sets, called AUTOMATED TEST EQUIPMENT (ATE). These test sets are capable of simulating actual operating conditions of the system being tested. Appropriate signal voltages are applied by the test set to the various functional levels of the system, and the output of each level is monitored. Testing sequences are prewritten and steps may be switched-in manually or automatically. The limits for each functional level are preprogrammed to give either a "go/no-go" indication or diagnose a fault to a component. A go/no-go indication means that a functional level either meets the test specifications (go) or fails to meet the specifications (no-go).

If a no-go indication is observed for a given function, the area of the system in which it occurs is then further tested. You can test the trouble area by using general-purpose electronic test equipment and the troubleshooting manual for the system. General purpose electronic test equipment (GPETE) will be discussed later in this topic. (Effective fault isolation at this point depends on the experience of the technician and the quality of the troubleshooting manual.) After the fault is located, the defective part is then replaced or repaired, depending on the nature of the defect. At this stage, the defective part is usually a circuit card, a module, or a discrete part, such as a switch, relay, transistor, or resistor.

BUILT-IN TEST EQUIPMENT

One type of fault isolation that can be either on-line or off-line is BUILT-IN TEST EQUIPMENT (BITE). BITE is any device that is permanently mounted in the prime equipment (system); it is used only for testing the equipment or system in which it is installed either independently or in association with external test equipment. The specific types of BITE are too varied to discuss here, but may be as simple as a set of meters and switches or as complex as a computer-controlled diagnostic system.

ON-LINE TEST EQUIPMENT

Functional-level testing and modular design have been successfully applied to most electronic systems in use today; however, the trend toward increasing the number of subassemblies within a module by incorporating microelectronics will make this method of testing less and less effective.

The increased circuit density and packaging possible with microelectronic components makes troubleshooting and fault location difficult or, in some cases, impossible. The technician's efforts must be aided if timely repairs to microelectronic systems are to be achieved. These repairs are particularly significant when considered in the light of the very stringent availability requirements for today's systems. This dilemma has led to the present trend of developing both ON-LINE and OFF-LINE automatic test systems. The on-line systems are designed to monitor performance continuously and to isolate faults automatically to removable assemblies. Off-line systems automatically check removable assemblies and isolate faults to the component level.

OFF-LINE TEST EQUIPMENT

Over the years several off-line testing programs have been developed. The ones mentioned below are being used throughout the fleet today.

Consolidated Automated Support System

Consolidated Automated Support System (CASS) has become the United States Navy’s Aviation community standard in automated test equipment (ATE), it has been established to replace 24 different types of computer based ATE systems with one modern, cost effective family of testers. The system increases repair capabilities and material readiness, decreases overall support and life cycle costs, and reduces the physical space currently required by other types of electronic testing equipment. Currently the system repairs over 600 different assets. As new test programs are written, it will support over 2,300 different Weapons Replaceable Assemblies (WRAs) and Shop Replaceable Assemblies (SRAs) from current and planned Naval Aviation inventory of aircraft to include F/A-18 (all models), EA-6B, F-14 (all models), H-60, E-2C, and V-22. The test set has automated capabilities for testing avionics systems whose technology encompasses frequency stimulus and measurement and digital functions. The capabilities include power conditioning, interface control, calibration, self-maintenance, instrumentation, and software functions necessary to perform end-to-end tests, fault isolation tests, and alignment or adjustment of units under test (UUT). UUTs are interfaced to the test set by test program sets (TPSs), interface devices (IDs), and accessories. Since one tester capable of meeting all these needs would be too large, CASS was designed to be modular. Based upon functional needs, configuration of CASS benches are grouped and defined as distinct configurations.

Module Test and Repair and Gold Disk Development

Module Test and Repair (MTR) Program develops and provides electrical/electronic module test and repair capabilities to organizational (O-level) and intermediate (I-level) maintenance facilities for both ashore and afloat commands. It also serves as the In-Service Engineering Agent (ISEA) for various MTR equipment, development and provides technical manuals on CD ROM, develops gold disks for circuit card assemblies, certifies gold disk developers and developer sites, provides for the maintenance and operation of MTR facilities, provides technical assistance and guidance for all aspects of the MTR Program; and is the gold disk verification agent for all DoD activities.

Gold Disk Development

A gold disk is a diagnostic troubleshooting routine used to isolate faulty components on circuit card assemblies (CCAs) or electronic modules (EMs). The same technology may also be used to determine whether an assembly is no fault evident (NFE). The primary purpose of a gold disk is to provide the technician all required logistical information to identify component level failures and complete necessary repair. The distribution of gold disk routines DoD-wide permits an organic repair capability to users possessing the AN/USM-646 (V) and AN/USM-658 (V) test stations. The diagnostic enhancement and organic repair capability supports reduction of funding expenditures and improvement of operational availability. Repair accomplished at the lowest practical maintenance level (progressive repair) assists activities in offsetting the cost of shipping suspect faulty CCAs/EMs back to a depot for repair/replacement.

GENERAL-PURPOSE ELECTRONIC TEST EQUIPMENT (GPETE)

When no automatic means of accomplishing fault isolation is available, general-purpose electronic test equipment and good troubleshooting procedures is used; however, such fault diagnosis should be attempted only by experienced technicians. Misuse of electrical probes and test equipment may permanently damage boards or microelectronic devices attached to them. The proximity of leads to one another and the effects of interconnecting the wiring make the testing of boards extremely difficult; these factors also make drift or current leakage measurements practically impossible.

Boards that have been conformally coated are difficult to probe because the coating is often too thick to penetrate for a good electrical contact. These boards must be removed for electrical probe testing. Many boards, however, are designed with test points that can be monitored either with special test sets or general-purpose test equipment. Another method of obtaining access to a greater number of test points is to use extender cards or cables. The use of extender cards or cables makes these test points easier to check.

Special care should be exercised when probing integrated circuits; they are easily damaged by excessive voltages or currents, and component leads may be physically damaged. Precautions, concerning the use of test equipment for troubleshooting equipments containing integrated circuits, are similar to those that should be observed when troubleshooting equipment containing semiconductor or other voltage and current-sensitive devices.

Voltage and resistance tests of resistors, transistors, inductors, and so forth, are usually effective in locating complete failures or defects that exhibit large changes from normal circuit characteristics; however, these methods are time-consuming and sometimes unsuccessful. The suspect device often must be desoldered, removed from the circuit, and then retested to verify the fault. If the defect is not verified, the device must be resoldered to the board again. If this procedure has to be repeated several times, or if the board is conformally coated, the defect may never be located. In fact, the circuit may be further damaged by the attempt to locate the fault. *For these reasons, the device should never be desoldered until all possible in-circuit tests are performed and the defect verified.*

Q7. List the three groups of test equipment used for fault isolation in 2M repair.

Q8. What test equipment continuously monitors electronic systems?

Q9. NELAT and VAST are examples of what type of test equipment?

REPAIR STATIONS

In addition to the requirements for special skills, the repair of 2M electronic circuits also requires special tools. Because these tools are delicate and expensive, they are distributed only to trained and certified 2M repair technicians.

2M repair stations are equipped with electrical and mechanical units, tools, and general repair materials. Such equipments are needed to make reliable repairs to miniature and microminiature component circuit boards.

Although most of the tools and equipments are common to both miniature and microminiature repair stations, several pieces of equipment are used solely with microminiature repair. Precision drill presses and stereoscopic-zoom microscopes are examples of microminiature repair equipment normally not found in a miniature repair station. A brief description of some of the tools and equipments and their uses will broaden your knowledge and understanding of 2M repair.

The 2M repair set consists of special electrical units, tools, and materials necessary to make high-reliability repairs to component circuitry. The basic repair set is made up of a repair station power unit, magnifier/light system, card holder, a high-intensity light, a Pana Vise, and a tool chest with specialized tools and materials. As mentioned previously, stations that have microminiature repair capabilities will include a stereoscopic-zoom microscope and precision drill press.

REPAIR STATION POWER UNIT

The repair station power unit is a standardized system that provides controlled soldering and desoldering of all types of solder joint configurations. The unit is shown in figure 2-1. Included in the control unit's capabilities are:

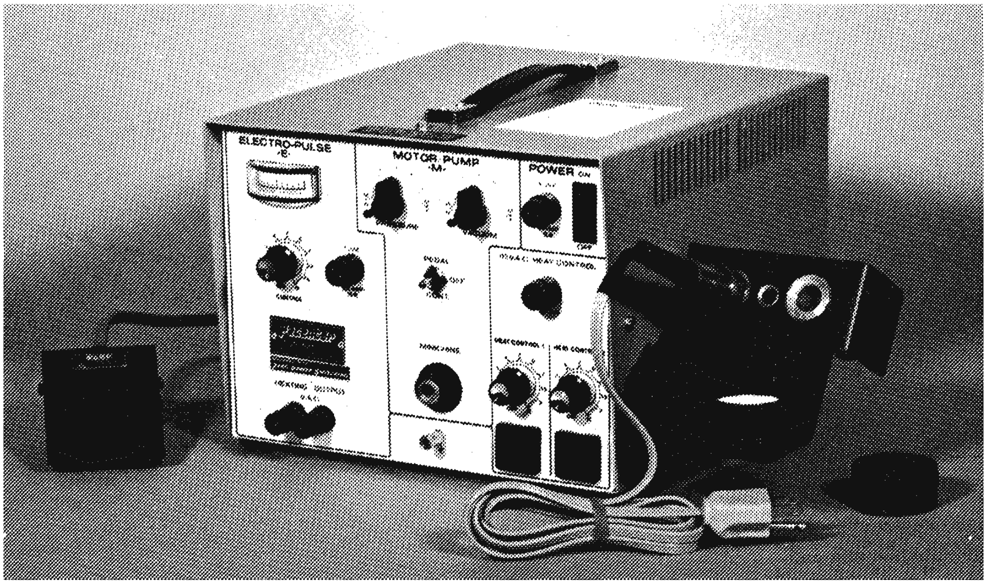

Figure 2-1.—Repair station power unit.

- "Spike free" power switching for attached electrical hand tools to eliminate damage to electrostatic discharge components.
- Abrading, milling, drilling, grinding, and cutting using a flexible shaft, rotary-drive machine. This allows the technician to remove conformal coatings, oxides, eyelets, rivets, damaged board material, and damaged platings from assemblies.
- Lap flow solder connections and thermal removal of conformal coatings.
- Resistive and conductive tweezer heating for connector soldering applications.
- Thermal wire stripping for removing polyvinyl chloride (PVC) and other synethetic wire coverings.

Power Source

The basic unit houses the power supply, power level indicator, motor control switch, hand tool temperature controls, air pressure and vacuum controls with quick connect fittings, positive ground terminal, the mechanical power-drive for the rotary-drive machine, and a vacuum/pressure pump. A two-position foot pedal, to the left of the power unit in the illustration, allows hand-free operation for all ancillary (additional) handpieces. The first detent on the pedal provides power to the voltage heating outputs. The second detent activates the motor drive or vacuum/pressure pump.

Handpieces

The handpieces used with the power unit are shown in figures 2-2 and 2-3. The lap flow handpiece, view (A) of figure 2-2, is used with the variable low-voltage power source. This handpiece allows removal of conformal coatings, release of sweat joints, and lap flow soldering capability. (Lap flow soldering will be discussed in topic 3.) The thermal wire stripper in view (B) is used to remove insulation from various sizes of wire easily and cleanly.

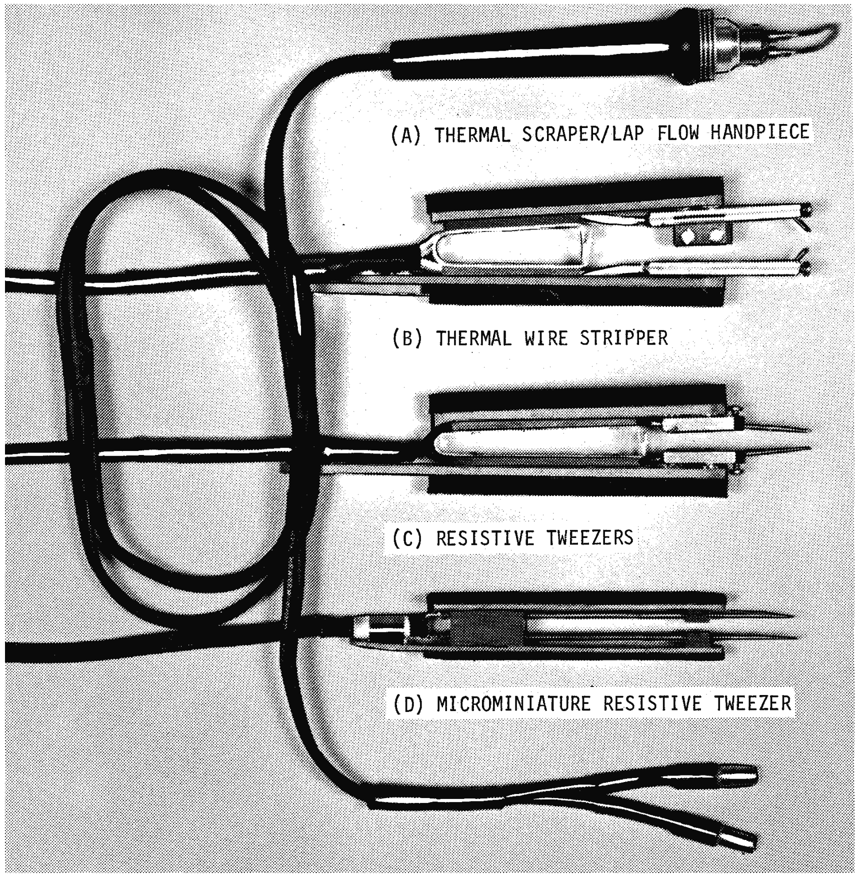

Figure 2-2.—Low voltage handpiece.

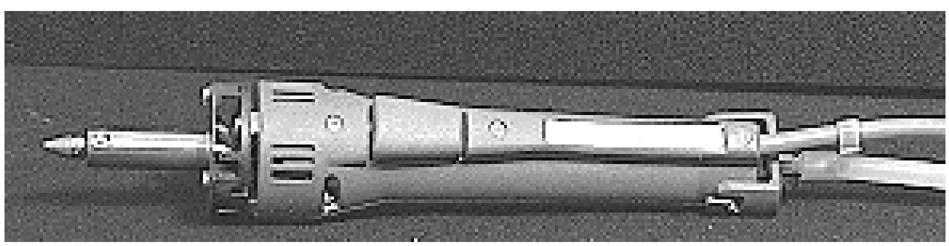

Figure 2-3.—Motorized solder extrator.

The resistive tweezers, shown in view (C), are used for soldering components. Two sizes [views (C) and (D)] are provided to meet the needs of the technician. Both the thermal stripper and the resistive tweezers are used with the low-voltage power supply.

The solder extractor, shown in figure 2-3, is connected to the variable high-voltage outlet. This handpiece allows airflow application (at controlled temperatures) of a vacuum or pressure to the selected area. Five sizes of extractor tips are provided. You can determine the one to be used by matching the tip with the circuit pad and the component being desoldered.

Soldering Irons

A soldering iron is shown in figure 2-4. This is connected to the 115-volt ac variable outlet of the power unit. You control the temperature by adjusting the voltage. The iron has replaceable tips. Chosen for their long life and good heat conductivity, soldering iron tips are high quality with iron-clad over copper construction. The tip shape and size and the heat range used are determined by the area and mass to be soldered.

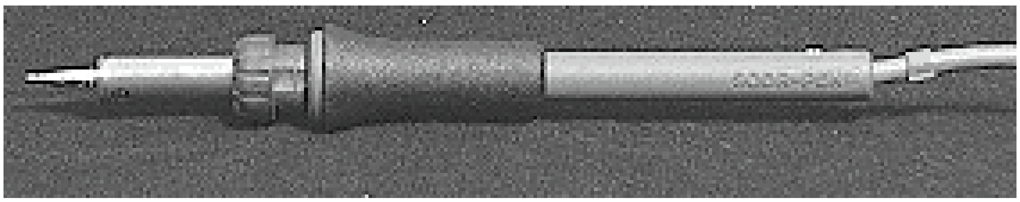

Figure 2-4.—Soldering iron.

ROTARY-DRIVE MACHINE

This variable-speed, rotary power drive adapts to standard diameter shank drill bits, ball mills, wheels, disks, brushes, and mandrels for most drilling and abrasive removal techniques (figure 2-5).

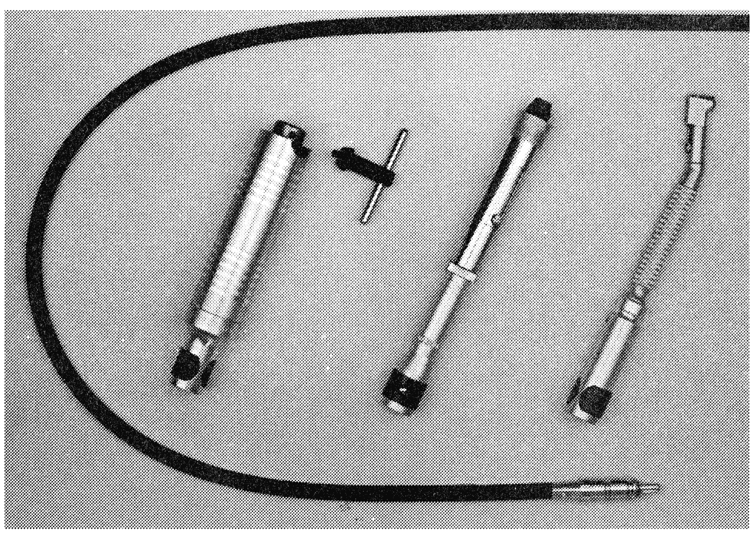

Figure 2-5.—Rotary-drive machine handpieces.

The accessories, used with the rotary-drive tool, are shown in views (A) through (F) of figure 2-6. Abrasive ball mills, wheels, discs, and brushes are either premounted on mandrels or can be mounted by the technician on the mandrels provided. These attachments are used for sanding and smoothing repaired areas, drilling holes, removing conformal coatings, and repairing burned or damaged areas. A chuck-equipped handpiece allows it to accept rotary tools with varying shank sizes.

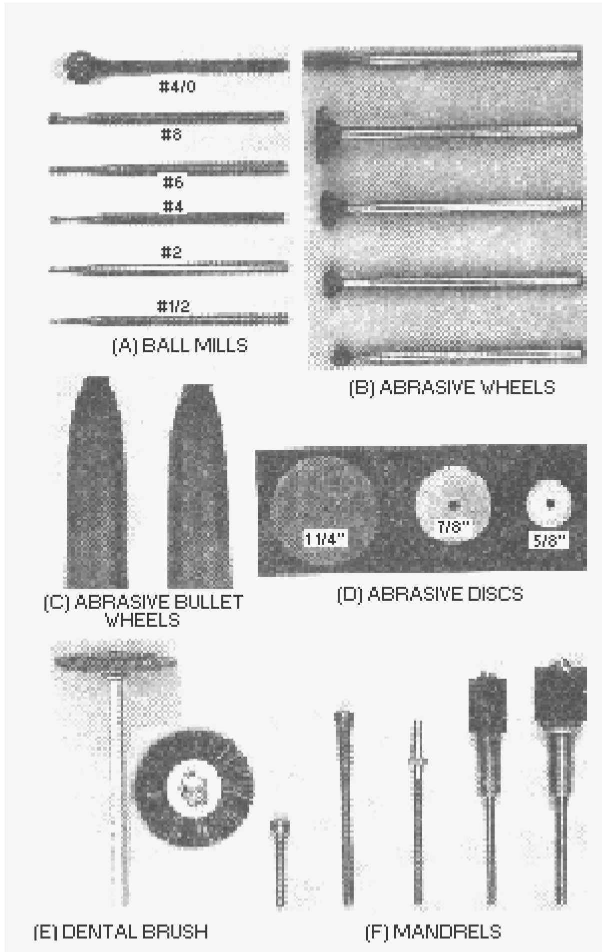

Figure 2-6.—Rotary-drive machine accessories. BALL MILLS

CIRCUIT CARD HOLDER AND MAGNIFIER

The circuit card holder is an adjustable, rotatable holder for virtually any size circuit card. Figure 2-7 shows the circuit card holder [view (A)] and the magnifier unit [view (B)]. The magnifier unit provides magnification when detail provided by a microscope is not required. The special lens allows the technician to view a rectangular area of over 14 square inches with low distortion, fine resolution, and excellent depth of field. The magnifier unit, which includes high intensity lamps, adapts to the vertical shaft of the circuit card holder.

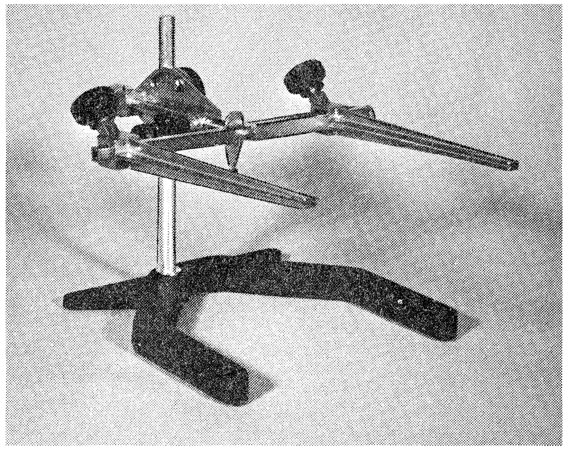

Figure 2-7.—Card holder and magnifier.

HIGH-INTENSITY LIGHT

The high-intensity light provides a variable, high-intensity, portable light source over the work area. The two flexible arms permit both front and back lighting of the workpiece and provide a balanced light that eliminates shadows (figure 2-8).

Figure 2-8.—High intensity lamp.

The high-intensity light uses 115-volt, 60-hertz input power. One brightness knob controls a flood-type bulb, and the other knob controls a spot-type bulb.

PANA VISE

This nylon-jawed, multiposition vise can rotate and tilt. With this flexibility the technician can achieve any compound angle for holding a workpiece during assembly, modification, or repair (figure 2-9).

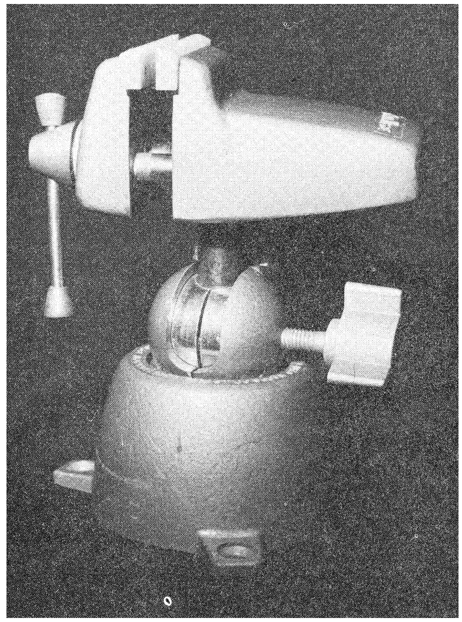

Figure 2-9.—Pana Vise.

HAND TOOLS

Figure 2-10, views (A) through (C), shows some representative types of hand tools used in 2M repair procedures.

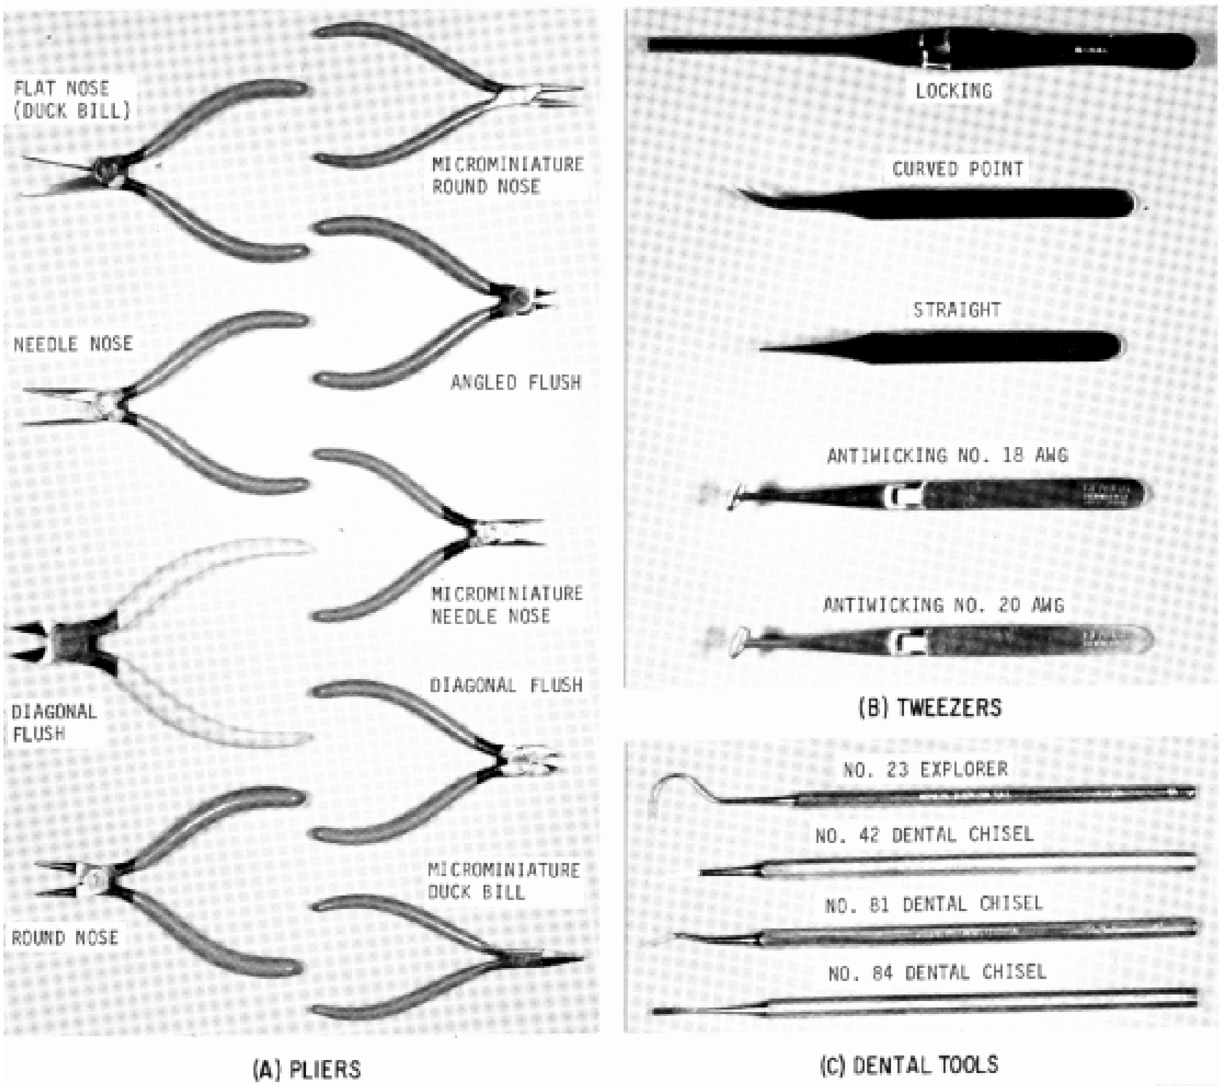

Figure 2-10.—Pliers, tweezers, and dental tools.

Pliers

In view (A), the figure shows the pliers preferred for 2M repair procedures. These precision pliers have a long and useful life if handled and cared for properly. The flush-cutting pliers are used to cut various sizes of wire and component leads. The needlenose, roundnose, and flatnose pliers are used for forming, looping, and bending wires and component leads. They are also used for gripping components and leads during removal or installation.

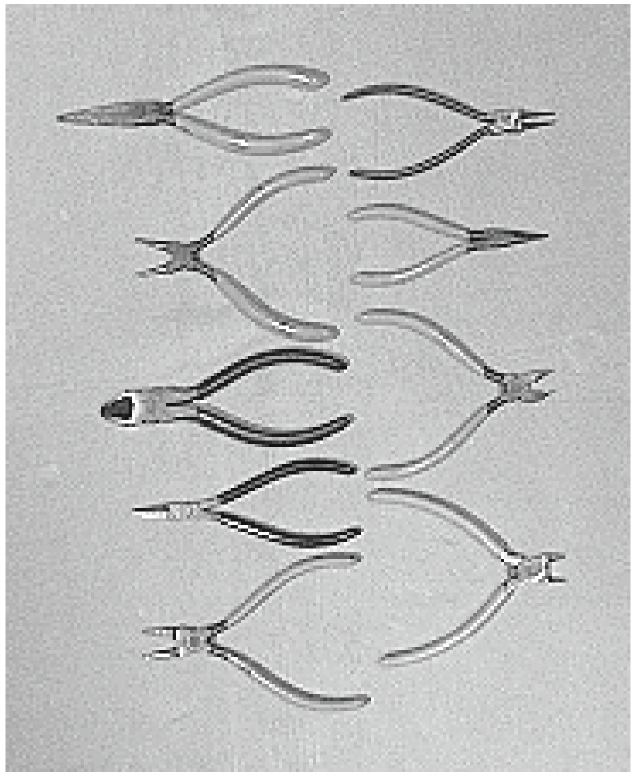

Figure 2-10a.—Pliers.

Tweezers

View (B) shows tweezers contained in the 2M repair set. The top two pairs of tweezers are used to hold small components during installation and repair procedures. The other pairs are anti-wicking tweezers used to tin and solder stranded wire leads.

Dental Tools

View (C) shows some of the dental tools contained in the 2M repair set. They are used for picking, chipping, abrading, mixing, and smoothing various conformal coatings used on printed circuit boards and other general pcb repair techniques.

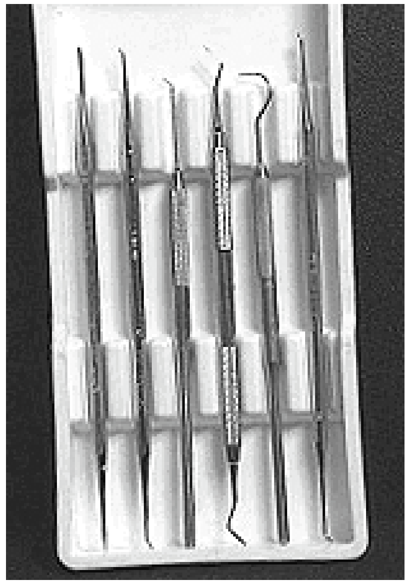

Figure 2-10c.—Dental tools.

Eyelet-Setting Tools

Among the repair procedures required of the 2M repair technician is the replacement of eyelets. Eyelets must sometimes be replaced because of the damage caused by incorrect repair procedures or complete failure of a printed circuit board. Figure 2-11 illustrates the tools used to replace these eyelets. Eyelets will be discussed in topic 3.

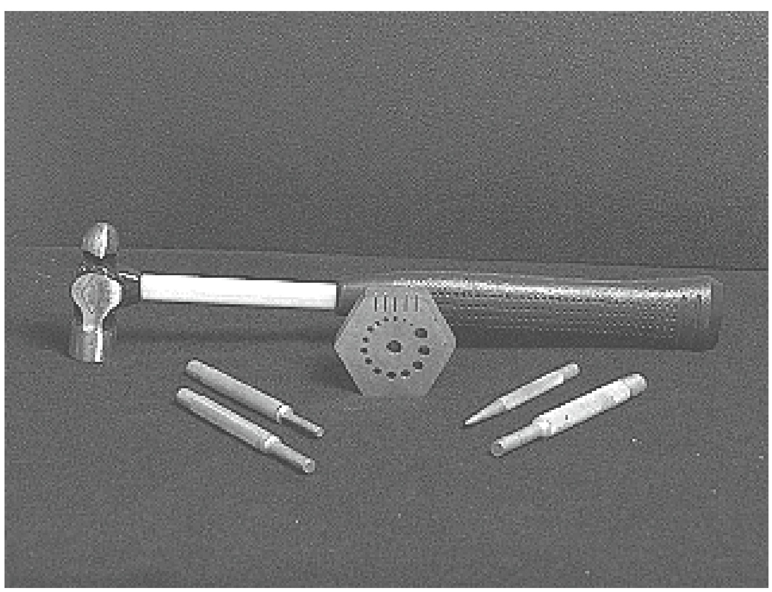

Figure 2-11.—Eyelet-setting tools.

MISCELLANEOUS TOOLS AND SUPPLIES

An assortment of some of the miscellaneous items used in 2M repair are shown in figure 2-12. A variety of brushes, files, scissors, thermal shunts, and consumables, such as solder wick, are included.

Even though all the items are not used in every repair procedure, it is extremely important that they be available for use should the need arise.

Figure 2-12.—Miscellaneous tools and supplies.

SAFETY EQUIPMENT

The nature of 2M repair requires items to be included in the tool kit for the personal safety of the technicians. The goggles and respirator illustrated in figure 2-13 have been approved for use by the technician. These should be worn at all times where dust, chips, fumes, and other hazardous substances are generated as a result of drilling, grinding, or other repair procedures.

Figure 2-13.—Safety equipment.

STEREOSCOPIC-ZOOM MICROSCOPE

The stereoscopic-zoom microscope provides a versatile optical viewing system. This viewing system is used in the fault detection, fault isolation, and repair of complex microminiature circuit boards and components. Figure 2-14 shows the microscope mounted on an adjustable stand. The microscope has a minimum of 3.5X and a maximum of 30X magnification to detect hairline cracks in conductor runs and stress cracks in solder joints.

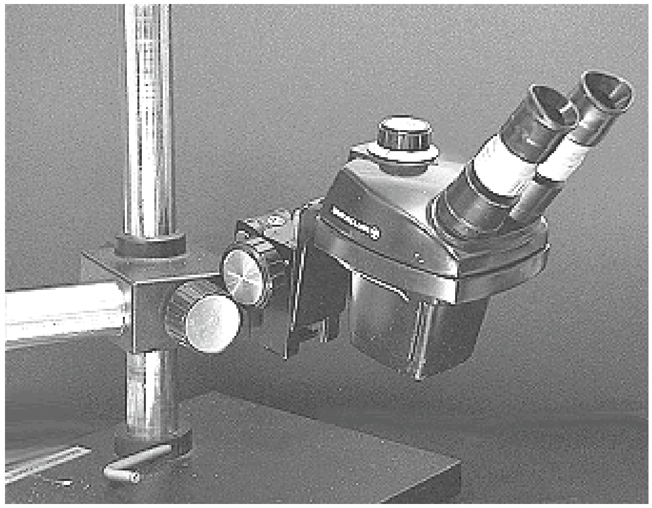

Figure 2-14.—Stereoscopic zoom microscope.

TOOL CHEST

The tool chest (not shown), provides storage space for the electronic repair hand tools, dental tools, abrasive wheels, solder and solder wicks, eyelets, abrasive disks, ball mills, various burrs, and other consumables used with the repair procedures. The chest is portable, lockable, and has variously sized drawers for convenience.

REPLACEMENT PARTS

Replacement parts are provided with the 2M repair set to ensure the technician has the capability to maintain the equipment properly. Actual preventive and corrective maintenance procedures, as well as data on additional spare parts and ordering information, are found in the technical manual for the 2M repair set equipment.

REPAIR STATION FACILITIES

To be effective, 2M electronic component repair must be performed under proper environmental conditions. Repair facility requirements, whether afloat or ashore, include adequate lighting, ventilation, noise considerations, work surface area, ESD (electrostatic discharge) protection, and adequate power availability. The recommended environmental conditions are discussed below. With the exception of requirements imposed by the Naval Environmental Health Center and other authorities for ship and shore work conditions, each activity tailors the requirements to meet local needs.

LIGHTING

The recommended lighting for a work surface is 100 footcandles from a direct lighting source. Light-colored overheads and bulkheads and off-white or pastel workbench tops are used to complement the lighting provided.

VENTILATION

Fumes from burning flux, coating materials, grinding dust, and cleaning solvents require adequate ventilation. The use of toxic, flammable substances, solvents, and coating compounds requires a duct system that vents gasses and vapors. This type of system must be used to prevent contamination often found in closed ventilation systems. This need is particularly important aboard ship. Vented hoods, ducts, or installations that are vented outside generally meet the minimum standards set by the Naval Environmental Health Center.

NOISE CONSIDERATIONS

Noise in the work area during normal work periods must be no greater than the acceptable level approved for each activity involved. Because the work is tedious and tiring, noise levels should be as low as possible. Ear protectors are required to be worn when a noise level exceeds 85 dB. Ear protectors should also be worn anytime the technician feels distracted by, or uncomfortable with, the noise level.

WORK SURFACE AREA

Work stations should have a minimum work surface of at least 60 inches wide and 30 inches deep. Standard Navy desks are excellent for this purpose. Standard shipboard workbenches are acceptable; however, off-white or pastel-colored heat-resistant tops should be installed on the workbenches. Chairs should be the type with backs and without arms. They should be comfortably padded and of the proper height to match the work surface height. Drawers or other suitable tool storage areas are usually provided.

ELECTROSTATIC DISCHARGE SENSITIVE DEVICE (ESDS) CAPABILITY

A 2M work station should be capable of becoming a static-free work station. This is specified in the Department of Defense Standard, Electrostatic DISCHARGE Control Program for Protection of Electrical and Electronic Parts, Assemblies, and Equipment. ESD will be discussed in greater detail in topic 3.

POWER REQUIREMENTS

No special power source or equipment mounting is required. The 2M repair equipment operates on 115-volt, 60-hertz power. A 15-ampere circuit is sufficient and six individual power receptacles should be available.

HIGH-RELIABILITY SOLDERING

The most common types of miniature and microminiature repair involve the removal and replacement of circuit components. The key to these repairs is a firm knowledge of solder and high-reliability soldering techniques.

Solder is a metal alloy used to join two or more metals with a metallic bond. The bonding occurs when molten solder dissolves a small amount of the metals and then cools to form a solid connection. The solder most commonly used in electronic assemblies is an alloy of tin and lead. Tin-lead alloys are identified by their percentage in the solder; the tin content is given first. Solder marked 60/40 is an alloy of 60 percent tin and 40 percent lead. The two most common alloys used in electronics are 60/40 and 63/37.

The melting temperature of tin-lead solder varies depending on the percentage of each metal. Lead melts at a temperature of 621 degrees Fahrenheit, and tin melts at 450 degrees Fahrenheit. Combinations of the two metals melt into a liquid at different temperatures. The 63/37 combination melts into a liquid at 361 degrees Fahrenheit. At this temperature, the alloy changes from a solid directly to a liquid with no plastic or semiliquid state. An alloy with such a sharp changing point is called a EUTECTIC ALLOY.

As the percentages of tin and lead are varied, the melting temperature increases. Alloy of 60/40 melts at 370 degrees Fahrenheit, and alloy of 70/30 melts at approximately 380 degrees Fahrenheit. Alloys, other than eutectic, go through a plastic or semiliquid state in their heating and cooling stages. Solder joints that are disturbed (moved) during the plastic state will result in damaged connections. For this reason, 63/37 solder is the best alloy for electronic work. Solder with 60/40 alloy is also acceptable, but it goes into a plastic state between 361 and 370 degrees Fahrenheit. When soldering joints with 60/40 alloy, you must exercise extreme care to prevent movement of the component during cooling.

USE OF FLUX IN SOLDER BONDING

Reliable solder connections can only be accomplished with clean surfaces. Using solvents and abrasives to clean the surfaces to be soldered is essential if you are to achieve good solder connections. In almost all cases, however, this cleaning process is insufficient because oxides form rapidly on heated metal surfaces. The rapid formation of oxides creates a nonmetallic film that prevents solder from contacting the metal. Good metal-to-metal contact must be obtained before good soldering joints may take place. Flux removes these surface oxides from metals to be soldered and keeps them removed during the soldering operation. Flux chemically breaks down surface oxides and causes the oxide film to loosen and break free from the metals being soldered.

Soldering fluxes are divided into three classifications or groups: CHLORIDE FLUX (commonly called ACID), ORGANIC FLUX, and ROSIN FLUX. Each flux has characteristics specific to its own group. Chloride fluxes are the most active of the three groups. They are effective on all common metals except aluminum and magnesium. Chloride fluxes, however, are NOT suitable for electronic soldering because they are highly corrosive, electrically conductive, and are difficult to remove from the soldered joint.

Organic fluxes are nearly as active as chloride fluxes, yet are less corrosive and easier to remove than chloride fluxes. Also, these fluxes are NOT satisfactory for electronic soldering because they must be removed completely to prevent corrosion.

Rosin fluxes ARE ideally suited to electronic soldering because of their molecular structure. The most common flux used in electronic soldering is a solution of pure rosin dissolved in suitable solvent. This solution works well with the tin- or solder-dipped metals commonly used for wires, lugs, and connectors. While inert at normal temperatures, rosin fluxes break down and become highly active at soldering temperatures. In addition, rosin is nonconductive.

Most electronic solder, in wire form, is made with one or more cores of rosin flux. When the joint or connection is heated and the wire solder is applied to the joint (not the iron), the flux flows onto the surface of the joint and removes the oxide. This process aids the wetting action of the solder. With enough heat the solder flows and replaces the flux. Insufficient heat results in a poor connection because the solder does not replace the flux.

Q10. Stereoscopic-zoom microscopes and precision drill presses are normally associated with what type of repair station?

Q11. Solder used in electronic repair is normally an alloy of what two elements?

Q12. In soldering, what alloy changes directly from a solid state to a liquid state?

Q13. Flux aids in soldering by removing what from surfaces to be soldered?

Q14. What type(s) of flux should never be used on electronic equipment?

SUMMARY

This topic has presented information on the Miniature and Microminiature 2M Repair Program and high-reliability soldering. The information that follows summarizes the important points of this topic.

The **MINIATURE/MICROMINIATURE (2M) REPAIR PROGRAM** provides training, tools and equipment, and certification for 2M repair personnel.

CERTIFICATION of technicians ensures the capability of high-quality, high-reliability repairs.

The three **SM&R** codes for maintenance of electronic devices are**: DEPOT (D)**, **INTERMEDIATE (I)**, and **ORGANIZATIONAL (O)**.

SM&R CODE D MAINTENANCE is characterized by extensive facilities and highly trained personnel. Code D activities are capable of the most complex type repairs.

CODE I activities provide direct support for user activities. This includes calibration, repair, and emergency manufacture of nonavailable parts.

CODE O maintenance is the responsibility of the user activity. It includes preventive maintenance and minor repairs.

ON-LINE TEST EQUIPMENT continuously monitors system performance and isolates faults to removable assemblies.

OFF-LINE TEST EQUIPMENT evaluates removable assemblies outside of the equipment and isolates faults to the component level.

FAULT ISOLATION USING GENERAL-PURPOSE ELECTRONIC TEST EQUIPMENT (GPETE) should only be attempted by experienced technicians.

2M REPAIR STATIONS are equipped according to the level of repairs to be accomplished.

ALLOYS, such as solder, which change directly from a solid state to a liquid are called eutectic alloys.

SOLDER with a tin/lead ratio of 63/37 is preferred for electronic work. A ratio of 60/40 is also acceptable.

ROSIN or **RESIN FLUXES** are the only fluxes to be used in electronic work.

ANSWERS TO QUESTIONS Q1. THROUGH Q14.

A1. Chief of Naval Operations (CNO).

A2. Naval Sea Systems Command (NAVSEASYSCOM) and Naval Air Systems Command (NAVAIRSYSCOM).

A3. Microminiature component repair.

A4. Microminiature repair technician.

A5. Depot, Intermediate, and Organizational.

A6. Organizational.

A7. On-line, off-line, and General Purpose Electronic Test Equipment (GPETE).

A8. On-line.

A9. Off-line.

A10. Microminiature repair station.

A11. Tin and lead.

A12. Eutectic.

A13. Oxides.

A14. Chloride or (acid) and organic.

CHAPTER 3

MINIATURE AND MICROMINIATURE REPAIR PROCEDURES

LEARNING OBJECTIVES

Upon completion of this topic, the student will be able to:

1. Explain the purpose of conformal coatings and the methods used for removal and replacement of these coatings.
2. Explain the methods and practices for the removal and replacement of discrete components on printed circuit boards.
3. Identify types of damage to printed circuit boards, and describe the repair procedures for each type of repair.
4. Describe the removal and replacement of the dual-in-line integrated circuit.
5. Describe the removal and replacement of the TO-5 integrated circuit.
6. Describe the removal and replacement of the flat-pack integrated circuit.
7. Describe the types of damage to which many microelectronic components are susceptible and methods of preventing damage.
8. Explain safety precautions as they relate to 2M repair.

INTRODUCTION

As you progress in your training as a technician, you will find that the skill and knowledge levels required to maintain electronic systems become more demanding. The increased use of miniature and microminiature electronic circuits, circuit complexity, and new manufacturing techniques will make your job more challenging. To maintain and repair equipment effectively, you will have to duplicate with limited facilities what was accomplished in the factory with extensive facilities. Printed circuit boards that were manufactured completely by machine will have to be repaired by hand.

To meet the needs for repairing the full range of electronic equipment, you must be properly trained. You must be capable of performing high-quality, reliable repairs to the latest circuitry.

MINIATURE AND MICROMINIATURE ELECTRONIC REPAIR PROCEDURES

As mentioned at the beginning of topic 2, 2M repair personnel must undergo specialized training. They are trained for a particular level of repair and must be certified at that level. Also, recertification is required to ensure the continued high-quality repair ability of these technicians.

CAUTION

THIS SECTION IS NOT, IN ANY WAY, TO BE USED BY YOU AS AUTHORIZATION TO ATTEMPT THESE TYPES OF REPAIRS WITHOUT OFFICIAL 2M CERTIFICATION.

In the following sections, you will study the general procedures used in the repair, removal, and replacement of specific types of electronic components. By studying these procedures, you will become familiar with some of the more common types of repair work. Before repair work can be performed on a miniature or microminiature assembly, the technician must consider the type of specialized coating that usually covers the assembly. These coatings are referred to as CONFORMAL COATINGS.

CONFORMAL COATINGS

Conformal coatings are protective material applied to electronic assemblies to prevent damage from corrosion, moisture, and stress. These coatings include epoxy, parylene, silicone, polyurethane, varnish, and lacquer. Coatings are applied in a liquid form; when dry, they exhibit characteristics that improve reliability. These characteristics are:

- *Heat conductivity* to carry heat away from components
- *Hardness and strength* to support and protect components
- *Low moisture* absorption
- *Electrical* insulation

Conformal Coating Removal

Because of the characteristics that conformal coatings exhibit, they must be removed before any work can be done on printed circuit boards. The coating must be removed from all lead and pad/eyelet areas of the component. It should also be removed to or below the widest point of the component body. *Complete* removal of the coating from the board is not done.

Methods of coating removal are thermal, mechanical, and chemical. The method of removal depends on the type of coating used. Table 3-1 shows suggested methods of removal of some types. Note that most of the methods are variations of mechanical removal.

Table 3-1.—Conformal Coating Removal Techniques

TYPES CONFORMAL COATING (LISTED IN DESCENDING ORDER OF HARDNESS)	SOLVENT	ROTARY BRISTLE BRUSH	GRIT-IMPREGNATED RUBBER WHEELS AND DISCS	HOT AIR JET AND ORANGEWOOD STICK	THERMAL PARTING TOOI	BALL MILLS, ETC.	CUTTING AND PEELING
PARYLENE			2		1 (F)	3	
EPOXY		3 (C)	4 (C)	1 *(C)	2 *	5 (B&D)	
ACRYLIC LACQUER	1 *(E)	3	4 (C)	2			
POLYURETHANE	5 (A&C)	3 (C)	4 (C)	1 *	2 *		
VARNISH	1 (A&C)	3	4	2 *			
RTV		2 (C)					1 *

* DENOTED METHOD THAT POSITIVELY IDENTIFIES TYPE OF CONFORMAL COATING.
A SPECIFIC TYPES OF COATING COMPOSITIONS ONLY.
B FOR THICK COATINGS ONLY (.025 AND THICKER).
C FOR THIN COATINGS ONLY.
D DO NOT ATTEMPT TO GRIND TO BOARD SURFACE WITH THIS METHOD.
E ORGANIC SOLVENTS ARE BEST.
F USE MODIFIED DRILL BIT FOR TIP (SHAPED TO BEVELED EDGE). CAUTION: USE WITH CARE, APPROXIMATELY 500° NEEDED AT TIP.

NOTE: THE PREFERRED ORDER FOR APPLYING INDIVIDUAL REMOVAL TECHNIQUES TO SPECIFIC COATINGS IS NUMERICALLY INDICATED. THESE REMOVAL TECHNIQUES ARE LISTED IN ASCENDING ORDER OF THEIR DAMAGEABILITY TO THE MODULE UNDER REPAIR. ANY OF THE METHODS LISTED MAY CAUSE DAMAGE IF NOT USED WITH CARE. ALWAYS TRY THE METHOD WHICH CAUSES THE LEAST AMOUNT OF DAMAGE FIRST. CONSIDER THE POSSIBILITY OF HEAT OR VIBRATION SENSITIVITY OF COMPONENTS. (VIBRATION ESPECIALLY WILL AFFECT ALL AREAS OF THE WORKPIECE.)

The coating material can best be identified through proper documentation; for example, technical manuals and engineering drawings. If this information is not available, the experienced technician can usually determine the type of material by testing the hardness, transparency, thickness, and solvent solubility of the coating. The thermal (heat) properties may also be tested to determine the ease of removal of the coating by heat. The methods of removal discussed here describe the basic concept, but not the step-by-step "how to" procedures.

THERMAL REMOVAL.—Thermal removal consists of using controlled heat through specially shaped tips attached to a handpiece. Soldering irons should never be used for coating removal because the high temperatures will cause the coatings to char, possibly damaging the board materials. Modified tips or cutting blades heated by soldering irons also are not used; they may not have proper heat capacity or allow the hand control necessary for effective removal. Also, the thin plating of the circuit may be damaged by scraping.

The thermal parting tool, used with the variable power supply, has interchangeable tips, as shown in figure 3-1, that allow for efficient coating removal. These thin, blade-like instruments act as heat generators and will maintain the heat levels necessary to accomplish the work. Tips can be changed easily to suit the configuration of the workpiece. These tips cool quickly after removal of power because their small thermal mass and special alloy material easily give up residual heat.

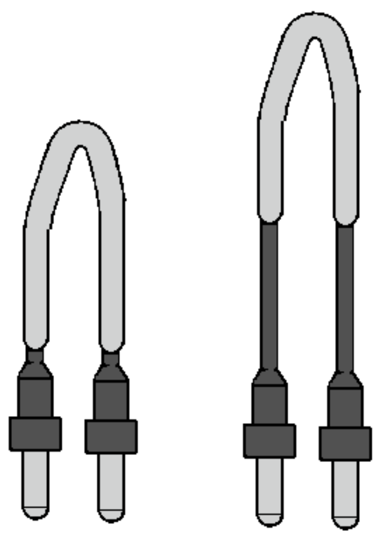

Figure 3-1.—Thermal parting tips.

The softening or breakdown point of different coatings vary, which is a concern when you are using this method. Ideally, the softening point is below the solder melting temperature. However, when the softening point is equal to or above the solder melting point, you must take care in applying heat at the solder joint or in component areas. The work must be performed rapidly to limit the heating of the area involved and to prevent damage to the board and other components.

HOT-AIR JET REMOVAL.—In principle, the hot-air jet method of coating removal uses controlled, temperature-regulated air to soften or break down the coating, as shown in figure 3-2. By controlling the temperature, flow rate, and shape of the jet, you may remove coatings from almost any workpiece configuration without causing any damage. When you use the hot-air jet, you do not allow it to contact the workpiece surface physically. Delicate work, handled in this manner, permits you to observe the removal process.

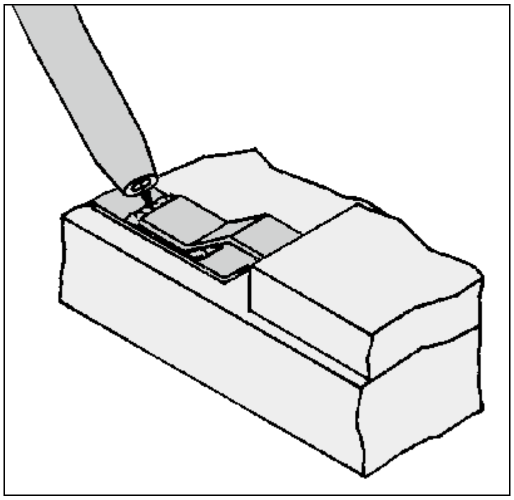

Figure 3-2.—Hot air jet conformal coating removal.

POWER-TOOL REMOVAL DESCRIPTION.—Power-tool removal is the use of abrasive grinding or cutting to remove coatings mechanically. Abrasive grinding/rubbing techniques are effective on thin coatings (less than 0.025 inch) while abrasive cutting methods are effective on coatings greater than 0.025 inch. This method permits consistent and precise removal of coatings without mechanical damage or dangerous heating to electronic components. A variable-speed mechanical drive handpiece permits fingertip-control and proper speed and torque to ease the handling of gum-type coatings. A variety of rotary abrasive materials and cutting tools is required for removal of the various coating types. These specially designed tools include BALL MILLS, BURRS, and ROTARY BRUSHES.

The ball mill design places the most efficient cutting area on the side of the ball, rather than at the end. Different mill sizes are used to enter small areas where thick coatings need to be removed (ROUTED). Rubberized abrasives of the proper grade and grit are ideally suited for removing thin, hard coatings from flat surfaces; soft coatings adhere to and coat the abrasive causing it to become ineffective. Rotary bristle brushes work better than rubberized abrasives on contoured or irregular surfaces, such as soldered connections, because the bristles conform to surface irregularities. Ball mill routing and abrasion removal are shown in figure 3-3.

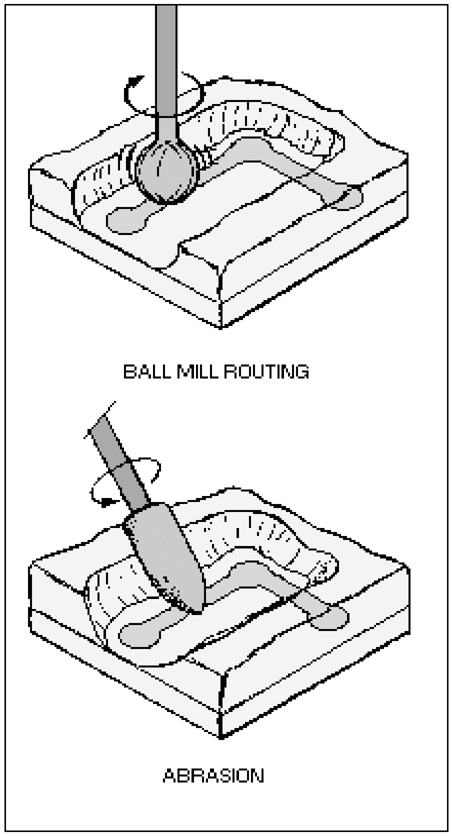

Figure 3-3.—Rotary tool conformal coating removal.

CUT AND PEEL.—Silicone coatings (also referred to as RTV) can easily be removed by cutting and peeling. As with all mechanical removal methods, care must be taken to prevent damage to either components or boards.

CHEMICAL REMOVAL.—Chemical removal uses solvents to break down the coatings. General application is not recommended as the solvent may cause damage to the boards by dissolving the adhesive materials that bond the circuits to the boards. These solvents may also dissolve the POTTING COMPOUNDS (insulating material that completely seals a component or assembly) used on other parts or assemblies. Only thin acrylic coatings (less than 0.025 inch) are readily removable by solvents. Mild solvents, such as ISOPROPYL ALCOHOL, XYLENE, or TRICHLOROETHANE, may be used to remove soluble coatings on a spot basis.

Evaluations show that many tool and technique combinations have proven to be reliable and effective in coating removal; no single method is the best in all situations. When the technician is determining the best method of coating removal to use, the first consideration is the effect that it will have on the equipment.

Conformal Coating Replacement

Once the required repairs have been completed, the conformal coating must be replaced. To ensure the same protective characteristics, you should use the same type of replacement coating as that removed.

Conformal coating application techniques vary widely. These techniques depend on material type, required thickness of application, and the effect of environmental conditions on curing. These procedures cannot be effectively discussed here.

Q1. What material is applied to electronic assemblies to prevent damage from corrosion, moisture, and stress?

Q2. What three methods are used to remove protective material?

Q3. What chemicals are used to remove protective material?

Q4. Abrasion, cutting, and peeling are examples of what type of protective material removal?

Q5. Why should the coating material be replaced once the required repair has been completed?

REMOVAL AND REPLACEMENT OF DISCRETE COMPONENTS

To perform the required repair properly, the 2M technician must be knowledgeable of the techniques used by manufacturers in the production of electronic assemblies. The techniques, materials, and types of components determine the repair procedures used.

Interconnections and Assemblies

Assemblies may range from simple, single-sided boards with standard-sized components to double-sided or multilayered boards with miniature and microminiature components. The variations in component lead termination and mounting techniques used by manufacturers present the technician with a complex task. For example, the 2M technician is concerned about the type of solder joints on the module. To determine the solder joint type, the technician must consider the board circuitry, hole reinforcement, and lead termination style.

Recall the discussion from topic 1 on printed circuit board construction and the types of interconnections used. Single-sided and some double-sided boards have UNSUPPORTED HOLES where component leads are soldered to the pad. The clearance-hole method is also an interconnection with no hole support. SUPPORTED HOLES are those that have metallic reinforcement along the hole walls.

In addition to the plated-through hole you studied earlier, EYELETS, shown in figure 3-4, view (A), view (B), and view (C), are also used in both manufacturing and repair. These hole-reinforcing devices are usually made of pure copper, but are often plated with gold, tin, or a tin-lead alloy. The copper-based eyelet is pliable; when set, it reduces the possibility of circuit board damage. Eyelets may be inserted into single-sided or double-sided boards and are of three different types - ROLL SET, FUNNEL SET, and FLAT SET. All three are types referred to as INTERFACIAL CONNECTIONS. Interfacial connections identify the procedure of connecting circuitry on one side of a board with the circuitry on the other side.

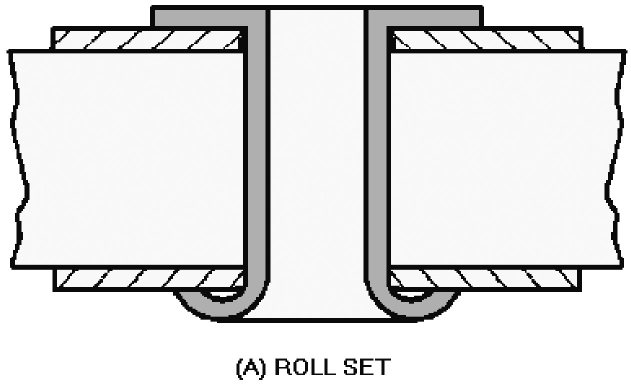

Figure 3-4A.—Eyelets (interfacial connections). ROLL SET

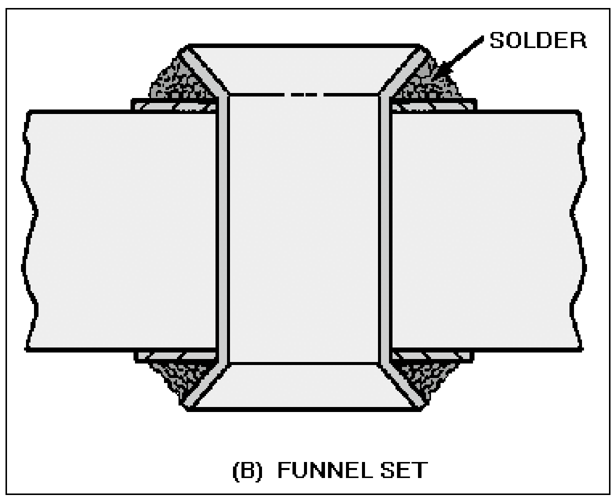

Figure 3-4B.—Eyelets (interfacial connections). FUNNEL SET

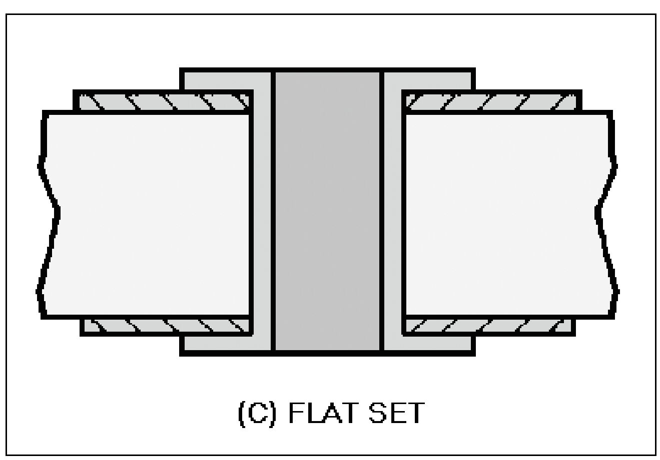

Figure 3-4C.—Eyelets (interfacial connections). FLAT SET

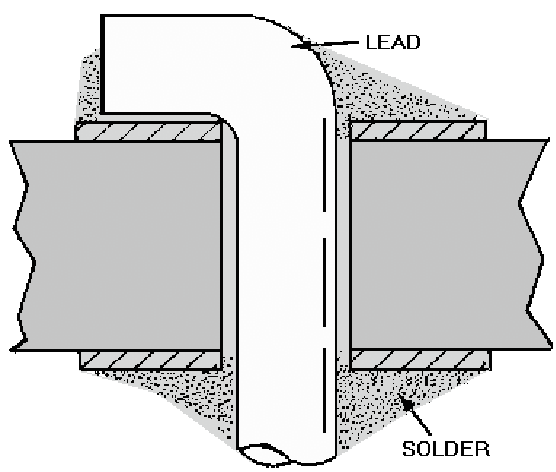
As you can see, the flat-set eyelet actually provides reinforcement for the pads on both sides of the circuit board and reinforces the hole itself. The design of the roll-set eyelet (which may trap gasses, flux, or other contaminants, and obscures view of the finished solder flow) is not acceptable as a repair technique. The funnel-set eyelet does not provide as much pad reinforcement as the other types. However, it provides better "outgassing" of flux, moisture, or solvents from the space between the eyelet and the hole wall. It also provides a better view of the finished solder connection than the roll-set eyelet.

Lead Terminations

The finished circuit board consists of conductive paths, pads, and drilled holes with components and/or wires assembled directly to it. Leads and wires may terminate in three ways: (1) through the hole in the board, (2) above the surface of the board, or (3) on the surface of the board.

THROUGH-HOLE TERMINATION.—This style provides extra support for the circuit pads, the hole, and the lead by a continuous solder connection from one side of the circuit board to the other. Three basic variations of through-hole termination are the CLINCHED LEAD (two types), STRAIGHT-THROUGH LEAD, and OFFSET PAD.

Clinched Lead.—The clinched-lead termination is usually used with unsupported holes, but is found with supported holes as well. Both clinched-lead types, FULLY CLINCHED and SEMICLINCHED (figure 3-5), provide component stability. Like the fully clinched lead, the semi-clinched lead also provides stability during assembly. However, this termination can be easily straightened to allow removal of the solder joint should rework or repair be required. Note that the fully clinched lead is bent 90 degrees while the semiclinched lead is bent 45 degrees.



(A) FULLY CLINCHED

Figure 3-5A.—Clinched leads. FULLY CLINCHED.

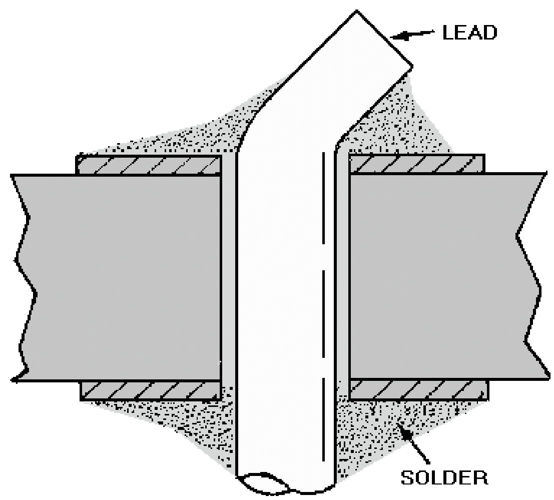


Figure 3-5B.—Clinched leads. SEMICLINCHED

Straight-Through Lead.—Straight-through terminations (figure 3-6) are used by manufacturers when the termination stability is not a prime consideration. This termination type may also be used with unsupported holes. The through-hole termination provides a better, solder-joint contact area and more solder support; the solder runs from the component side to the conductor. The straight-through termination is the easiest to remove and rework.

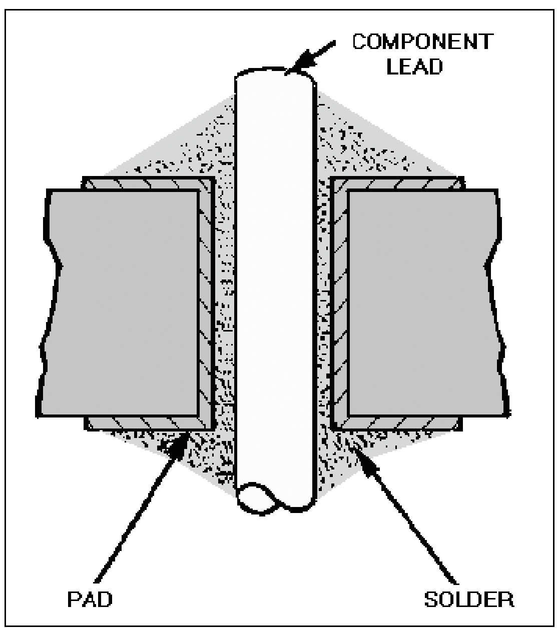

Figure 3-6.—Straight-through termination.

The Offset-Pad Termination.—This termination, shown in view (A) of figure 3-7, is a variation of clinch-lead termination. The pad is set off from the centerline of the hole. The lead clinch is also offset from the hole centerline so that it may contact the pad [view (B)].

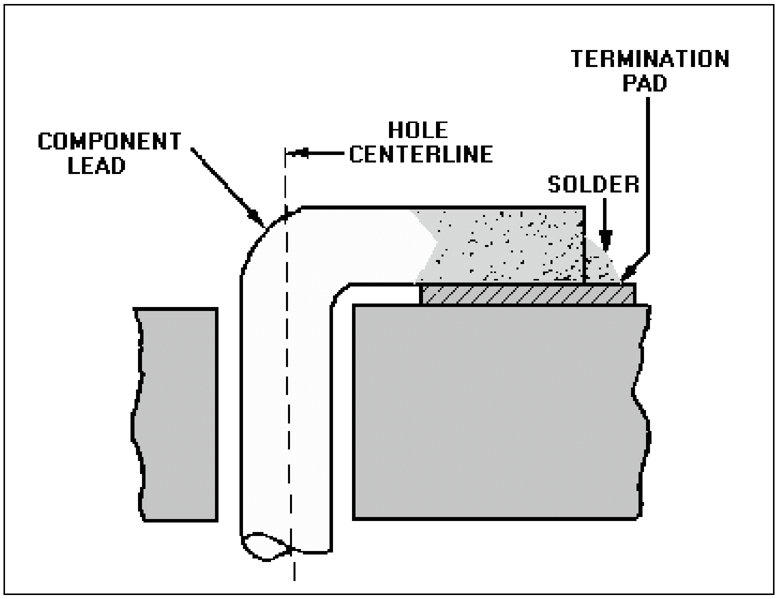

Figure 3-7A.—Offset pad termination SIDE VIEW.

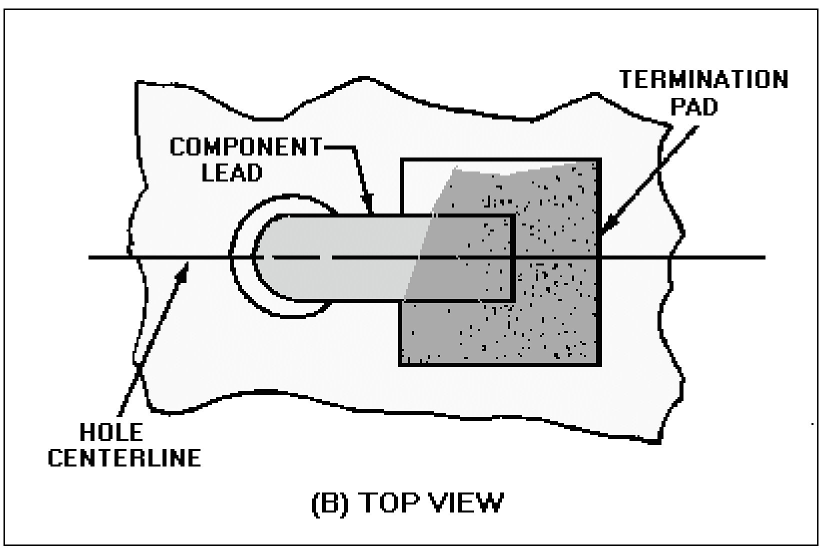

Figure 3-7B.—Offset pad termination TOP VIEW

ABOVE-THE-BOARD TERMINATION.—Above-the-board termination is accomplished through the use of terminals or posts. Terminals are used for a variety of reasons. The type of terminal depends on its use. Although many configurations are used, all terminals fall into one of the five categories covered in this section [figure 3-8, views (A) through (E)].

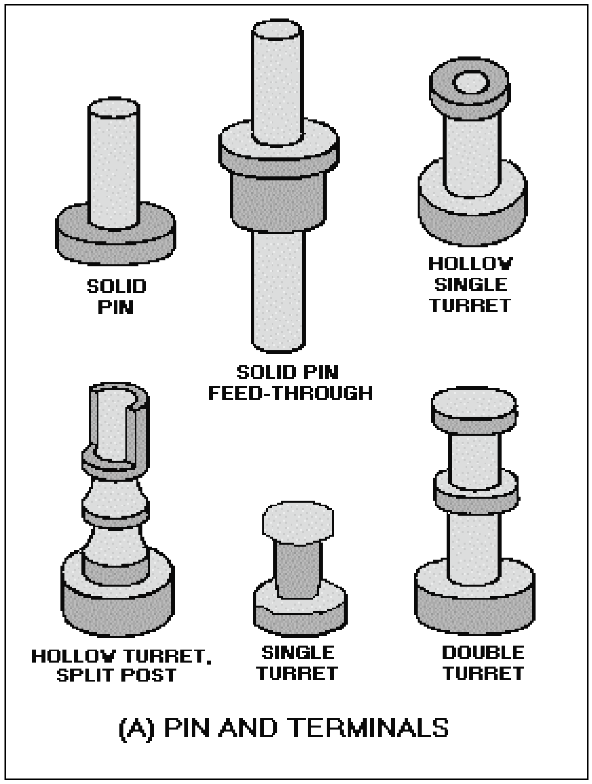

Figure 3-8A.—Terminals. PIN AND TERMINALS.

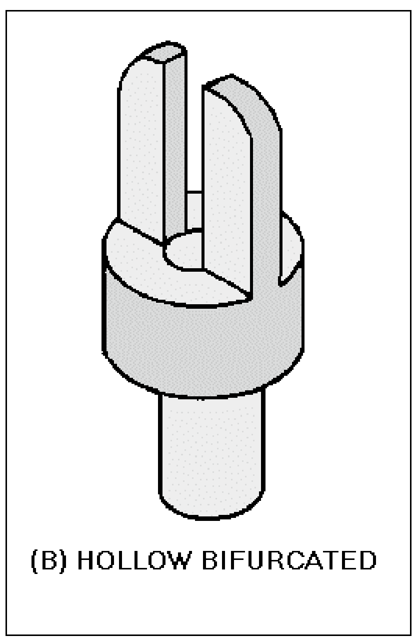

Figure 3-8B.—Terminals. HOLLOW.

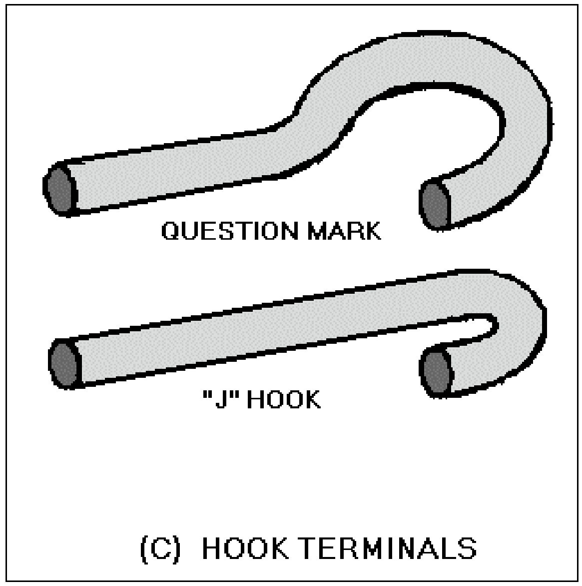

Figure 3-8C.—Terminals. HOOK TERMINALS.

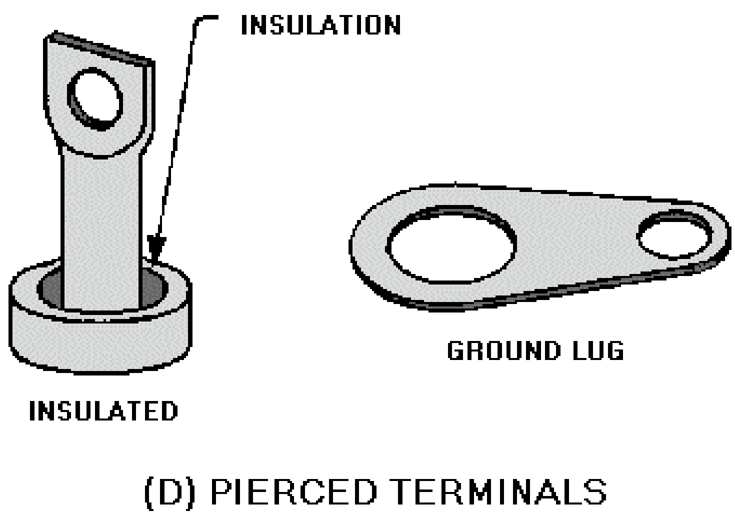

Figure 3-8D.—Terminals. PIERCED TERMINALS.

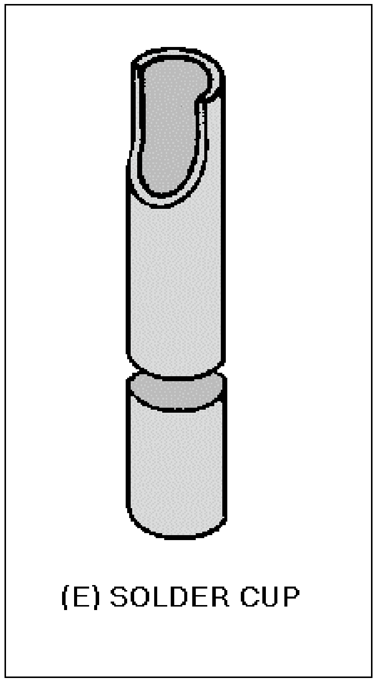

Figure 3-8E.—Terminals. SOLDER CUP

- PIN TERMINALS AND TURRET TERMINALS [view (A)] are single-post terminals, either insulated or uninsulated, solid or hollow, stud or feed-through. Stud terminals protrude from one side of a board; feed-throughs protrude from both sides.
- BIFURCATED OR FORK TERMINALS [view (B)] are solid or hollow double-post terminals.
- HOOK TERMINALS [view (C)] are made of cylindrical stock formed in the shape of a hook or question mark.
- PERFORATED OR PIERCED TERMINALS [view (D)] describe a class of terminals that uses a hole pierced in flat metal for termination (e.g., terminal lugs).
- SOLDER CUP TERMINALS [view (E)] are a common type found on connectors.

Turret and bifurcated terminals are used for interfacial connections on printed circuit boards, terminal points for point-to-point wiring, mounting components, and as tie points for interconnecting wiring. Hook terminals are used to provide connection points on sealed devices and terminal boards.

Terminals, used for wire or component lead terminations, are normally made of brass with a solderable coating. Uninsulated terminals may be installed on an insulating substrate to form a terminal board. They may also be added to a printed circuit board or installed on a metal chassis. Insulated terminals are installed on a metal chassis.

ON-THE-BOARD TERMINATION.—On-the-board termination (figure 3-9) is also called LAP FLOW termination. In a lap flow solder termination, the component lead does not pass through the circuit board. This form of planar mounting may be used with both round and flat leads.

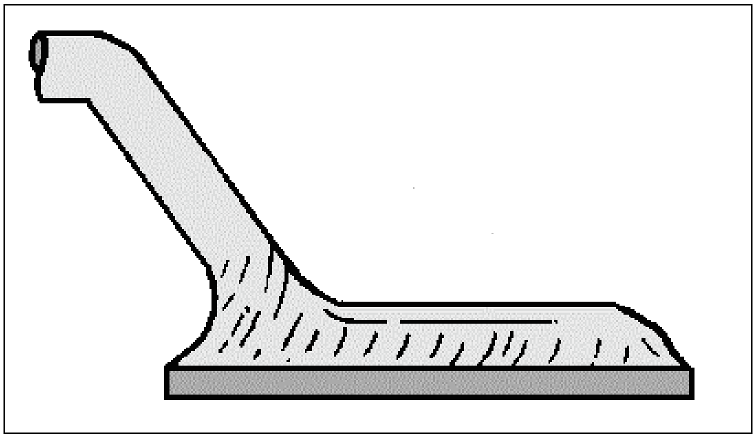

Figure 3-9.—On-the-board termination.

Q6. What term is used to identify the procedure of connecting one side of a circuit board with the other?

Q7. Name two types of through-hole termination.

Q8. Turret, bifurcated, and hook terminals are used for what type of termination?

Q9. When a lead is soldered to a pad without passing through the board, it is known as what type of termination?

Component Desoldering

Most of the damage in printed circuit board repair occurs during disassembly or component removal. More specifically, much of this damage occurs during the desoldering process. To remove components for repair or replacement, the technician must first determine the type of joint that is used to connect the component to the board. The technician may then determine the most effective method for desoldering these connections.

Three generally accepted methods of solder connection removal involve the use of SOLDER WICK, a MANUALLY CONTROLLED VACUUM PLUNGER, or a motorized solder extractor using CONTINUOUS VACUUM AND/OR PRESSURE. Of all the extraction methods currently in use, continuous vacuum is the most versatile and reliable. Desoldering becomes a routine operation and the quantity and quality of desoldering work increases with the use of this technique.

SOLDER WICKING.—In this technique, finely stranded copper wire or braiding (wick) is saturated with liquid flux. Most commercial wick is impregnated with flux; the liquid flux adds to the effectiveness of the heat transfer and should be used whenever possible. The wick is then applied to a solder joint between the solder and a heated soldering iron tip, as shown in figure 3-10. The combination of heat, molten solder, and air spaced in the wick creates a capillary action and causes the solder to be drawn into the wick.

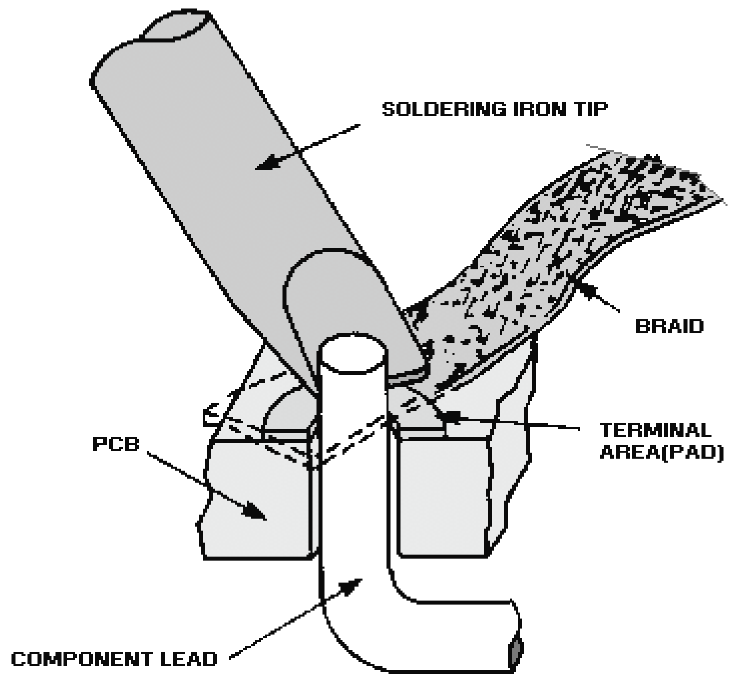

Figure 3-10.—Solder wicking.

This method should be used to remove surface joints only, such as those found on single-sided and double-sided boards without plated-through holes or eyelets. It can also remove excessive solder from flat surfaces and terminals. The reason is that the capillary action of the wicking is not strong enough to overcome the surface tension of the molten solder or the capillary action of the hole.

MANUALLY CONTROLLED VACUUM PLUNGER.—The second method of removing solder involves a manually controlled and operated, one-shot vacuum source. This vacuum source uses a plunger mechanism with a heat resistant orifice. The vacuum is applied through this orifice. Figure 3-11 shows the latest approved, manual-type desoldering tool. This technique involves melting the solder joint and inserting the solder-extractor tip into the molten solder over the soldering iron tip. The plunger is then released, creating a short pulse of vacuum to remove the molten solder. Although this method offers a positive vacuum, rather than the capillary force of the wicking method, it still has limited application. This method will not remove 100 percent of the solder and may cause circuit pad lifting because of the extremely high vacuum generated and the jarring caused by the plunger action.

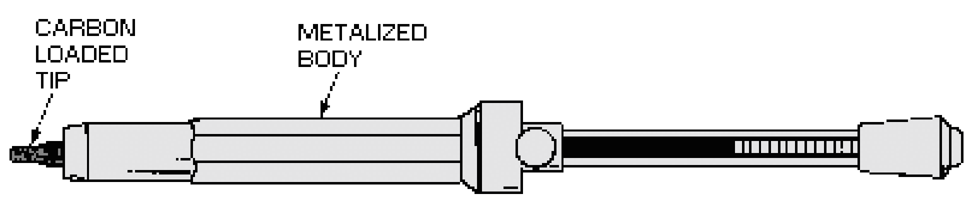

Figure 3-11.—Manual desoldering tool.

Because 100 percent of the solder cannot be removed, the extraction method is not usually successful with the plated-through solder joint. The component lead in a plated-through hole joint usually rests against the side wall of the hole. Even though most of the molten solder is removed by a vacuum, the small amount of solder left between the lead and side walls causes a SWEAT JOINT to form. A sweat joint is a paper-thin solder joint formed by a minute amount of solder remaining on the conductor lead surfaces.

MOTORIZED VACUUM/PRESSURE METHOD.—The most effective method for solder joint removal is motorized vacuum extraction. The solder extractor unit, described in topic 2, is used for this type of extraction. This method provides controlled combinations of heat and pressure or vacuum for solder removal. The motorized vacuum is controlled by a foot switch and differs from the manual vacuum in that it provides a continuous vacuum. The solder extraction device is a coaxial, in-line instrument similar to a small soldering iron. The device consists of a hollow-tipped heating element, transfer tube, and collecting chamber (in the handle) that collects and solidifies the waste solder. This unit is easily maneuvered, fully controllable, and provides three modes of operation (figure 3-12): (1) heat and vacuum (2) heat and pressure, and (3) hot-air jet. Some power source models provide variable control for pressure and vacuum levels as well as temperature control for the heated tubular tip. The extraction tip and heat source are combined in one tool. Continuous vacuum allows solder removal with a single heat application. Since the slim heating element allows access to confined areas, the technician is protected from contact with the hot, glass, solder-trap chamber. Continuous vacuum extraction is the only consistent method for overcoming the resweat problem for either dual or multilead devices terminating in through-hole solder joints.

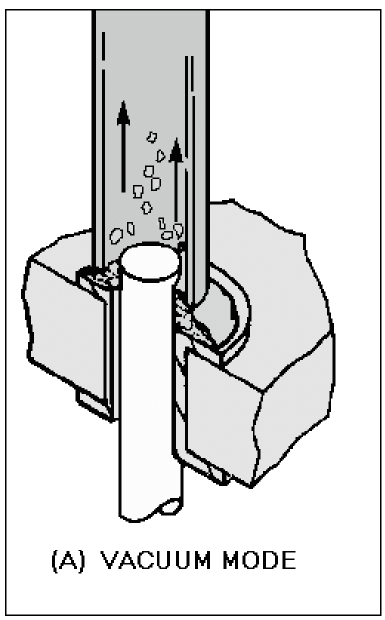

Figure 3-12A.—Motorized vacuum/pressure solder removal. VACUUM MODE.

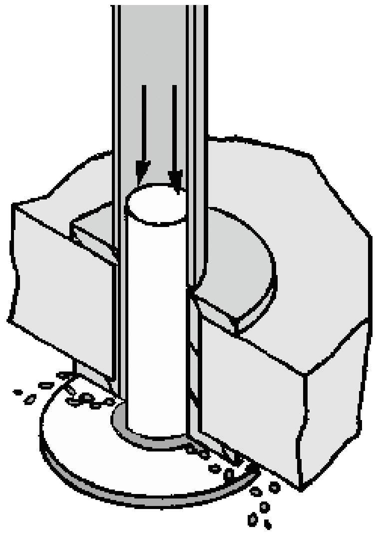

Figure 3-12B.—Motorized vacuum/pressure solder removal. PRESSURE MODE.

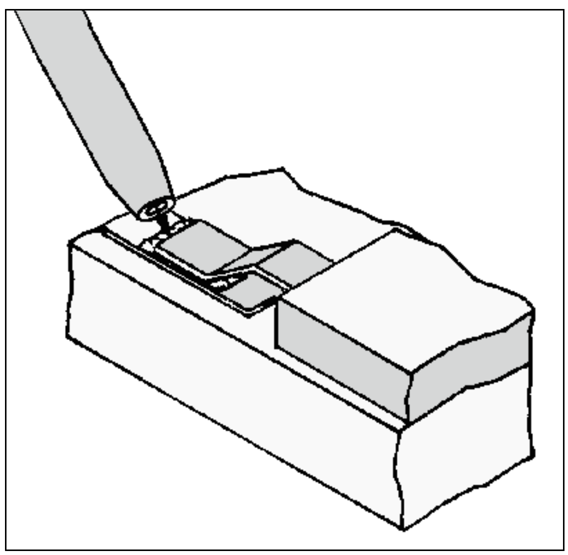

Figure 3-12C.—Motorized vacuum/pressure solder removal. HOT AIR JET MODE.

Motorized Vacuum Method.—In the motorized vacuum method, the heated tip is applied to the solder joint. When melted solder is observed, the vacuum is activated by the technician causing the solder to be withdrawn from the joint and deposited into the chamber. If the lead is preclipped, it may also be drawn into a holding chamber. To prevent SWEATING (reforming a solder joint) to the side walls of the plated-through hole joint, the lead is "stirred" with the tip while applying the vacuum. This permits cool air to flow into and around the lead and side walls causing them to cool.

Motorized Pressure Method.—In the pressure method, the tip is used to apply heat to a pin for melting a sweat joint. The air pressure is forced through the hole to melt sweat joints without contacting the delicate pad. This method is seldom used because it is not effective in preventing sweating of the lead to the hole nor for cooling the workpiece.

Hot-Air Jet Method.—The hot-air jet method uses pressure-controlled, heated air to transfer heat to the solder joint without physical contact from a solder iron. This permits the reflow of delicate joints while minimizing mechanical damage.

When the solder is removed from the lead and pad area, the technician can observe the actual condition of the lead contact to the pad area and the amount of the remaining solder joint. From these observed conditions, the technician can then determine a method of removing the component and lead.

With straight-through terminations, the component and lead may be lifted gently from uncoated boards with pliers or tweezers. Working with clinched leads on uncoated boards requires that all sweat joints be removed and that the leads be unclinched before removal.

The techniques that have been described represent the successful methods of desoldering components. As mentioned at the beginning of this section, the 2M technician must decide which method is best suited for the type of solder joint. Two commonly used but unacceptable methods of solder removal are heat-and-shake and heat-and-pull methods.

In the heat-and-shake method, the solder joint is melted and then the molten solder is shaken from the connection. In some cases, the shaking action may include striking the assembly against a surface to shake the molten solder out of the joint. This method should NEVER be used because all the solder may not be removed and the solder may splatter over other areas of the board. In addition, striking the board against a surface can lead to broken boards, damaged components, and lifted pads or conductors.

The heat-and-pull method uses a soldering iron or gang-heater blocks to melt individual or multiple solder joints. The component leads are pulled when the solder is melted. This method has many shortcomings because of potential damage and should NOT be attempted. Heating blocks are patterned to suit specific configurations; but when used on multiple-lead connections, the joints may not be uniformly heated. Uneven heating results in plated-through hole damage, pad delamination, or blistering. Damage can also result when lead terminations are pulled through the board.

When desoldering is complete, the workpiece must undergo a careful physical inspection for damage to the circuit board and the remaining components. The technician should also check the board for scorching or charring caused by component failure. Sometimes MEASLING is present. Measling is the appearance of light-colored spots. It is caused by small areas of fiberglass strands that have been damaged by epoxy overcuring, heat, abrasion, or internal moisture. No cracks or breaks should be visible in the board material. None of the remaining components should be cracked, broken, or show signs of overheating. The solder joints should be of good quality and not covered by loose or splattered solder, which may cause shorts. The technician should examine the board for nicked, cracked, lifted, or delaminated conductors and lifted or delaminated pads.

Q10. When does most printed circuit board damage occur?

Q11. What procedure involves the use of finely braided copper wire to remove solder?

Q12. What is the most effective method of solder removal?

Q13. When, if at all, should the heat-and-shake or the heat-and-pull methods of solder removal be used?

INSTALLATION AND SOLDERING OF PRINTED CIRCUIT COMPONENTS

The 2M technician should restore the electronic assembly at least to the original manufacturer's standards. Parts should always be remounted or reassembled in the same position and with termination methods used by the original manufacturer. This approach ensures a continuation of the original reliability of the system.

High reliability connections require thoroughly cleaned surfaces, proper component lead formation and termination, and appropriate placement of components on the board. The following paragraphs describe the procedures for properly installing components on a board including the soldering of these components.

Termination Area Preparation

The termination areas on the board and the component leads are thoroughly cleaned to remove oxide, old solder, and other contaminants. Old or excess solder is removed by one of the desoldering techniques explained earlier in this topic. A fine abrasive, such as an oil-free typewriter eraser, is used to remove oxides. This is not necessary if the area has just been desoldered. All areas to be soldered are cleaned with a solvent and then dried with a lint-free tissue to remove cleaning residue.

Component Lead Preparation

Component leads are formed before installation. Both machine- and hand-forming methods are used to form the leads. Improper lead formation causes many repairs to be unacceptable. Damage to the SEALS (point where lead enters the body of the component) occurs easily during the forming process and results in component failure. Consequently, lead-forming procedures have been established. To control the lead-forming operation and ensure conformity and quality of repairs, the technician should ensure the following:

1. The component is centered between the holes, and component leads are formed with proper bend-radii and body seal-to-bend distance.
2. The possibility of straining component body seals during lead forming is eliminated.
3. Stress relief loops are formed without straining component seals while at the same time providing the desired lead-to-lead distances.
4. Leads are measured and formed for both horizontal and vertical component mounting.
5. Transistor leads are formed to suit standard hole spacing.

Lead-Forming Specifications

Component leads are formed to provide proper lead spacing.

- The minimum distance between the seal (where the lead enters the body of the component) and the start of the lead bend must be no less than twice the diameter of the lead, as shown in figure 3-13.

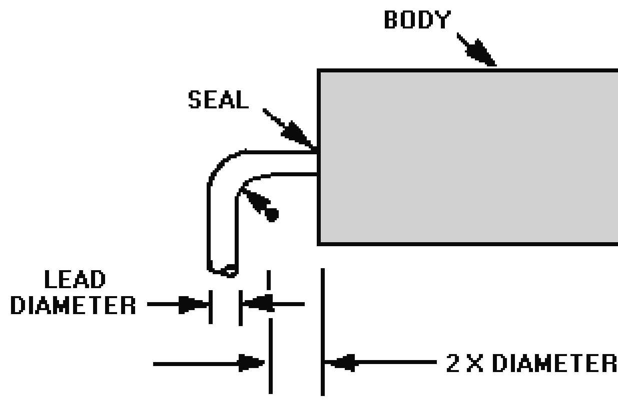

Figure 3-13.—Minimum distance lead bend to component body.

- Leads must be approximately 90 degrees from their major axis to ensure free movement in hole terminations, as shown in figure 3-14.

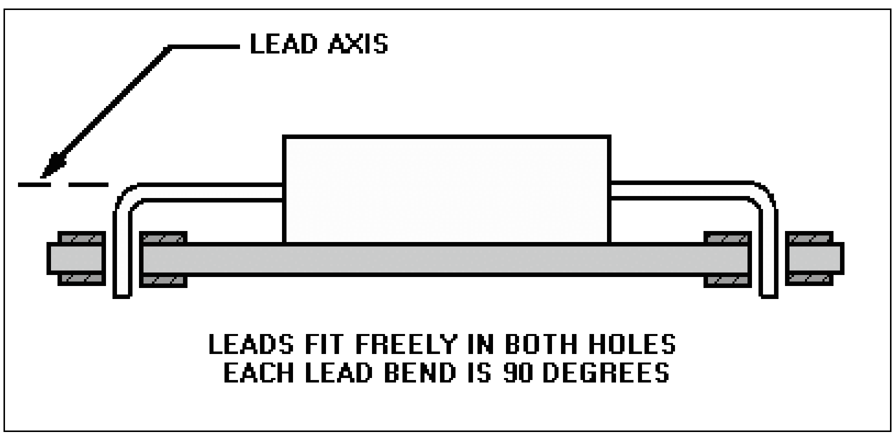

Figure 3-14.—Ideal lead formation.

- In lead-forming, the lead must not be damaged by nicking.

- Energy from the bending action must not be transmitted into the component body.

COMPONENT PLACEMENT.—Where possible, parts are remounted or reassembled as they were in the original manufacturing process. To aid recognition, manufacturers use a coding system of colored dots, bands, letters, numbers, and signs. Replacement components are mounted to make all identification markings readable without disturbing the component. When components are mounted like the original, all the identification markings are readable from a single point.

Component identification reads uniformly from left to right, top to bottom, unless polarity requirements determine otherwise, as shown in figure 3-15. To locate the top, position the board so the part number may be read like a page in a book. By definition, the top of the board is the edge above the part number.

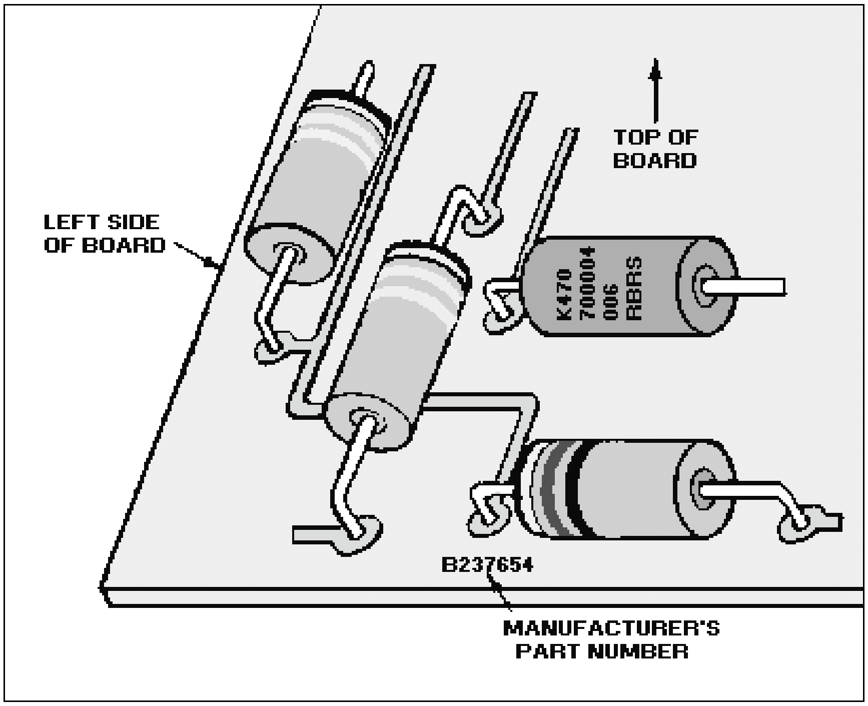

Figure 3-15.—Component arrangement.

When possible, component identification markings should be visible after installation. If you must choose between identification and electrical value markings, the priority of selection is as follows: (1) electrical value, (2) reliability level, and (3) part number.

Components are normally mounted parallel to and on the side opposite the printed circuitry and in contact with the board.

FORMATION OF PROPER LEAD TERMINATION.—After component leads are formed and inserted into the board, the proper lead length and termination are made before the lead is soldered. Generally, if the original manufacturer clinched (either full or semi) the component leads, the replacement part is reinstalled with clinched leads.

When clinching is required, leads on single- and double-sided boards are securely clinched in the direction of the printed wiring connected to the pad. Clinching is performed with tools that prevent damage to the pad or printed wiring. The lead is clinched in the direction of the conductor by bending the lead. The leads are clipped so that their minimum clinched length is equal to the radius of the pad. Under no circumstances does the clinched lead extend beyond the pad diameter. Natural springback away from the pad or printed wiring is acceptable. A gap between the lead end and the pad or printed wiring is acceptable when further clinching endangers the pad or printed wiring. These guidelines ensure uniform lead length.

Q14. To what standards should a technician restore electronic assemblies?

Q15. How is oxide removed from pads and component leads?

Q16. Leads are formed approximately how many degrees from their major axis?

Q17. When you replace components, identification marks must meet what requirements?

Q18. In what direction are component leads clinched on single- and double-sided boards?

Soldering of PCB Components

The fundamental principles of solder application must be understood and observed to ensure consistent and satisfactory results. As discussed in topic 2, the soldering process involves a metal-solvent action that joins two metals by dissolving a small amount of the metals at their point of contact.

SOLDERABILITY.—As the solder interacts with the base metals, a good metallurgical bond is obtained and metallic continuity is established. This continuity is good for electrical and heat conductivity as well as for strength. Solderability measures the ease with which molten solder wets the surfaces of the metals being joined. WETTING means the molten solder leaves a continuous permanent film on the metal surface. Wetting can only be done properly on a clean surface. All dirt and grease must be removed and no oxide layer must exist on the metal surface. Using abrasives and/or flux to remove these contaminants produces highly solderable surfaces.

HEAT SOURCE.—The soldering process requires sufficient heat to produce alloy- or metal-solvent action. Heat sources include CONDUCTIVE, RESISTIVE, CONVECTIVE, and RADIANT types. The type of heat source most commonly used is the conductive-type soldering iron. Delicate electronic assemblies require that the thermal characteristics of a soldering iron be carefully balanced and that the iron and tip be properly matched to the job. Successful soldering depends on the combination of the iron tip temperature, the capacity of the iron to sustain temperature, the time of iron contact with the joint, and the relative mass and heat transfer characteristics of the object being soldered.

SELECTION OF PROPER TIP.—The amount of heat and how it is controlled are critical factors to the soldering process. The tip of the soldering iron transfers heat from the iron to the work. The shape and size of the tip are mainly determined by the type of work to be performed. The tip size and the wattage of the element must be capable of rapidly heating the mass to the melting temperature of solder.

After the proper tip is selected and attached to the iron, the operator may control the heat by using the variable-voltage control. The most efficient soldering temperature is approximately 550 degrees Fahrenheit. Ideally, the joint should be brought to this temperature rapidly and held there for a short period of time. In most cases the soldering action should be completed within 2 or 3 seconds. When soldering a small-mass connection, control the heat by decreasing the size of the tip.

Before heat is applied to solder the joint, a thermal shunt is attached to sensitive component leads (diodes, transistors, and ICs). A thermal shunt is used to conduct heat away from the component. Because of its large heat content and high thermal conductivity, copper is usually used to make thermal shunts. Aluminum also has good conductivity but a smaller heat content; it is also used to conduct heat, especially if damage from the physical weight of the clamp is possible. Many types, shapes, and sizes of thermal shunts are available. The most commonly used is the clamp design; this is a spring clip (similar to an alligator clip) that easily fastens onto the part lead, as shown in figure 3-16.

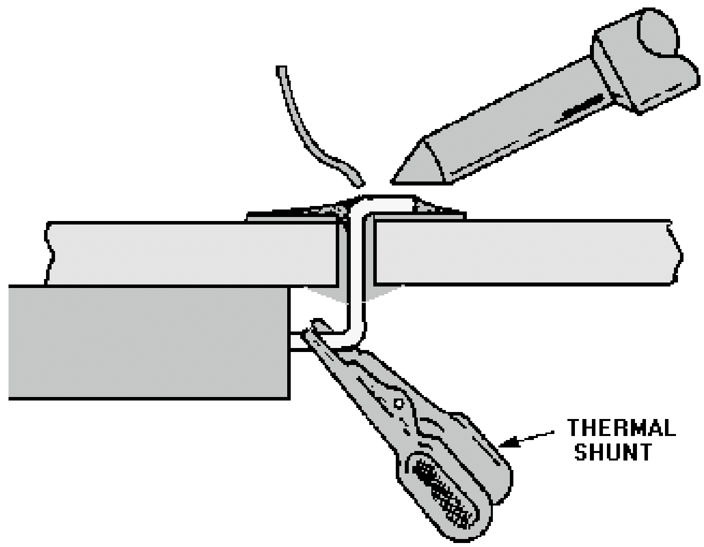

Figure 3-16.—Thermal shunt.

APPLICATION OF SOLDER AND SOLDERING IRON TIP.—Before solder is applied to the joint, the surface temperature of the parts being soldered is increased above the solder melting point. In general, the soldering iron is applied to the point of greatest mass at the connection. This increases the heat in the parts to be soldered. Solder is then applied to a clean, fluxed, and properly heated surface. When properly applied, the solder melts and flows without direct contact with the heat source and provides a smooth, even surface that feathers to a thin edge.

Molten solder forms between the tip and the joint, creating a heat bridge or thermal linkage. This heat bridge causes the tip to become part of the joint and allows rapid heat transfer. A solder (heat) bridge is formed by melting a small amount of solder at the junction of the tip and the mass being soldered as the iron is applied. After the tip makes contact with the lead and the pad and after the heat bridge is established, the solder is applied with a wiping motion to form the solder bond. The completed solder joint should be bright and shiny in appearance. It should have no cracks or pits, and the solder should cover the pad. Examples of preferred solder joints are shown in figure 3-17. They are referred to as full fillet joints.

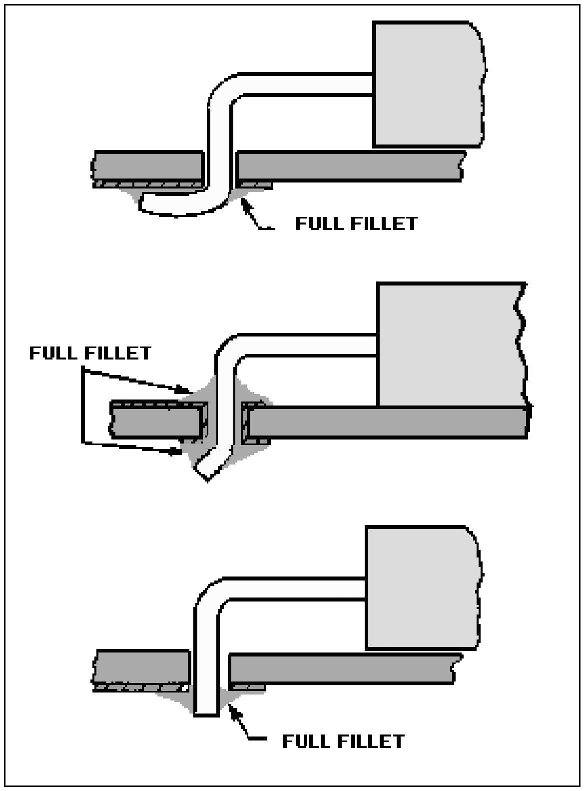

Figure 3-17.—Preferred solder joint.

When a solder joint is completed, solvent must be used to remove all flux residue. The two most highly recommended solvents, in the order of their effectiveness, are 99.5 percent pure ethyl alcohol and 99.5 percent pure isopropyl alcohol.

Q19. What is solderability?

Q20. What is the most common source of heat in electronic soldering?

Q21. What determines the shape and size of a soldering iron tip?

Q22. What term describes a device used to conduct heat away from a component?

Q23. What is the appearance of a properly soldered joint?

REMOVAL AND REPLACEMENT OF DIPS

In topic 1 you learned the advantages of DIPs. They are easily inserted by hand or machine and require no special spreaders, spacers, insulators, or lead-forming tools. Standard hand tools and soldering equipment can be used to remove and replace DIPS.

DIPs may be mounted on a board in two ways: (1) They may be mounted by plugging them into DIP mounting sockets that are soldered to the printed circuit boards or (2) they are soldered in place and may or may not be conformally coated. Although plug-ins are very easy to service, they lack the reliability of soldered-in units, do not meet MILSPECS, and are seldom used in military designed equipment. They are susceptible to loosening because of vibration and to poor electrical contact because of dust and dirt and corrosion.

Removal of Plug-In DIPs

To remove plug-in DIPs, use an approved DIP puller, such as the one shown in figure 3-18. The puller shown is a plastic device that slips over the ends of the DIP and lifts the DIP evenly out of the socket. Before the DIP is removed, the board is marked or a sketch is made of the DIP reference mark location; then the reference mark for the replacement part will be in the proper position. The DIP is grasped with the puller and gently lifted straight out of the socket. Lifting one side or one end first results in bent leads. If the removed DIP is to be placed back in the circuit, particular care is taken in straightening bent leads to prevent breaking. To straighten bent leads, the technician grasps the wide portion of the lead with one pair of smooth-jaw needle nose pliers; with another pair, the technician then bends the lead into alignment with the other leads. Tools, used for lead straightening, should be cleaned with solvent to remove contaminants.

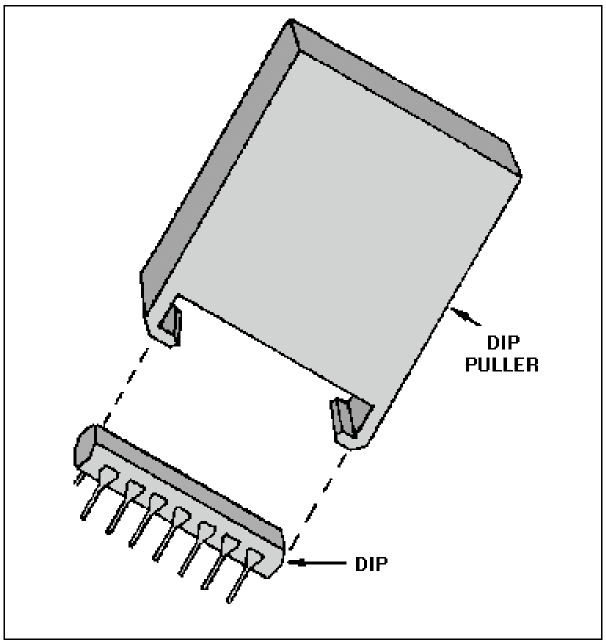

Figure 3-18.—Typical DIP puller.

To replace a plug-in DIP, the technician should clean the leads with solvent and then check the proper positioning of the reference mark. To do this, the technician holds the DIP body between the thumb and forefinger and places the part on the socket to check pin alignment. *The pins are not touched*. If all pins are properly aligned, the technician presses the part gently into the socket until the part is firmly seated. As pressure is applied, each pin is checked to ensure that all pins are going into the socket. If pins tend to bend, the part is removed and the pins are straightened. The socket is then inspected to make sure the holes are not obstructed. Then the process is repeated. After a thorough visual inspection, the card should be ready for testing.

Removal and Replacement of Soldered-In DIPs

The removal of soldered-in DIPs without conformal coatings is essentially the same as the removal of discrete components, except that a skipping pattern is always used. A skipping pattern is one that skips from pad to pad, never heating two pads next to each other. This reduces heat accumulation and reduces the chance of damage to the board. Of course, many more leads should be desoldered before the part can be removed. Special care must be exercised to make sure all leads are completely free before an attempt is made to lift the part off the board. If the part is known to be faulty or if normal removal may damage the board, then the leads should be clipped. Once this has been done, desoldering can be done from both sides of the board. After the clipped leads have been desoldered, they can be removed with tweezers or pliers.

The removal of DIPs from boards with conformal coatings should be completed in the same manner as for other components. The coating should be removed using the preferred method of removal for that particular type of material. The coating should be removed from both sides of the board after masking off the work area. Particular care should be taken when removing the material from around the delicate leads. If the part is to be reused, as much of the coating should be removed from the leads as possible. As with DIPs without conformal coatings, if the part is known to be bad or if the possibility of board damage exists, the leads are clipped; the part and leads are then removed as described earlier in this section. Once the part has been removed, the work area should be completely cleaned to remove any remaining coating or solder.

The steps for replacing a soldered-in DIP are similar to those for replacing a plug-in DIP. Once the part is in position, it is soldered using the same standard used by the manufacturer, or as close to that standard as is possible with the available equipment. The joints should be soldered as quickly as possible using only as much heat as is necessary using a skipping pattern. The repaired card should then be visually inspected for defects in workmanship, and testing of the card should take place. Once the successful repair has been accomplished, a conformal coating should be applied to the work area.

REMOVAL AND REPLACEMENT OF TO PACKAGES

You should recall from chapter 1 of this module, that TO packages are mounted in two ways—plugged-in or embedded. The term *plug-in,* when referring to TOs, should not be confused with DIP plug-ins. TOs are normally soldered in place. You will come across sockets for TOs, but not as frequently as for DIPs. Figure 3-19 shows the methods of mounting TOs. Notice that plug-ins may either be mounted flush with the board surface or above the surface with or without a spacer. The air gap or spacer may be used by the manufacturer for a particular purpose. This type of mounting could be used for heat dissipation, short circuit protection, or to limit parasitic interaction between components. The spacer also provides additional physical support for the TO. The technician is responsible for using the same procedure as the manufacturer to replace TOs or any other components.

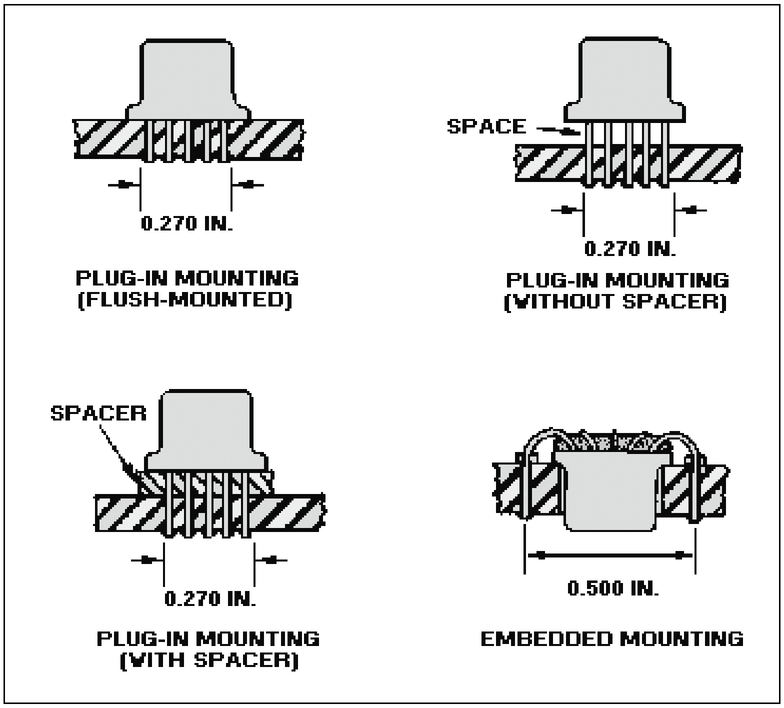

Figure 3-19.—TO mounting techniques.

The procedure for removal of plug-in TOs (with or without conformal coatings) is the same as that used for a similarly mounted DIP or discrete component. The conformal coating is removed if required. Leads are desoldered and gently lifted out of the board. Then board terminals and component leads are cleaned.

In some plug-ins, the leads must be formed before they are placed in a circuit. Care should be taken to ensure that seal damage does not occur and that formed leads do not touch the TO case. This would result in a short-circuit.

When the new part or the one that was removed is installed, the leads are slipped through the spacer if required, and the part is properly positioned (reference tab in the proper location). The leads are aligned with the terminal holes and gently pressed into position. The part is soldered into place and visually inspected. Then the card is tested and the conformal coating is replaced if required.

The removal of an imbedded TO package varies only slightly from the removal of other types of mountings. First, the work area is masked and the conformal coating is removed if required. Then the desoldering handpiece is used to remove the solder from each lead. When all leads are free, the TO is pushed out of the board. If all the leads are free, the TO should slip out of the board easily. The package should not be forced out of the board. Excessive pressure may cause additional damage. If the leads are not completely free, the leads must be clipped and removed after the package is out of the board. This process is shown in figure 3-20.

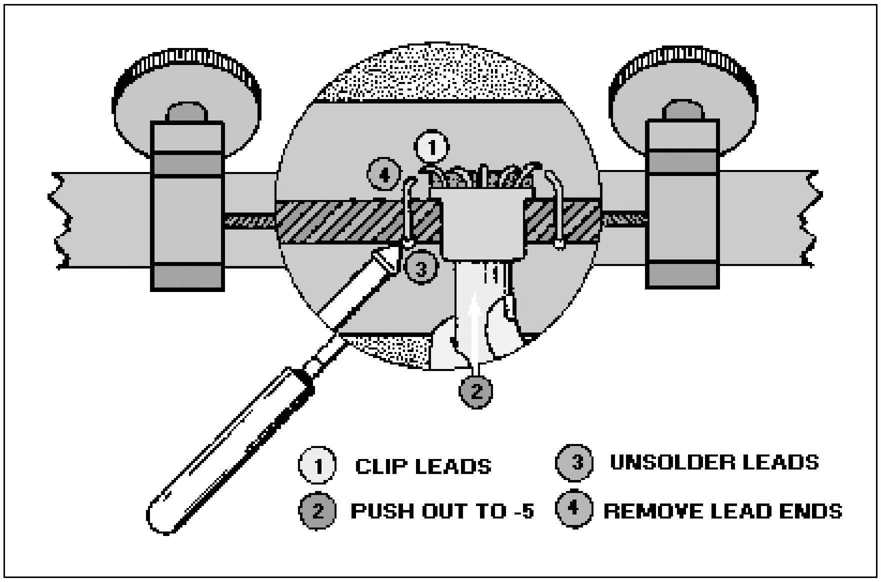

Figure 3-20.—Imbedded TO removal.

The most critical part of replacing an imbedded TO is the lead formation. The leads are formed to match the original part as closely as possible. Once the body and leads are seated, the leads can be soldered and the board inspected.

REMOVAL AND REPLACEMENT OF FLAT PACKS

Up to this point, all of the components discussed have had through-the-board leads. In addition, the removal and replacement of discrete components, DIPs, and TOs have been similar.

PLANAR-MOUNTED COMPONENTS (FLAT-PACKS)

Different techniques are used in the removal and replacement of flat packs and devices with on-the-board terminations. Lap-flow solder joints require that the technician pay particular attention to workmanship. Some of the standards of workmanship will be discussed later in this section.

Flat-Pack Removal

Prior to the removal of a flat pack, as with other ICs, a sketch should be prepared to identify the proper positioning of the part. The conformal coating should be removed as required.

To remove the flat pack, the 2M technician carefully heats the leads and lifts them free with tweezers. If the part is to be reused, special care is taken not to damage or bend the leads. The work area around the component should then be thoroughly cleaned and prepared for the new part.

Flat-Pack Replacement

Flat packs attached to boards normally have formed and trimmed leads. Manufacturers form and trim the leads in one operation with a combination die. However, most replacement flat packs are received in a protective holder (figure 3-21) and the leads must be formed and trimmed by hand. Cost prevents equipping the repair station with the variety of tools and dies to form leads because of the variety of component configurations.

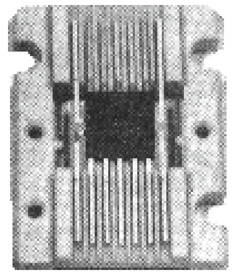

Figure 3-21.—Flat pack in protective holder.

LEAD-BENDING TECHNIQUES.—The 2M technician learns several methods of lead forming that will provide proper contact for soldering and circuit operations. The techniques used to bend leads include the use of specialized tools and such common items as flat toothpicks, bobby pins, and excess component leads. Care is taken not to stress the seal of the component during any step of the lead forming. Figure 3-22 illustrates two views, view (A) and view (B), of properly formed flat-pack leads.

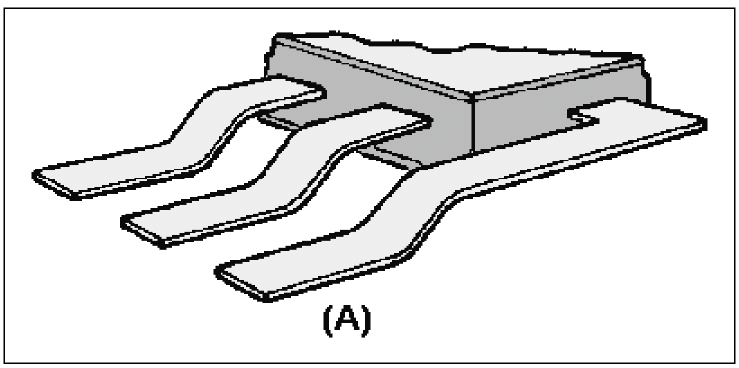

Figure 3-22A.—Properly formed flat pack leads.

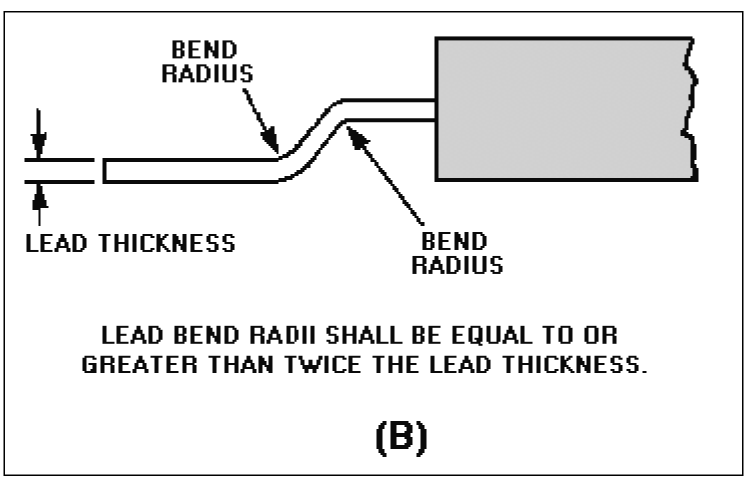

Figure 3-22B.—Properly formed flat pack leads.

Because most replacement flat packs come with leads that are longer than required, they must be trimmed before they are soldered. The removed part is used as a guide in determining lead length. Surgical scissors or scalpels are recommended for use in cutting flat-pack leads. Surgical scissors permit all leads to be cut to the required lead length in a smooth operation with no physical shock transmitted to the IC.

LAP-SOLDERING CONNECTIONS.—Before a connection is lap-soldered, the solder pads are cleaned and pretinned and the component leads are tinned. This is particularly important if they are gold plated. The IC is properly positioned on the pad areas, and the soldering process is a matter of "sweating" the two conductors together. When multilead components, such as ICs, are soldered, a skipping pattern is used to prevent excessive heat buildup in a single area of the board or component. When soldering is completed, all solder connections are thoroughly cleaned. All joints should be inspected and tested. The standards of workmanship are more specific for flat-pack installation.

Q24. When removing the component, under what circumstances may component leads be clipped?

Q25. How are imbedded TOs removed once the leads are free?

Q26. How is a flat pack removed from a pcb?

Q27. How do you prevent excessive heat buildup on an area of a board when soldering multilead components?

Q28. What are the two final steps of any repair?

REPAIR OF PRINTED CIRCUIT BOARDS AND CARDS

Removal and replacement of components on boards and circuit cards are, by far, the most common types of repair. Equally important is the repair of damaged or broken cards. Proper repair of damaged boards not only maintains reliability of the board but also maintains reliability of the system.

Cards and boards may be damaged in any of several ways and by a number of causes. *Untrained personnel making improper repairs and technicians using improper tools are two major causes of damage.* Improper shipping, packaging, storage, and use are also common sources of damage. The source of damage most familiar to technicians is operational failure. Operational failures include cracking caused by heat, warping, component overheating, and faulty wiring.

Before attempting board repairs, the technician should thoroughly inspect the damage. The decision to repair or discard the piece depends on the extent of damage, the level of maintenance authorized, operational requirements, and the availability of repair parts and materials. The following procedures will help you become familiar with the steps necessary to repair particular types of damage. *Remember, only qualified personnel are authorized to attempt these repairs.*

Repair of Conductor and Termination Pads

Conductor (run) and pad damage is very common. The technician must examine the board for nicks, tears, or scratches that have not broken the circuit, as well as for complete breaks, as shown in figure 3-23. Crack damage may exist as nicks or scratches in the conductor. These nicks or scratches must be repaired if over one-tenth of the cross-sectional area of the conductor is affected as current-carrying capability is reduced. Cracks may also penetrate the conductor.

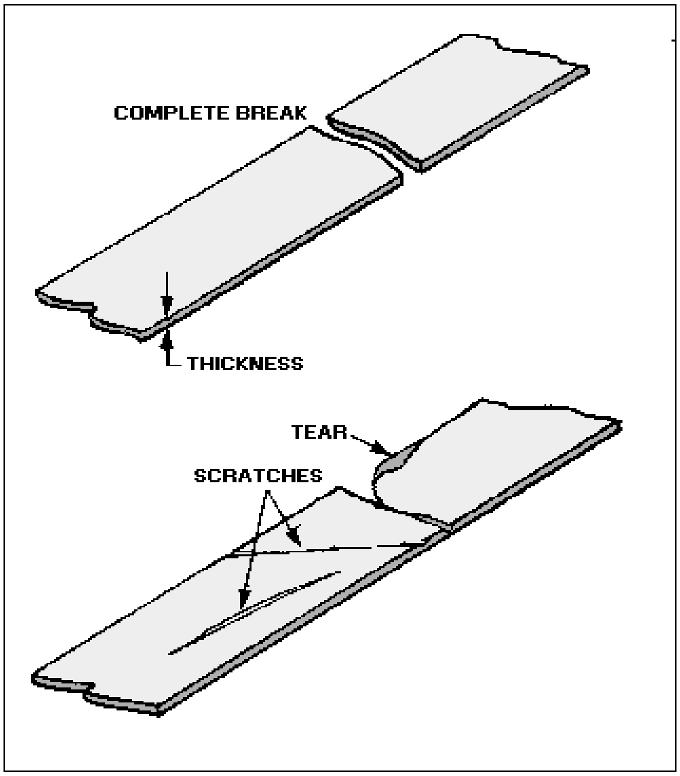

Figure 3-23.—Pcb conductor damage.

CRACK REPAIR.—Four techniques are used to repair cracks in printed circuit conductors. One method is to flow solder across the crack to form a solder bridge. This is not a high-reliability repair since the solder in the break will crack easily.

The second method is to lap-solder a piece of wire across the crack. This method produces a stronger bond than a solder bridge; but it is not highly reliable, as the solder may crack.

A third repair technique is to drill a hole through the board where the crack is located and then to install an eyelet in the hole and solder it into place.

The fourth method is to use the clinched-staple method, shown in figure 3-24. It is the most reliable method and is recommended in nearly all cases.

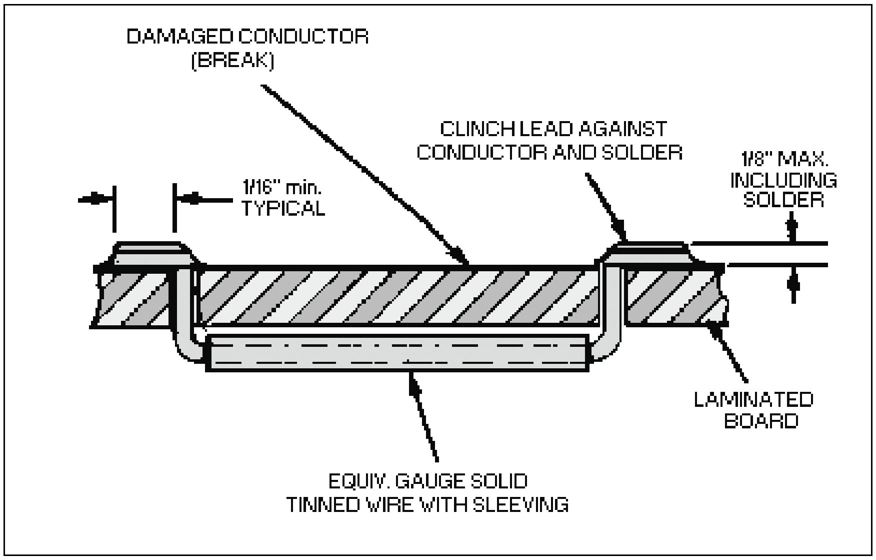

Figure 3-24.—Clinched-staple repair of broken conductor.

Pads or conductor runs may be completely missing from the board. These missing pads or runs must be replaced. Also included in this type of damage are conductors that are present but damaged beyond repair.

REPLACING DAMAGED OR MISSING CONDUCTORS.—The procedures used to replace damaged or missing conductors are essentially the same as using the clinched-staple method of conductor repair.

REPLACING THE TERMINATION PAD.—Many times the termination pad, as well as part of the conductor, is missing on the board. In these cases, a replacement pad is obtained from a scrap circuit board. Refer to figure 3-25 as you study each step.

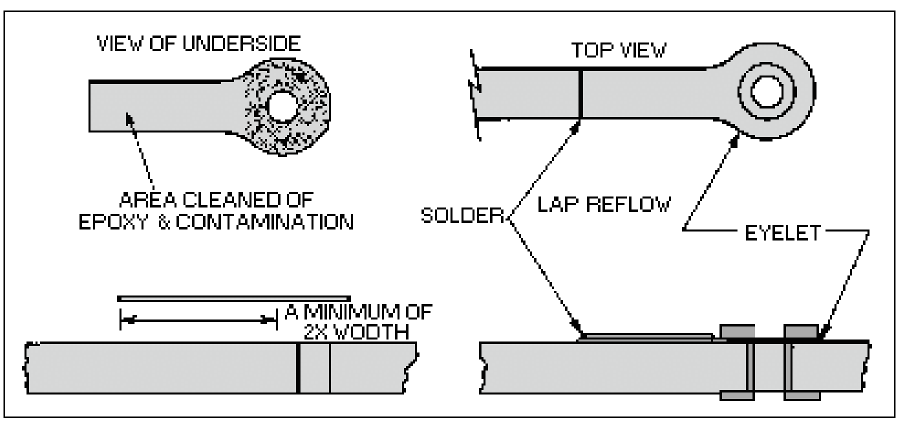

Figure 3-25.—Replacement of damaged termination pad.

The underside of the replacement pad and the area where it will be installed is cleaned. An epoxy is used to fasten the replacement pad to the board. An eyelet is installed to reinforce the pad before the epoxy sets and cures. This ensures a good mechanical bond between the board and pad and provides good electrical contact for components. After the epoxy cures, the new pad is lap-soldered to the original run.

REPAIRING DELAMINATED CONDUCTORS.—DELAMINATED CONDUCTORS (figure 3-26) are classified as conductors no longer bonded to the board surface. Separation of the laminations may occur only on a part of the conductor. Proper epoxying techniques ensure complete bonding of the conductor to the circuit board laminate. The following procedures are used to obtain a proper bond:

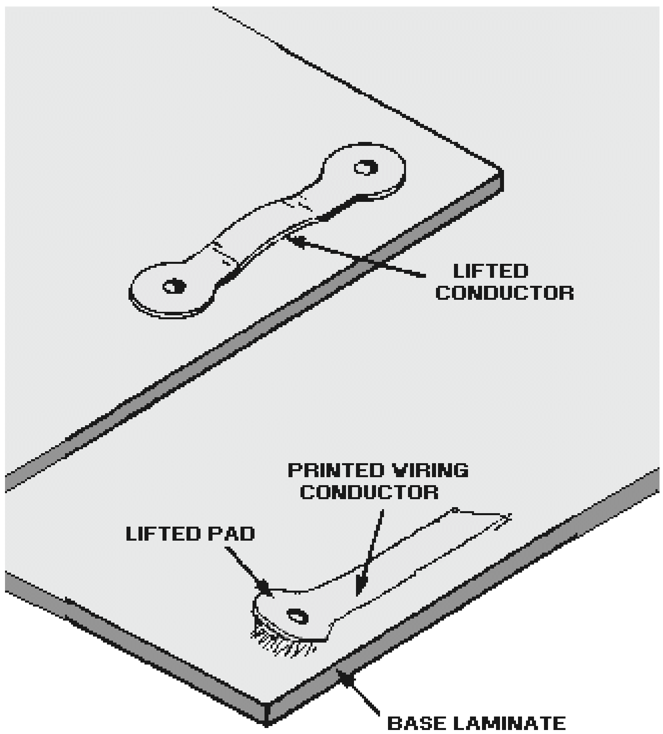

Figure 3-26.—Delaminated conductors.

1. A small amount of epoxy is mixed and applied to the conductor and the conductor path; no areas are left uncoated.

2. The conductor is clamped firmly against the board surface until the epoxy has completely cured.

REPLACING EYELETS.—Eyelets have been referred to in several places in this topic. Not only are they used for through-the-board terminations, but also to reinforce some types of board repairs. As with any kind of material, eyelets are subject to damage. Eyelets may break, they may be installed improperly, or they may be missing from the equipment. When an eyelet is missing or damaged, regardless of the kind of damage, it should be replaced. The guidelines for the selection and installation of new eyelets are far too complex to explain here. However, they do comprise a large part of the 2M technician's training.

Repair of Cracked Boards

When boards are cracked, the length and depth of the cracks must be determined. Also, the disruption to conductors and components caused by cracks must be determined by visual inspection. To avoid causing additional damage, the technician must exercise care when examining cracked boards and must not flex the board. Rebuilding techniques must be used to repair damage, such as cracks, breaks, and holes, that extend through the board. The following steps are used to repair cracks:

1. Abrasive methods are used to remove all chips and fractured material.

2. The edges of the removed area are beveled and undercut to provide bond strength.

3. A smoothly surfaced, nonporous object is fastened tightly against one side of the removed area.

4. The cutaway area is filled with a compound of epoxy and powdered fiberglass (figure 3-27). Extreme care is exercised to prevent the formation of voids or air bubbles in the mixture.

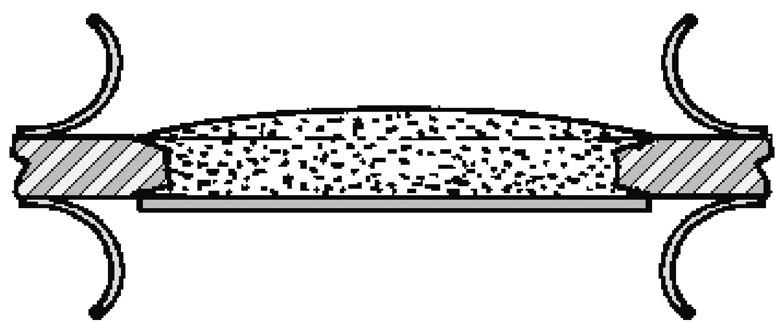

Figure 3-27.—Repair of cracked pcbs.

5. The surface of the filled area is smoothed to make it level with the surface of the original board.

6. The board is cured, smoothed, redrilled, and cleaned.

Broken Board Repair

Broken boards should be examined to determine if all parts of the board are present and if circuit conductors or components are affected by the break. They are also examined to determine if the broken pieces may be rejoined reliably or if new pieces must be manufactured.

Breaks and holes are repaired in the same manner as cracks unless broken pieces are missing or the hole exceeds 1/2 inch in diameter. In such cases, the following repair steps are used:

1. The same technique used in repairing cracks is used to prepare the damaged edge.

2. A piece as close in size to the missing area as possible is cut from a scrap board of the same type and thickness. The edges of this piece are prepared in the same manner as the edges of the hole.

3. A smooth-surfaced object is tightly fastened over one side of the repair area, and the board is firmly clamped in an immovable position with the uncovered area facing up.

4. The replacement piece is positioned as nearly as possible to the original board configuration and firmly clamped into place.

5. The repair is completed using the same epoxy-fiberglass mixture and repair techniques used in the patching repair method discussed in the following section on "Burned Board Repair."

Burned Board Repair

Scorched, charred, or deeply burned boards should be inspected to determine the size of the discolored area and to identify melted or blackened conductors and burned, melted, or blackened components. The depth of the damage, which may range from a slight surface discoloration to a hole burned through the circuit board, should also be determined. Damage not extending through the board may be repaired by patching (figure 3-28). The following procedure is used in the repair of these boards.

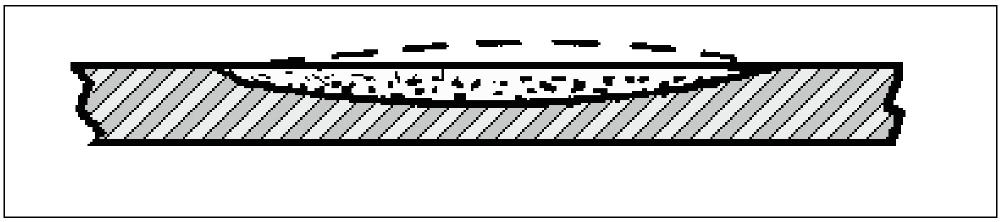

Figure 3-28.—Repair of surface damage.

1. If the board is scorched, charred, or burned, all discolored board material is removed by abrasive methods, as shown in figure 3-29. Several components in the affected area may have to be desoldered and removed before the repair is continued.

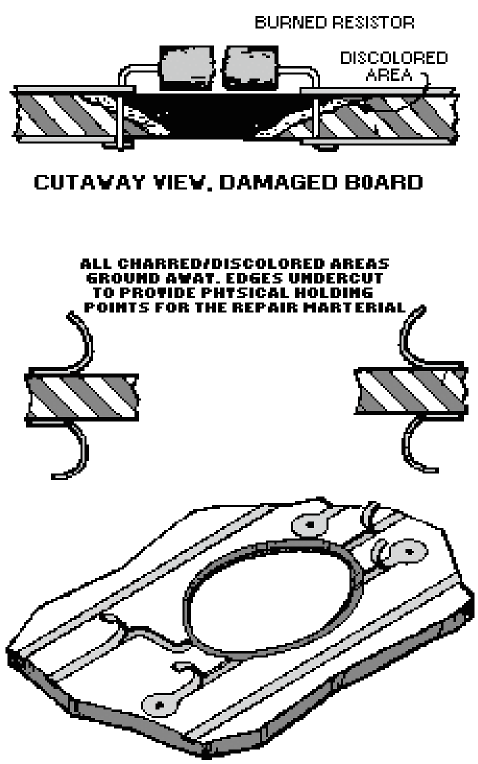

Figure 3-29.—Repair of burned boards.

2. Repairable delaminations not extending to the edge of the circuit board should be cut away by abrasive methods until no delaminated material remains.

3. Delaminated material is not removed if it is repairable.

4. After all damaged board material is removed, the edge of the removed area is beveled and undercut to provide holding points for the repair material.

5. Solvent is used to clean thoroughly and to remove all loose particles.

6. A compound of epoxy and powdered fiberglass is mixed and used to fill the cutaway area.

7. The epoxy repair mixture is cured according to the manufacturer's instructions.

8. The surface of the filled area is leveled after the compound is cured.

9. If delaminations extend to the edge of the board, the delaminated layers are filled completely with the repair mixture and clamped firmly together between two flat surfaces.

10. After the cure is completed, abrasive methods are used to smooth the repaired surface to the same level as the original board.

11. If necessary, needed holes are redrilled in the damaged area, runs are replaced, eyelets and components are installed, and the area is cleaned. Figure 3-30 shows the repaired area ready for components.

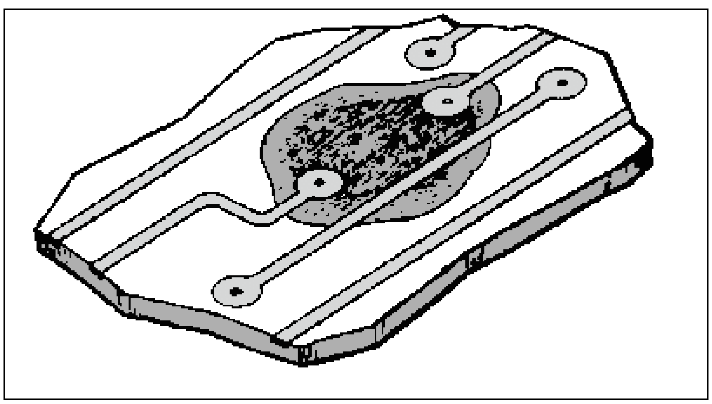

Figure 3-30.—Repaired board ready for components.

Q29. List three causes of damage to printed circuit boards.

Q30. What is the preferred method of repairing cracked runs on boards?

Q31. Damaged or missing termination pads are replaced using what procedure?

Q32. How is board damage caused by technicians?

Q33. What combination of materials is used to patch or build up damaged areas of boards?

SAFETY

Safety is a subject of utmost importance to all technical personnel. Potentially hazardous situations exist in almost any work area. The disregard of safety precautions can result in personal injury or in the loss of equipment or equipment capabilities.

In this section we will discuss two types of safety factors. First, we will cover damage that can occur to electronic components because of electrostatic discharge (ESD) and improper handling and stowage of parts and equipment. Second, we will cover personal safety precautions that specifically concern the technician.

ELECTROSTATIC DISCHARGE

Electrostatic discharge (ESD) can destroy or damage many electronic components including integrated circuits and discrete semiconductor devices. Certain devices are more susceptible to ESD damage than others. Because of this, warning symbols are now used to identify ESD-sensitive (ESDS) items (figure 3-31).

Figure 3-31.—Warning symbols for ESDS devices.

Static electricity is created whenever two substances (solid or fluid) are rubbed together or separated. This rubbing or separation causes the transfer of electrons from one substance to the other; one substance then becomes positively charged and the other becomes negatively charged. When either of these charged substances comes in contact with a conductor, an electrical current flows until that substance is at the same electrical potential as ground.

You commonly experience static build-up during the winter months when you walk across a vinyl or carpeted floor. (Synthetics, especially plastics, are excellent generators of static electricity.) If you then touch a doorknob or other conductor, an electrical arc to ground may result and you may receive a slight shock. For a person to experience such a shock, the electrostatic potential created must be 3,500 to 4,000 volts. Lesser voltages, although present and similarly discharged, normally are not apparent to a person's nervous system. Some typical measured static charges caused by various actions are shown in table 3-2.

Table 3-2.—Typical Measured Statics Charges (in volts)

ITEM	RELATIVE HUMIDITY	
	LOW (10-20%)	HIGH (65-90%)
WALKING ACROSS CARPET	35,000	1,500
WALKING OVER VINYL FLOOR	12,000	250
WORKER AT BENCH	6,000	100
VINYL ENVELOPES FOR WORK INSTRUCT.	7,000	600
POLY BAG PICKED UP FROM BENCH	20,000	1,200
WORK CHAIR PADDED WITH URETHANE FOAM	18,000	1,500

Metal oxide semiconductor (MOS) devices are the most susceptible to damage from ESD. For example, an MOS field-effect transistor (MOSFET) can be damaged by a static voltage potential of as little as 35 volts. Commonly used discrete bipolar transistors and diodes (often used in ESD-protective circuits), although less susceptible to ESD, can be damaged by voltage potentials of less than 3,000 electrostatic volts. Damage does not always result in sudden device failure but sometimes results in device degradation and early failure. Table 3-2 clearly shows that electrostatic voltages well in excess of 3,000 volts can be easily generated, especially under low-humidity conditions. ESD damage of ESDS parts or circuit assemblies is possible wherever two or more pins of any of these devices are electrically exposed or have low impedance paths. Similarly, an ESDS device in a printed circuit board, or even in another pcb that is electrically connected in a series can be damaged if it provides a path to ground. Electrostatic discharge damage can occur during the manufacture of equipment or during the servicing of the equipment. Damage can occur anytime devices or assemblies are handled, replaced, tested, or inserted into a connector.

Technicians should be aware of the many sources of static charge. Table 3-3 lists many common sources of electrostatic charge. Although they are of little consequence during most daily activity, they become extremely important when you work with ESD material.

Table 3-3.—Common Sources of Electrostatic Charge

OBJECT OR PROCESS	MATERIAL OR ACTIVITY
WORK SURFACES	• WAXED, PAINTED, OR VARNISHED SURFACES • COMMON VINYL OR PLASTICS
FLOORS	• SEALED CONCRETE • WAXED, FINISHED WOOD • COMMON VINYL TILE OR SHEETING
CLOTHES	• COMMON CLEAN ROOM SMOCKS • COMMON SYNTHETIC PERSONNEL GARMENTS • NONCONDUCTIVE SHOES • VIRGIN COTTON*
CHAIRS	• FINISHED WOOD • VINYL • FIBERGLASS
PACKAGING AND HANDLING	• COMMON PLASTIC—BAGS, WRAPS, ENVELOPES • COMMON BUBBLE PACK, FOAM • COMMON PLASTIC TRAYS, PLASTIC TOTE BOXES, VIALS, PARTS BINS
ASSEMBLY, CLEANING, TEST AND REPAIR AREAS	• SPRAY CLEANERS • COMMON PLASTIC SOLDER SUCKERS • SOLDER IRONS WITH UNGROUNDED TIPS • SOLVENT BRUSHES (SYNTHETIC BRISTLES) • CLEANING OR DRYING BY FLUID OR EVAPORATION • TEMPERATURE CHAMBERS • CRYOGENIC SPRAYS • HEAT GUNS AND BLOWERS • SAND BLASTING • ELECTROSTATIC COPIERS
PERSONNEL ITEMS	• STYROFOAM COFFEE OR PLASTIC DRINK CUPS • PLASTIC OR RUBBER HAIR COMBS OR BRUSHES • CELLOPHANE OR PLASTIC CANDY, GUM OR CIGARETTE WRAPPERS • VINYL PURSES

*VIRGIN COTTON CAN BE A STATIC SOURCE AT LOW RELATIVE HUMIDITIES (BELOW 30 PERCENT)

Prevention of ESD Damage

Certified 2M technicians are trained in procedures for reducing the causes of ESD damage. The procedures are similar for all levels of maintenance. The following procedure is an example of some of the protective measures used to prevent ESD damage.

1. Before starting to service equipment, the technician should be grounded to discharge any static electric charge built up on the body. This can be accomplished with the use of a test lead (a single-wire conductor with a series resistance of 1 megohm equipped with alligator clips on each end). One clip end is connected to the grounded equipment frame, and the other clip end is

touched with a bare hand. Figure 3-32 shows a more refined ground strap which frees both hands for work.

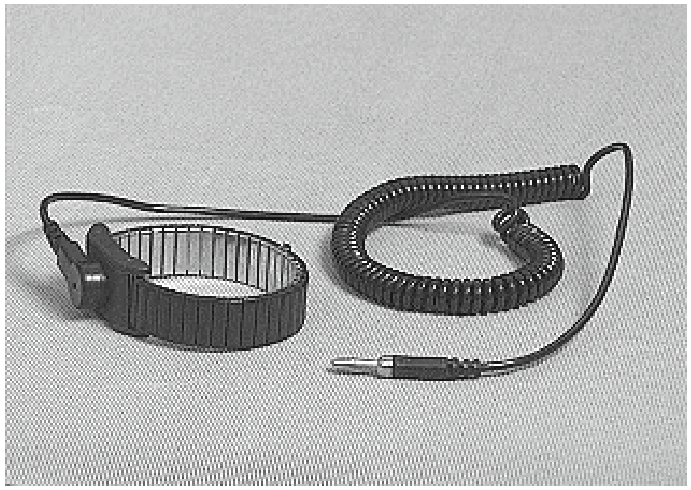

Figure 3-32.—ESD wrist strap.

2. Equipment technical manuals and packaging material should be checked for ESD warnings and instructions.

3. Prior to opening an electrostatic unit package of an electrostatic sensitive device or assembly, clip the free end of the test lead to the package. This will cause any static electricity which may have built up on the package to discharge. The other end remains connected to the equipment frame or other ESD ground. Keep the unit package grounded until the replacement device or assembly is placed in the unit package.

4. Minimize handling of ESDS devices and assemblies. Keep replacement devices or assemblies, with their connector shorting bars, clips, and so forth, intact in their electrostatic-free packages until needed. Place removed repairable ESD devices or assemblies with their connector shorting bars/clips installed in electrostatic-free packages as soon as they are removed from the equipment. ESDS devices or assemblies are to be transported and stored only in protective packaging.

5. Always avoid unnecessary physical movement, such as scuffing the feet, when handling ESDS devices or assemblies. Such movement will generate additional charges of static electricity.

6. When removing or replacing an ESDS device or assembly in the equipment, hold the device or assembly through the electrostatic-free wrap if possible. Otherwise pick up the device or assembly by its body only. Do not touch component leads, connector pins, or any other electrical connections or paths on boards, even though they are covered by conformal coating.

7. Do not permit ESDS devices or assemblies to come in contact with clothing or other ungrounded materials that could have an electrostatic charge. The charges on a nonconducting material are not equal. A plastic storage bag may have a −10,000 volt potential 1/2 inch from a +15,000 volt potential, with many such charges all over the bag. Placing a circuit card inside the bag allows the charges to equalize through the pcb conductive paths and components, thereby causing failures. Do not hand an ESD device or assembly to another person until the device or assembly is protectively packaged.

8. When moving an ESDS device or assembly, always touch (with bare skin) the surface on which it rests for at least one second before picking it up. Before placing it on any surface, touch the surface with your free hand for at least one second. The bare skin contact provides a safe discharge path for charges accumulated while you are moving around.

9. While servicing equipment containing ESD devices, do not handle or touch materials such as plastic, vinyl, synthetic textiles, polished wood, fiberglass, or similar items which create static charges; or, be sure to repeat the grounding action with the bare hands after contacting these materials. These materials are prime electrostatic generators.

10. If possible, avoid repairs that require soldering at the equipment level. Soldering irons must have heater/tips assemblies that are grounded to ac electrical ground. Do not use ordinary plastic solder suckers (special antistatic solder suckers are commercially available).

11. Ground the leads of test equipment momentarily before you energize the test equipment and before you probe ESD items.

Grounded Workbenches

Workbenches on which ESDS items will be placed and that will be contacted by personnel should have ESD protective work surfaces. These protective surfaces should cover the areas where ESD items will be placed. Personnel ground straps are also necessary for ESD protective workbench surfaces. These straps prevent people from discharging a static charge through an ESDS item to the work bench surface. The workbench surface should be connected to ground through a ground cable. The resistance in the bench top ground cable should be located at or near the point of contact with the workbench top. The resistance should be high enough to limit any leakage current to 5 milliamperes or less; this is taking into consideration the highest voltage source within reach of grounded people and all parallel resistances to ground, such as wrist ground straps, table tops, and conductive floors. See figure 3-33 for a typical ESD ground workbench.

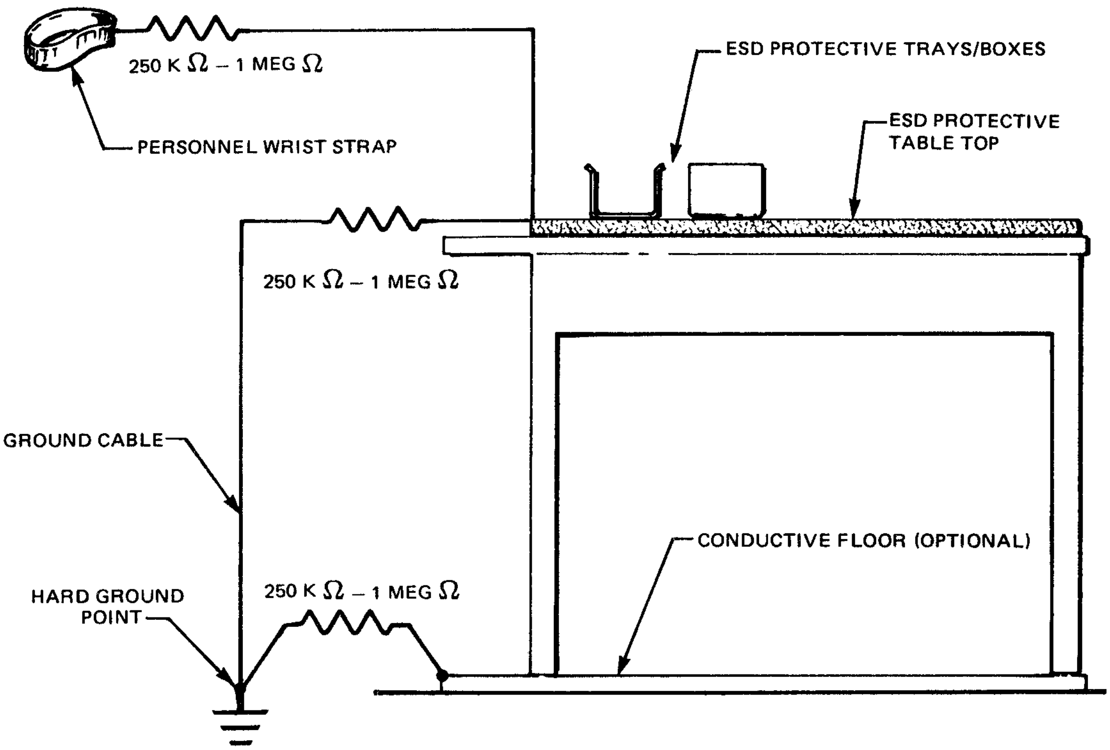

Figure 3-33.—Typical ESD ground workbench.

Energized equipment provides protection from ESD damage through operating circuitry. Circuit cards with ESD sensitive devices are generally considered safe when installed in an equipment rack; but they may be susceptible to damage if a "drawer" or "module" is removed and if connector pins are touched (even putting on plastic covers can transfer charges that do damage). *There must not be any energized equipment placed on the conductive ESD work surface.* An ESD work area is for "dead" equipment ONLY.

ESD protection is critical. If you should be assigned to 2M repair school, your education in ESD prevention will be quite extensive.

PERSONAL SAFETY

Throughout your career you will be aware of emphasis placed on safety. Safety rules remind you of potential dangers in work. Most accidents are preventable. Accidents don't happen without a cause. Most accidents are the result of not following prescribed safe operating procedures.

This would be a good time to review the safety section in topic 5 of NEETS, Module 2, *Introduction to Alternating Current and Transformers*. That section covers the basics of electrical shock and how to prevent it.

The 2M technician should be aware of other potential dangers in addition to the dangers of electrical shock. These dangers are discussed in the following paragraphs.

Power Tools

Hazards associated with the use of power tools include electrical shock, cuts, and particles in the eye. Safe tool use practices reduce or eliminate such accidents. Listed below are some of the general safety precautions that you should observe when your work requires the use of power tools.

- Ensure that all metal-cased power tools are properly grounded.
- Do not use spliced cables unless an emergency warrants the risks involved.
- Inspect the cord and plug for proper connection. Do not use any power tool that has a frayed cord or broken or damaged plug.
- Make sure that the on/off switch is in the OFF position before inserting or removing the plug from the receptacle.
- Always unplug the extension cord from the receptacle before the portable power tool is unplugged from the extension cord.
- Ensure all cables are positioned so they will not constitute a tripping hazard.
- Wear eye protection (goggles) in work areas where particles may strike the eye.
- After completing a task requiring a portable power tool, disconnect the power cord as described above and store the tool in its assigned location.

Soldering Iron

When using a soldering iron, remember the following:

- To avoid burns, always assume that a plugged-in soldering iron is HOT.
- Never rest a heated iron anywhere but in a holder provided for that purpose. Faulty action on your part could result in fire, extensive equipment damage, and/or serious injuries.
- Never use an excessive amount of solder. Drippings can cause serious skin or eye burns and can cause short circuits.
- Do not swing an iron to remove excess solder. Bits of hot solder can cause serious skin or eye burns or may ignite combustible material in the work area.
- When cleaning an iron, use a natural fiber cleaning cloth; never use synthetics, which melt. Do not hold the cleaning cloth in your hand. Always place the cloth on a suitable surface; then wipe the iron across it to avoid burning your hand.
- Hold small soldering jobs with pliers or a suitable clamping device to avoid burns. Never hold the work in your hand.
- Do not use an iron that has a frayed cord or damaged plug.

- Do not solder electronic equipment unless the equipment is electrically disconnected from the power supply circuit.

- After completing a task requiring a soldering iron other than the iron that is part of a work station, disconnect the power cord from the receptacle. When the iron has cooled, store it in its assigned stowage area.

Cleaning Solvents

The technician who smokes while using a cleaning solvent is inviting disaster. Unfortunately, many such disasters have occurred. For this reason, the Navy does not permit the use of gasoline, benzine, ether, or like solvents for cleaning since they present potential fire or explosion hazards. Only nonvolatile solvents should be used to clean electrical or electronic apparatus.

In addition to the potential hazard of accidental fire or explosion, most cleaning solvents can damage the human respiratory system where the fumes are breathed for a period of time.

The following positive safety precautions should be followed when performing cleaning operations.

- Use a blower or canvas wind chute to blow air into a compartment in which a cleaning solvent is being used.

- Open all usable port holes and place wind scoops in them.

- Place a fire extinguisher nearby.

- If it can be done, use water compounds instead of other solvents.

- Wear rubber gloves to prevent direct contact with solvents.

- Use goggles when a solvent is being sprayed on surfaces.

- Hold the nozzle close to the object being sprayed.

Where water compounds cannot be used, inhibited methyl chloroform (1.1.1 trichloroethane) should be used. Carbon tetrachloride is not used. Cleaning solvents that end with ETHYLENE are NOT safe to use. Methyl chloroform is an effective cleaner and is as safe as can be expected when reasonable care is exercised, such as adequate ventilation and the observance of fire precautions. When using inhibited methyl chloroform, avoid direct inhalation of the vapor. It is not safe for use, even with a gas mask, because its vapor displaces oxygen in the air.

Aerosol Dispensers

A 2M technician will encounter several uses for aerosol dispensers. The most common type is in applying conformal coatings.

Specific instructions concerning the precautions and procedures that must be observed to prevent physical injury cannot be given in this section because of the many available industrial sprays. However, all personnel concerned with handling aerosol dispensers containing volatile substances must clearly understand the hazards involved. They must also understand the importance of exercising protective measures to prevent personal injury. Strict compliance with the instructions printed on the aerosol dispensers will prevent many accidents that result from misapplication, mishandling, or improper storage of industrial sprays.

The rules for safe use of aerosol dispensers are listed below:

- Carefully read and comply with the instructions printed on the container.
- Do not use any dispenser that is capable of producing dangerous gases or other toxic effects in an enclosed area unless the area is adequately ventilated.
- If a protective coating must be sprayed in an inadequately ventilated space, either an air respirator or a self-contained breathing apparatus should be provided. However, fresh air supplied from outside the enclosure by exhaust fans or portable blowers is preferred. Such equipment prevents inhalation of toxic vapors.
- Do not spray protective coating on warm or energized equipment because this creates a fire hazard.
- Avoid skin contact with the liquid. Contact with some liquids may cause burns, while milder exposure may cause rashes. Some toxic materials are actually absorbed through the skin.
- Do not puncture the dispenser. Because it is pressurized, injury can result.
- Keep dispensers away from direct sunlight, heaters, and other heat sources.
- Do not store dispensers in an environment where the temperature exceeds the limits printed on the can. High temperatures may cause the container to burst.

Q34. List two causes of damage to ESD-sensitive electronic components.

Q35. What is the purpose of the wrist ground strap?

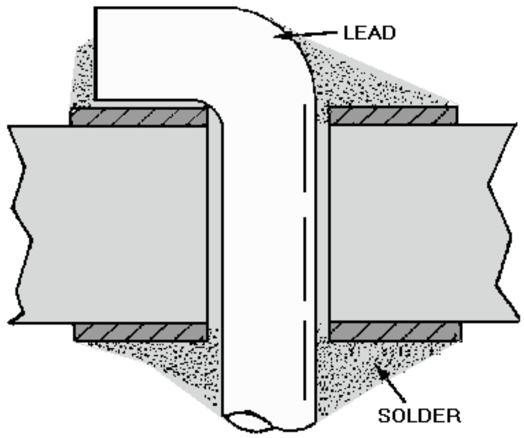
Q36. What is the cause of most accidents?

SUMMARY

This topic has presented information on miniature and microminiature (2M) repair procedures and 2M safety precautions. The information that follows summarizes the important points of this topic.

CONFORMAL COATINGS are protective materials applied to electronic assemblies to prevent damage caused by corrosion, moisture, and stress.

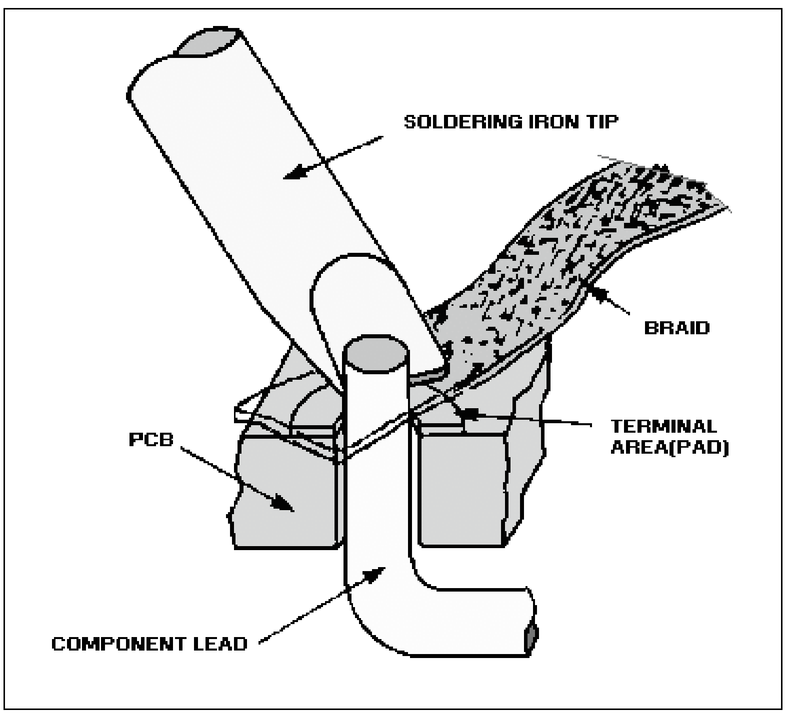
CONFORMAL COATINGS REMOVAL is accomplished mechanically, chemically, or thermally, depending on the material used.



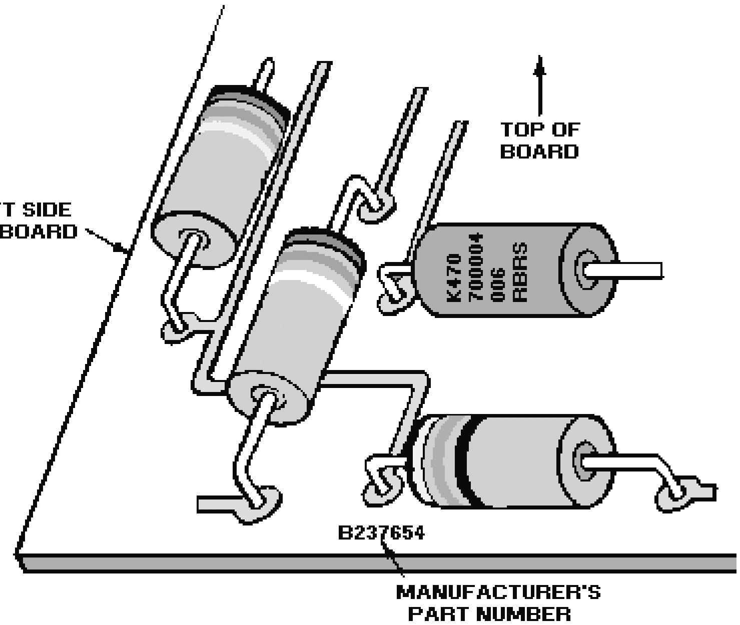
(A) FULLY CLINCHED

Component **LEADS** are terminated either through the board, above the board, or on the board.

SOLDER may be removed by wicking, by a manual vacuum plunger, or by a continuous vacuum solder extractor.



ELECTRONIC ASSEMBLIES should be restored to the original manufacturer's standards using the same orientation and termination method.

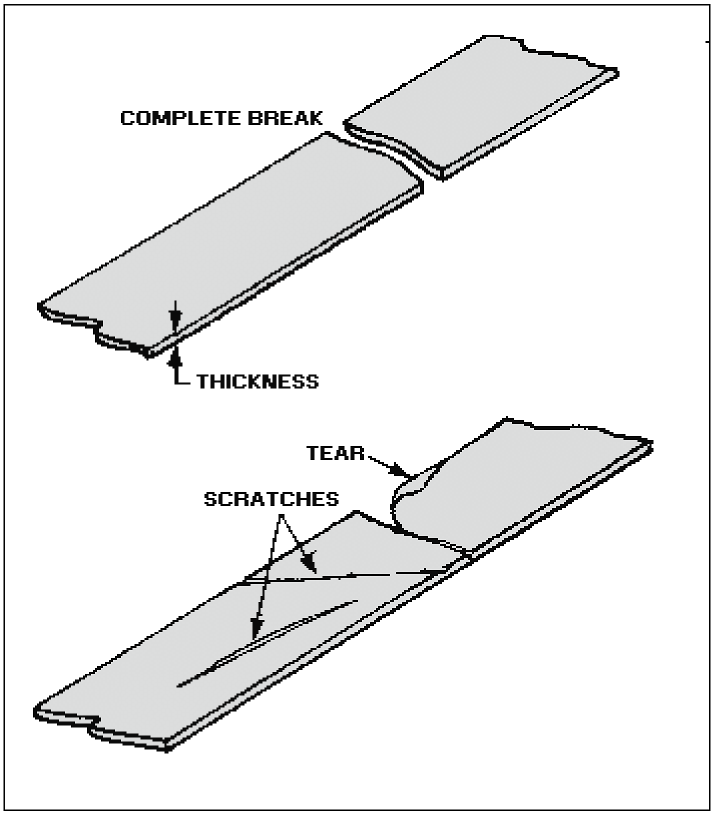


A **GOOD SOLDER JOINT** is bright and shiny with no cracks or pits.

When **REPLACING DIPs**, **TOs**, AND **FLAT PACKS**, make certain that pins are placed in the proper position.

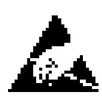
COMPONENT LEADS may be clipped prior to removal only if the part is known to be bad or if normal removal will result in board damage.

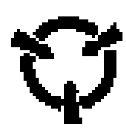
The technician must determine through **INSPECTION** what method of repair is necessary for the board.

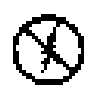


ELECTROSTATIC DISCHARGE (ESD) can damage or destroy many types of electronic components including integrated circuits and discrete components.

Special handling is required for **ELECTROSTATIC-DISCHARGE-SENSITIVE (ESDS)** devices or components.







USE PRESCRIBED SAFETY PRECAUTIONS when you use power tools, soldering irons, cleaning solvents, and aerosol dispensers.

ANSWERS TO QUESTIONS Q1. THROUGH Q36.

A1. Conformal coating.

A2. Chemical, mechanical, and thermal.

A3. Solvents or xylene and trichloroethane.

A4. Mechanical.

A5. To ensure protective characteristics are maintained.

A6. Interfacial connections.

A7. Clinched lead, straight-through, and offset pad.

A8. Above-the-board termination.

A9. On-the-board termination.

A10. During disassembly or repair.

A11. Wicking.

A12. Continuous vacuum.

A13. These methods should not be used.

A14. Manufacturer's standards.

A15. A fine abrasive.

A16. 90 degrees.

A17. They should be readable from a single point.

A18. In the direction of the run.

A19. The ease with which molten solder wets the surfaces of the metals to be joined.

A20. Conductive-type soldering iron.

A21. The type of work to be done.

A22. A thermal shunt.

A23. Bright and shiny with no cracks or pits.

A24. If the component is known to be defective or if the board may be damaged by normal desoldering.

A25. By pushing it gently out of the board.

A26. Heat each lead and lift with tweezers.

A27. Use a skipping pattern.

A28. Inspect and test.

A29. Operational failures, repairs by untrained personnel, repair using improper tools, mishandling, improper shipping, packaging, and storage.

A30. Clinched staple.

A31. Epoxy a replacement pad to the board, set an eyelet, and solder it.

A32. Repairs by untrained personnel and technicians using improper tools.

A33. Epoxy and fiberglass powder.

A34. Esd, improper stowage, and improper handling.

A35. To discharge any static charge built up in the body.

A36. Deviation from prescribed safe operating procedures.

APPENDIX I

GLOSSARY

ALLOWANCE PARTS LIST (APL)—Repair parts required for unit having the equipment/ component listed.

ALLOWANCE EQUIPAGE LIST (AEL)—Equipment requirements for a unit having the exact equipment/component listed.

BEAM-LEAD CHIP—Semiconductor chip with electrodes (leads) extended beyond the wafer.

BONDING WIRES—Fine wires connecting the bonding pads of the chip to the external leads of the package.

BUILT-IN TEST EQUIPMENT (BITE)—Permanently mounted to the equipment for the purpose of testing the equipment.

CABLE HARNESS—A group of wires or ribbons of wiring used to interconnect electronic systems and subsystems.

CATHODE SPUTTERING—Process of producing thin film components.

CERMET—A combination of powdered precious-metal alloys and an inorganic material such as alumina. Used in manufacturing resistors, capacitors, and other components for high-temperature applications.

CORDWOOD MODULE.—A method of increasing the number of discrete components in a given space. Resembles wood stacked for a fireplace.

CRYSTAL FURNACE.—Device for artificially growing cylindrical crystals for producing semi-conductor substrates.

DEPOT-LEVEL MAINTENANCE (SM&R Code D)—Supports S&R Code I and SM&R Code O activities through extensive shop facilities and equipment and more highly skilled personnel.

DICE—Uncased chips.

DIE BONDING—Process of mounting a chip to a package.

DIFFUSION—Controlled application of impurity atoms to a semiconductor substrate.

DISCRETE COMPONENTS—Individual transistors, diodes, resistors, capacitors, and inductors.

DOPING—*See* Diffusion.

DUAL IN-LINE PACKAGE (DIP)—IC package having two parallel rows of preformed leads.

ENCAPSULATED—Imbedded in solid material or enclosed in glass or metal.

EPITAXIAL PROCESS—The depositing of a thin uniformly doped crystalline region (layer) on a substrate.

EUTECTIC ALLOY—An alloy that changes directly from a solid to a liquid with no plastic or semiliquid state.

EUTECTIC SOLDER—An alloy of 63 percent tin and 37 percent lead. Melts at 361º F.

FILM ICs—Conductive or nonconductive material deposited on a glass or ceramic substrate. Used for passive circuit components, resistors, and capacitors.

FLAT PACK—IC package.

FLIP CHIP—Monolithic IC packaging technique that eliminates need for bonding wires.

FLUX—Removes surface oxides from metals being soldered.

GENERAL PURPOSE ELECTRONIC TEST EQUIPMENT (GPETE)—Multimeters, oscilloscopes, voltmeters, signal generators, etc.

GROUND PLANES—Copper planes-used to minimize interference between circuits and from external sources.

HYBRID ICs—Two or more integrated circuit types, or one or more integrated circuit types and discrete components on a single substrate.

INTEGRATED CIRCUIT (IC)—Elements inseparably associated and formed on or within a single substrate.

INTERMEDIATE-LEVEL MAINTENANCE (SR&R Code I)—Direct support and technical assistance to user organizations. Tenders and shore-based repair facilities.

ISOLATION—The prevention of unwanted interaction or leakage between components.

LANDS—Conductors or runs on pcbs.

LARGE SCALE INTEGRATION (lsi)—An integrated circuit containing 1,000 to 2,000 logic gates or up to 64,000 bits of memory.

MASK—A device used to deposit materials on a substrate in the desired pattern.

MICROCIRCUIT—A small circuit having high equivalent-circuit-element density, which is considered as a single part composed of interconnected elements on or within a single substrate to perform an electronic-circuit function.

MICROELECTRONICS—That area of electronics technology associated with electronic systems built of extremely small electronic parts or elements.

MICROCIRCUIT MODULE—An assembly of microcircuits or a combination of microcircuits and discrete components that perform one or more distinct functions.

MODIFIED TRANSISTOR OUTLINE (TO)—IC package resembling a transistor.

MODULAR PACKAGING—Circuit assemblies or subassemblies packaged to be easily removed for maintenance or repair.

MODULE—A circuit or portion of a circuit packaged as a removable unit. A separable unit in a packaging scheme displaying regularity of dimensions.

MILITARY STANDARDS (MILSTD)—Standards of performance for components or equipment that must be met to be acceptable for military systems.

MINIATURE ELECTRONICS—Modules, packages, pcbs, and so forth, composed exclusively of discrete components.

2M—Miniature/Microminiature repair program.

MONOLITHIC IC—ICs that are formed completely within a semiconductor substrate. Silicon chips.

OFF-LINE TEST EQUIPMENT—Tests andisolates faults in modules or assemblies removed from systems.

OHMS PER SQUARE—The resistance of any square area of thin film resistive material as measured between two parallel sides.

ON-LINE TEST EQUIPMENT—Continuously monitors the performance of electronic systems.

ORGANIZATIONAL-LEVEL MAINTENANCE (SM&R Code O)—Responsibility of the user organization.

PACKAGING LEVELS—System developed to assist maintenance personnel in isolating faults.

PHOTO ETCHING—Chemical process of removing unwanted material in producing printed circuit boards.

POINT-TO-POINT WIRING—Individual wires run from terminal to terminal to complete a circuit.

PRINTED CIRCUIT BOARD (peb)—The general term for completely processed printed circuit or printed wiring configurations. It includes single-layered, double-layered, and multi-layered boards.

SCREENING—Process of applying nonconductive or semiconductive materials to a substrate to form thick film components.

SHIELDING—Technique designed to minimize internal and external interference.

SOURCE, MAINTENANCE, AND RECOVER-ABILITY CODES (SM&R CODES)—Specify maintenance level for repair of components or assemblies.

SUBSTRATE—Mounting surface for integrated circuits. May be semiconductor or insulator material depending on type of IC.

THICK FILM COMPONENTS—Passive circuit components (resistors and capacitors) having a thickness of 0.001 centimeter.

THIN FILM COMPONENTS—Passive circuit elements (resistors and capacitors) deposited on a substrate to a thickness of 0.0001 centimeter.

VACUUM EVAPORATION—Process of producing thin film components.

VERY LARGE SCALE INTEGRATION (vlsi)—An integrated circuit containing over 2,000 logic gates or 64,000 bits of memory.

WAFER—A slice of semiconductor material upon which monolithic ICs are produced.

MODULE 14 INDEX

ASSIGNMENT 1

Textbook assignment: Chapter 1, “Microelectronics,” pages 1-1 through 1-56. Chapter 2, “Miniature/Microminiature (2M) Repair Program and High-Reliability Soldering,” pages 2-1 through 2-22.

1-1. What term is used to describe electronic systems that are made up of extremely small parts or elements?

1. Microelectronics
2. Modular packages
3. Integrated circuits
4. Solid-state technology

1-2. During World War II, which of the following limitations were considered unacceptable for military electronics systems?

1. Large size, heavy weight, and wide bandwidth
2. Excessive power requirements, large size, and complex manning requirements
3. Large size, heavy weight, and excessive power requirements
4. Heavy weight, complex circuits and limited communications range

1-3. The development of which of the following types of components had the greatest impact on the technology of microelectronics?

1. Vacuum tubes and resistors
2. Transformers and capacitors
3. Vacuum tubes and transistors
4. Transistors and solid-state diodes

1-4. For a vacuum tube to operate properly in a variety of different circuit applications, additional components are often required to "adjust" circuit values. This is because of which of the following variations within the vacuum tube?

1. Element size
2. Warm-up times
3. Plug-in mountings
4. Output characteristics

1-5. Point-to-point wiring in a vacuum tube circuit often caused which of the following unwanted conditions?

1. Heat interactions
2. Inductive interactions
3. Capacitive interactions
4. Both 2 and 3 above

1-6. Functional blocks of a system that can easily be removed for troubleshooting and repair are called

1. sets
2. chassis
3. modules
4. vacuum tubes

1-7. Which of the following characteristics of a printed circuit board (pcb) is NOT an advantage over a point-to-point wired tube circuit?

1. The pcb weighs less
2. The pcb eliminates the need for point-to-point wiring
3. The pcb eliminates the need for a heavy metal chassis
4. The pcb contains a limited number of components

1-8. A module in which the components are supported by end plates is referred to as

1. a pcb
2. cordwood
3. a substrate
4. encapsulated

1-9. A module which is difficult to repair because it is completely imbedded in solid material is one which has been

1. balanced
2. enveloped
3. integrated
4. encapsulated

1-10. All components and interconnections are formed on or within a single substrate in which of the following units?

1. Cordwood
2. Integrated circuit
3. Equivalent circuit
4. Printed circuit board

1-11. Monolithic integrated circuits are usually referred to as

1. hybrids
2. substrates
3. silicon chips
4. selenium rectifiers

1-12. In integrated circuits, a conductive or nonconductive film is used for which of the following types of components?

1. Capacitors and diodes
2. Transistors and diodes
3. Resistors and capacitors
4. Resistors and transistors

1-13. Which of the following types of electronic circuits is NOT a hybrid integrated circuit?

1. Thick film and transistors
2. Thin film and silicon chips
3. Transistors and vacuum tubes
4. Silicon chips and transistors

1-14. What maximum number of logic gates should be expected in a large-scale integration circuit?

1. 20
2. 200
3. 2,000
4. 20,000

1-15. Integrated circuits containing more than 64,000 bits of memory are referred to as

1. hybrid integration
2. large-scale integration
3. small-scale integration
4. very large-scale integration

1-16. Which of the following pieces of equipment is used to prepare component layout in complex ICs?

1. A mask
2. A camera
3. A computer
4. A microscope

1-17. A device that allows the depositing of material in selected areas of a semiconductor substrate, but not in others, is known as a

1. blind
2. screen
3. filter
4. wafer mask

1-18. Which of the following types of material is preferred for film circuit substrates?

1. Silicon
2. Ceramic
3. Germanium
4. Fiberglass

1-19. A typical silicon wafer has approximately (a) what diameter and (b) what thickness?

1. (a) 2 inches (b) 0.01 to 0.02 inches
2. (a) 2 inches (b) 0.21 to 0.40 inches
3. (a) 3 inches (b) 0.21 to 0.40 inches
4. (a) 3 inches (b) 0.01 to 0.20 inches

1-20. Artificially grown silicon or germanium crystals are used to produce substrates for which of the following types of integrated circuits?

1. Hybrid
2. Thin-film
3. Thick-film
4. Monolithic

1-21. Elements penetrate the semiconductor substrate in (a) what type of IC but (b) do NOT penetrate the substrate in what type of IC?

1. (a) Diffused (b) thin-film
2. (a) Diffused (b) epitaxial
3. (a) Thick-film (b) epitaxial
4. (a) Thick-film (b) thin-film

1-22. Pn junctions are protected from contamination during the fabrication process by which of the following materials?

1. Oxide
2. Silicon
3. Germanium
4. Photoetch

1-23. The prevention of unwanted interaction or leakage between components is accomplished by which of the following techniques?

1. Isolation
2. Insulation
3. Integration
4. Differentiation

1-24. Vacuum evaporation and cathode sputtering are two methods used to produce which of the following types of components?

1. Diodes
2. Thin-film
3. Thick-film
4. Transistors

1-25. To deposit highly reactive materials on a substrate, you should use which of the following methods..

1. Photoetching
2. Photolithography
3. Cathode sputtering
4. Vacuum evaporation

1-26. To produce thin film resistors, you should use which of the following materials?

1. Nichrome
2. Tantalum
3. Titanium
4. Each of the above

1-27. Which of the following is a major advantage of hybrid ICs?

1. Ease of manufacture
2. Ease of replacement
3. Design flexibility
4. Easy availability

1-28. IC packaging is required for which of the following reasons?

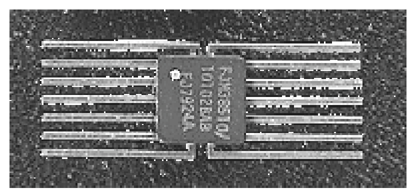
1. To dissipate heat
2. For ease of handling
3. To increase shelf life
4. To meet stowage requirements

IN ANSWERING QUESTIONS 1-29 AND 1-30, MATCH THE IC PACKING EXAMPLES IN THE QUESTIONS TO THE PACKAGING DESCRIPTIONS IN FIGURE 1A.

A.	**TO**
B.	**DIP**
C.	**Flatpack**
D.	**Hybrid**

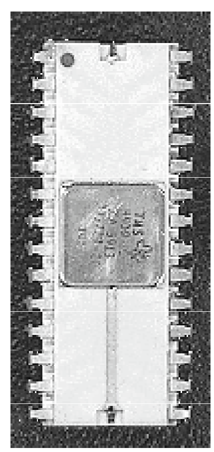
Figure 1A. —Packaging descriptions.

1-29.



1. A
2. B
3. C
4. D

1-30.



1. A
2. B
3. C
4. D

1-31. Which of the following types of DIPs are most commonly used in the Navy's microelectronics systems?

1. Glass
2. Metal
3. Ceramic
4. Plastic

1-32. In IC production, gold or aluminum bonding wires are used for which of the following purposes?

1. To bond the chip to the package
2. To provide component isolation
3. To connect the package to the circuit board
4. To connect the chip to the package leads

1-33. IC packages that may be easily installed by hand or machine on mounting boards fall into which of the following categories?

1. TO
2. DIP
3. Flatpack
4. Each of the above

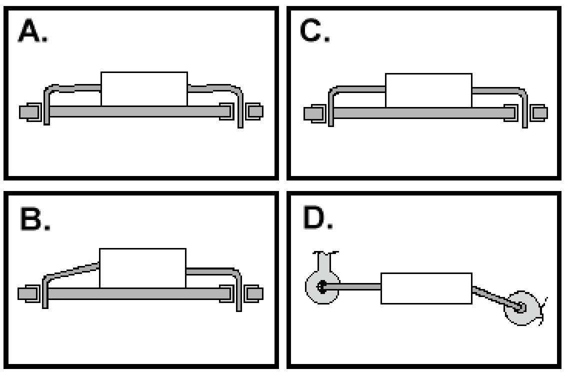
1-34. The need for bonding wires has been eliminated by which of the following production techniques?

1. LSI
2. Beam lead
3. Flip chip
4. Both 2 and 3 above

THIS SPACE LEFT BLANK INTENTIONALLY.

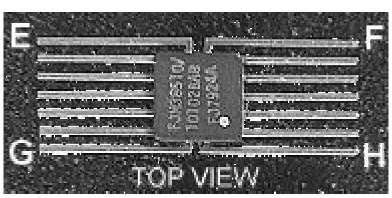
IN ANSWERING QUESTIONS 1-35 THROUGH 1-37, MATCH THE LETTER IN EACH OF THE FIGURES THAT IDENTIFIES PIN 1.

1-35.



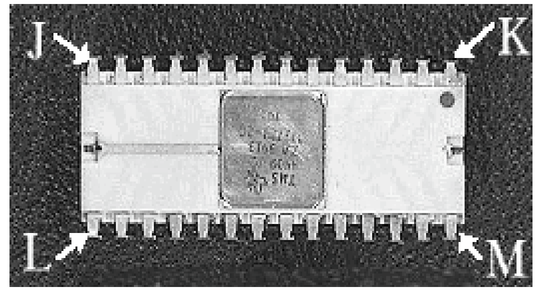
1. A
2. B
3. C
4. D

1-36.



1. E
2. F
3. G
4. H

1-37.



1. J
2. K
3. L
4. M

1-38. Letters and numbers stamped on the body of an IC serve to provide which of the following types of information?

1. Use
2. Serial number
3. Date of manufacture
4. Applicable equipment

1-39. Descriptive information about a particular type of IC may be found in which of the following documents?

1. The manufacturer's data sheet
2. The equipment Allowance Part List (APL)
3. The National Stock Number (NSN)
4. The IC identification number list

1-40. Assemblies made up EXCLUSIVELY of discrete electronic parts are classified as

1. vacuum-tube circuits
2. microcircuit modules
3. hybrid microcircuits
4. miniature electronics circuits

1-41. An assembly of microcircuits or a combination of microcircuits and discrete components is referred to as a

1. mother board
2. microprocessor
3. miniature module
4. microcircuit module

1-42. A technician has isolated a problem to a plug-in module on a printed circuit board. What is this level of system packaging?

1. Level O
2. Level I
3. Level II
4. Level III

1-43. A faulty transistor would be identified as what level of packaging?

1. Level O
2. Level I
3. Level II
4. Level III

1-44. A chassis located in a radar antenna pedestal would be identified as what level of system packaging?

1. Level I
2. Level II
3. Level III
4. Level IV

1-45. Which of the following characteristics is NOT an advantage of multilayer printed circuit boards?

1. Allows greater wiring density on boards
2. Provides shielding for a large number of conductors
3. Eliminates complicated wiring harnesses
4. Reduces the number of components per board

1-46. Which of the following circuit connection methods is NOT used in making interconnections on a multilayer printed circuit board interconnection?

1. Terminal lug
2. Clearance hole
3. Layer build-up
4. Plated-through hole

1-47. The most complex to produce and difficult to repair printed circuit boards are those made using which of the following methods?

1. Layer-buildup
2. Clearance-hole
3. Step-down-hole
4. Plated-through-hole

1-48. Environmental performance requirements for ICs are set forth in which of the following publications?

1. 2M repair manual
2. Military Standards
3. System maintenance manuals
4. Manufacturer's data sheet

1-49. Ground planes and shielding are used to prevent which of the following electrical interactions?

1. Cross talk
2. External interference
3. The generation of rf within the system
4. All of the above

1-50. Training requirements for miniature and microminiature (2M) repair personnel was established by which of the following authorities?

1. Chief of Naval Education and Training
2. Chief of Naval Technical Training
3. Chief of Naval Operations
4. Commander, Naval Sea Systems Command

1-51. The standards of workmanship and guidelines for specific repairs to equipment are contained in which of the following Navy publications?

1. Introduction to Microelectronics
2. NAVSHIPS' Technical Manual
3. Electronics Installation and Maintenance Books (EIMB)
4. Miniature/Microminiature (2M) Electronic Repair Program

1-52. A technician is authorized to perform 2M repairs upon satisfactory completion of which of the following types of training?

1. A 2M training class
2. On-the-job training
3. NEETS, Module 14
4. Any electronics class "A" school

1-53. Repairs that are limited to discrete components and single- and double-sided boards are classified as what level of repairs?

1. Intermediate
2. Organizational
3. Miniature component
4. Microminiature component

1-54. To ensure that a 2M technician maintains the minimum standards of workmanship, the Navy requires that the technician meet which of the following requirements?

1. Be licensed
2. Be certified
3. Be experienced
4. Be retrained

1-55. If a technician should fail to maintain the required standards of workmanship, the technician's certification is subject to what action?

1. Cancellation
2. Recertification
3. Reduction to next lower level
4. Withholding pending requalification

1-56. The most extensive shop facilities and highly skilled technicians are located at what SM & R level of maintenance?

1. Depot
2. Operational
3. Intermediate
4. Organizational

1-57. SM & R code D maintenance facilities are usually located at which of the following activities?

1. Shipyards
2. Contractor maintenance organizations
3. Shore-based facilities
4. All of the above

1-58. Direct support to user organizations is provided by which of the following SM & R code maintenance levels?

1. Depot
2. Operational
3. Intermediate
4. Organizational

1-59. Inspecting, servicing, and adjusting equipment is the function of which of the following SM & R code maintenance levels?

1. Depot
2. Operational
3. Intermediate
4. Organizational

1-60. The maintenance level at which normal 2M repairs are performed is set forth in the maintenance plan and specified by the

1. NAVSEA 2M Repair Program
2. Source, Maintenance, and Recoverability (SM & R) code
3. Chief of Naval Operations
4. Equipment manufacturers' documentation

1-61. Boards or modules that are SM & R code D may be repaired at the organizational level under which of the following conditions?

1. On a routine basis
2. When parts are available
3. To meet an urgent operational commitment
4. When code D repair will take six weeks or longer

1-62. Source, Maintenance, and Recovery (SM & R) codes that list where repair parts may be obtained, who is authorized to make the repair, and the maintenance level for the item are found in which of the following documents?

1. Allowance Equipage Lists (AEL)
2. Allowance Parts Lists (APL)
3. Manufacturer's Parts List
4. Navy Stock System

1-63. Test equipment that continuously monitors performance and automatically isolates faults to removable assemblies is what category of equipment?

1. On-line
2. Off-line
3. General purpose
4. Fault isolating

1-64. A dc voltmeter that is permanently attached to a power supply for the purpose of monitoring the output is an example of what type test equipment?

1. General Purpose Electronic Test Equipment (GPETE)
2. Built in Test Equipment (BITE)
3. Off-line test equipment
4. Specialized test equipment

1-65. Which of the following types of test equipment is classified as off-line automatic test equipment?

1. Centralized Automatic Test System (CATS)
2. Versatile Avionic Shop Test System (VAST)
3. General Purpose Electronic Test Equipment (GPETE)
4. Test Evaluation and Monitoring System (TEAMS)

1-66. Fault diagnosis using GPETE should only be attempted by which of the following personnel?

1. Officers
2. Technician strikers
3. Experienced technicians
4. Basic Electricity and Electronics school graduates

1-67. During fault isolation procedures, a device or component should be desoldered and removed from the circuit only at which of the following times?

1. After defect verification
2. For out-of-circuit testing
3. During static resistance checks
4. At any time the technician desires

1-68. 2M repair stations are equipped according to the types of repairs to be accomplished. The use of microscopes and precisions drill presses would be required in which of the following types of repair?

1. Miniature
2. Microminiature
3. Both 1 and 2 above
4. Emergency

1-69. In the selection of a soldering iron tip, which of the following factors should be considered?

1. The complexity of the pcb
2. The composition of the pcb
3. The area and mass being soldered
4. The type of component being soldered

1-70. The handpiece that can be used for the greatest variety of operations is the

1. solder extractor
2. rotary-drive tool
3. resistive tweezers
4. lap flow and thermal scraper hand tool

1-71. Regardless of location, 2M repair stations require adequate work surface area, lighting, power, and what other minimum requirement?

1. Heat source
2. Ventilation
3. Illumination
4. Dust-free space

1-72. Solder used in electronics is an alloy composed of which of the following metals?

1. Tin and zinc
2. Tin and lead
3. Lead and zinc
4. Lead and copper

1-73. A roll of solder is marked 60/40. What do these numbers indicate?

1. 60% tin, 40% lead
2. 60% tin, 40% copper
3. 60% lead, 40% tin
4. 60% lead, 40% copper

1-74. Which of the following alloys will melt directly into a liquid and have no plastic or semiliquid state?

1. Metallic alloy
2. Eutectic alloy
3. Zinc-lead alloy
4. Copper-zinc alloy

1-75. The PREFERRED solder alloy ratio for electronic repair is 63/37. Which of the following alloy ratios is also ACCEPTABLE for this type of repair?

1. 30/70
2. 50/50
3. 60/40
4. 70/30

ASSIGNMENT 2

Textbook assignment: Chapter 3, "Miniature and Microminiature Repair Procedures," pages 3-1 through 3-51.

2-1. Which of the following requirements must be met by a 2M technician to be authorized to perform repairs at a particular level?

1. Have knowledge of that level
2. Be certified at that level
3. Be experienced at that level
4. Be licensed at the next higher level

2-2. Protective materials applied to electronic assemblies to prevent damage caused by corrosion, moisture, and stress are called

1. conformal coatings
2. isolation materials
3. electrical insulation
4. encapsulation coatings

2-3. Before working on a pcb, the conformal coating should be removed from what part of the board?

1. The entire board
2. The component side
3. The area of the repair
4. The side opposite the component side

2-4. What are the approved methods of conformal coating removal?

1. Peeling and abrading
2. Stripping and heating
3. Mechanical and thermal only
4. Mechanical, thermal, and chemical

2-5. Most methods of conformal coating removal are variations of which of the following types of removal?

1. Thermal
2. Chemical
3. Mechanical
4. Electrical

2-6. What is the preferred method of removing epoxy conformal coatings?

1. Solvent
2. Ball mill
3. Hot-air jet
4. Thermal parting tool

2-7. A conformal coating is considered to be thin if it is less than what thickness?

1. 0.025 inches
2. 0.040 inches
3. 0.050 inches
4. 0.250 inches

2-8. Of the various mechanical methods of conformal coating removal, physical contact with the work piece is NOT required using which of the following methods?

1. Cutting
2. Grinding
3. Hot-air jet
4. Thermal parting

2-9. Cutting and peeling is an easy method of removing which of the following types of coatings?

1. Epox
2. Varnish
3. Parylene
4. Silicone

2-10. Thin acrylic coatings are readily removed in which of the following ways?

1. Routing
2. Hot-air jet
3. Cut and peel
4. Mild solvents

2-11. When you are applying an application of conformal coating, which of the following conditions is true?

1. The board should be clean and moist
2. The coating should be applied only to the component replaced
3. The coating should be the same type as that used by the manufacturer
4. The coating should be applied only to the solder joints

2-12. The procedure of connecting circuitry on one side of a board with the circuitry on the other side is known as

1. mounting
2. termination
3. hole reinforcement
4. interfacial connections

2-13. Reinforcement for circuit pads on both sides of the board is provided by which of the following types of eyelets?

1. Flat-set
2. Roll-set
3. Funnel-set

2-14. The manner in which wires and leads are attached to an assembly is described by which of the following terms?

1. Termination
2. Solder joints
3. Lead formation
4. Interfacial connections

2-15. Clinched leads, straight-through leads, and offset pads are variations of what type of termination?

1. Solder cup
2. On-the-board
3. Above-the-board
4. Through-hole

2-16. What total number of degrees of bend are (a) fully clinched leads and (b) semiclinched leads?

1. (a) 45 (b) 90
2. (a) 45 (b) 45
3. (a) 90 (b) 45
4. (a) 90 (b) 90

2-17. Which of the following types of terminals are used as tie points for interconnecting wiring?

1. Pins
2. Hooks
3. Solder cups
4. Turrets

2-18. During assembly, component stability is provided by which of the following types of lead termination?

1. Hook terminal
2. Clinched lead
3. Turret terminal
4. On-the-board (lap-flow)

2-19. Which of the following types of lead terminations is the easiest to remove and rework?

1. Offset-pad
2. Semiclinched
3. Fully clinched
4. Straight-through

2-20. Turret, fork, and hook terminals are examples of what type of termination?

1. Off-set
2. On-the-board
3. Above-the-board
4. Through-the-board

2-21. When a lead is soldered to a pad without passing it through the board, what type of termination has been made?

1. Lap-flow
2. Off-set pad
3. Clinched lead
4. Straight-through lead

2-22. Most damage to printed circuit boards occurs at which of the following times?

1. During troubleshooting
2. During component removal
3. During component replacement
4. During normal system operations

2-23. Of the solder removal methods listed below, which one is most versatile and reliable?

1. Wicking
2. Heat and shake
3. Motorized solder extractor
4. Manually controlled vacuum plunge

2-24. When you are removing solder with a solder wick, where should the wick be placed in relation to the solder joint and the iron?

1. Below both the joint and the iron
2. Between the joint and the iron
3. Above the joint and the iron

2-25. The motorized solder extractor may be operated in three different modes. Which of the following is NOT one of those modes?

1. Hot-air jet
2. One-shot vacuum
3. Heat and vacuum
4. Heat and pressure

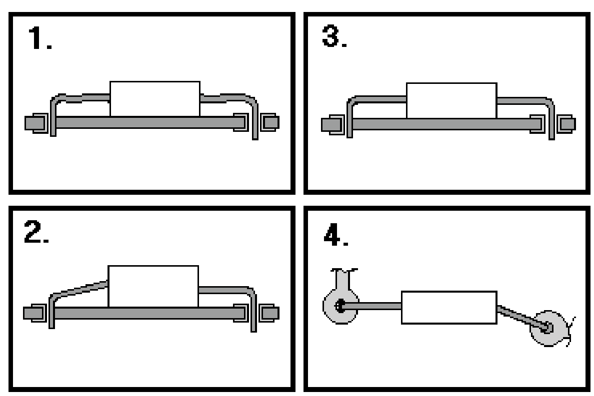
2-26. Stirring the lead during desoldering prevents which of the following unwanted results?

1. Sweat joints
2. Overheating
3. Cold solder joints
4. Pad delamination

2-27. Of the following solder removal methods, which one is acceptable for removing solder?

1. Hot-air jet
2. Heat and pull
3. Heat and shake
4. Heat and squeeze

2-28. Which of the following examples represents properly formed leads?



2-29. A 2M technician is repairing a board that is manufactured with semiclinched leads. What type of termination should the technician use in replacing components?

1. Lap flow
2. Clinched lead
3. Semiclinched lead
4. Straight-through-lead

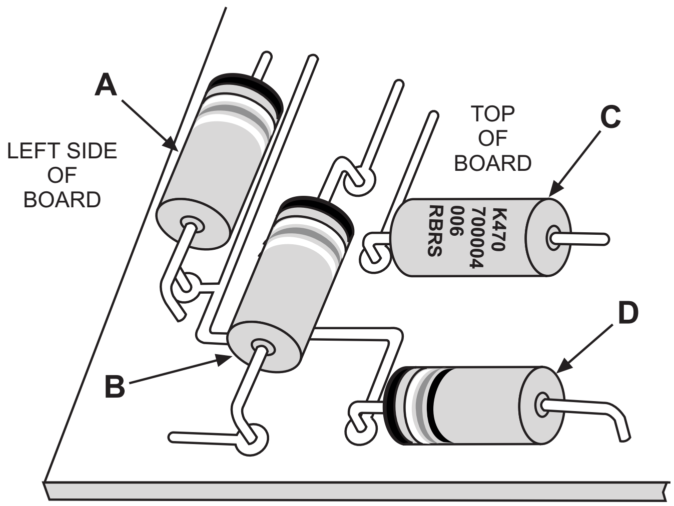


Figure 2A.—Component mounting.

IN ANSWERING QUESTION 2-30, REFER TO FIGURE 2A.

2-30. What component on the board is NOT properly mounted?

1. A
2. B
3. C
4. D

2-31. What type of heat source is a soldering iron?

1. Radiant
2. Resistive
3. Conductive
4. Convective

2-32. The shape and size of the soldering iron tip to be used is determined by which of the following factors?

1. The type of flux to be used
2. The type of work to be done
3. The type of solder to be used
4. The voltage source for the iron

2-33. A thermal shunt is attached to the leads of a transistor prior to applying solder to the joint. This shunt serves what purpose?

1. Prevents short circuits
2. Retains heat at the joint
3. Conducts heat away from the component
4. Physically supports the lead during soldering

2-34. What is the appearance of a good solder joint?

1. Dull gray
2. Crystalline
3. Bright and shiny
4. Shiny with small pits

2-35. What is the most efficient soldering temperature?

1. 360°F
2. 440°F
3. 550°F
4. 800°F

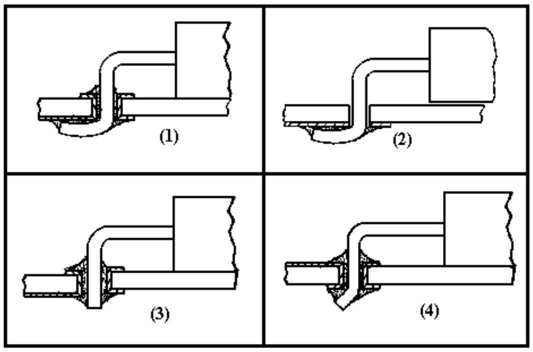

Figure 2B. —Solder joints.

IN ANSWERING QUESTION 2-36, REFER TO FIGURE 2B.

2-36. All the solder joints in the figure have two things in common. The first is that all are through-the-board terminations. The other is that they are all what type of joint?

1. Sweat
2. Full-fillet
3. Unacceptable
4. Clinched-lead

2-37. Plug-in DIPs are mounted by using which of the following aids/parts?

1. Insulators
2. Special tools
3. Clinched leads
4. Mounting sockets

2-38. Plug-in DIPs are susceptible to loosening because of which of the following causes?

1. Heat
2. Stress
3. Warpage
4. Vibration

2-39. Component leads may be clipped to aid in their removal under which of the following conditions?

1. When the component is conformally coated
2. When the component is known to be defective
3. When board damage may result from normal removal methods
4. Both 2 and 3 above

2-40. Visual inspection of a completed repair is conducted to evaluate which of the following aspects of the repair?

1. Workmanship quality
2. Component placement
3. In-circuit quality test
4. Conformal coating integrity

2-41. When speaking of TO mounting techniques, the term "plug-in" refers to the same technique as is used with DIPs.

1. True
2. False

2-42. In addition to heat dissipation and physical support, which of the following needs might justify the use of a spacer with a TO mount?

1. Vibration elimination
2. Proper lead formation
3. Proper lead termination
4. Short-circuit protection

2-43. For the removal of imbedded TOs in which all the leads are free, which of the following methods is recommended?

1. Push out gently
2. Pull out with pliers
3. Pull out with fingers
4. Tap out with soft mallet

2-44. What is the most critical step in replacing an imbedded TO?

1. Seating the leads
2. Forming the leads
3. Soldering the leads
4. Seating the body of the TO

2-45. When a TO or a DIP is replaced on a printed circuit board, what type of termination is normally used?

1. Lap flow
2. On-the-board
3. Above-the-board
4. Through-the-board

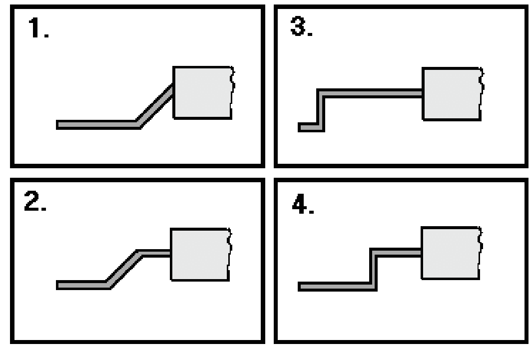
2-46. What type of termination is used in the replacement of a flat pack?

1. Lap flow
2. Solder cup
3. Solder plug
4. Full fillet

2-47. Heating the leads and lifting them free with tweezers is the preferred method of removing which of the following components?

1. TOs
2. DIPs
3. Flat packs
4. Transistors

2-48. Which of the examples shows the correct lead formation for a flat pack?



2-49. Use of a skipping pattern when soldering multilead components prevents

1. cold solder joints
2. excessive heat buildup
3. the component from moving
4. the need to visually inspect the piece

2-50. Cards and boards may be damaged under which of the following conditions?

1. When unauthorized repairs are attempted by untrained personnel
2. When technicians use improper tools
3. When improperly stored
4. Each of the above

2-51. DS3 Spark is preparing to repair a cracked conductor on a card. For this type of damage, which of the following repair methods is preferred?

1. Solder bridge
2. Clinched staple
3. Install an eyelet at the crack and solder in place
4. Lap-flow soldered wire across the break

2-52. To ensure a good mechanical bond between the board and replacement pad and to provide good electrical contact for components, you should use which of the following procedures?

1. Epoxying the pad to the run
2. Electroplating the repair area
3. Installing an eyelet in the pad
4. Lap-flow soldering the repair area

2-53. Breaks, holes, and cracks in pcbs are repaired by using a mixture of

1. fiberglass and rosin
2. epoxy and powdered carbon
3. conformal coating and RTV
4. epoxy and powdered fiberglass

2-54. What is the first step in the repair of burned or scorched boards?

1. Filling the burned area with epoxy and fiberglass
2. Removing all discolored material
3. Removing all delaminated conductors
4. Cleaning all surfaces with solvent

2-55. Which of the following statements is correct concerning the repair of repairable delaminated conductors?

1. All delaminations are removed
2. Repairable delaminations are not removed
3. All delaminations are epoxied to the board
4. All delaminations are replaced with insulated wire

2-56. Damage to some electronic components can occur at what minimum electrostatic potential?

1. 14 volts
2. 35 volts
3. 350 volts
4. 3,500 volts

2-57. Electrostatic discharge (ESD) has the greatest effect on which of the following devices?

1. Silicon diodes
2. Selenium rectifiers
3. Germanium transistors
4. Metal-oxide transistor

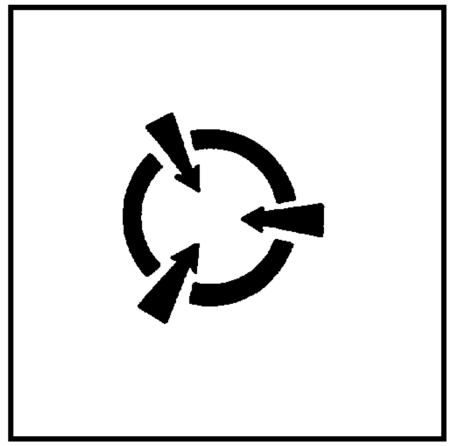


Figure 2C. —Symbol.

IN ANSWERING QUESTION 2-58, REFER TO FIGURE 2C.

2-58. The symbol shown in the figure is found on a component package. What does it indicate about the component?

1. It is a high cost item
2. It is a bipolar device
3. It is an integrated circuit
4. It is electrostatic discharge sensitive

2-59. Electrostatic charges may develop as high as which of the following voltages?

1. 3,000 volts
2. 15,000 volts
3. 20,000 volts
4. 35,000 volts

2-60. To prevent an electrostatic charge built up on the body of the technician from damaging ESDS devices, the technician should take which of the following precautions?

1. Be grounded
2. Wear gloves
3. Ground the device
4. Handle the device with insulated tools

2-61. The best source of information concerning the application, handling, and storage of any aerosol dispensers may be found in/on which of the following sources?

1. NAVSEA 2M manual
2. NEETS, Module 14, Topic 3
3. On the aerosol dispenser
4. Applicable military standards

NONRESIDENT
TRAINING
COURSE

Navy Electricity and Electronics Training Series

Module 15—Principles of Synchros, Servos, and Gyros

NAVEDTRA 14187

Notice: NETPDTC is no longer responsible for the content accuracy of the NRTCs.

For content issues, contact the servicing Center of Excellence: Center for Surface Combat System (CSCS); (540) 284-1061 or DSN: 249-1061.

PREFACE

About this course:

This is a self-study course. By studying this course, you can improve your professional/military knowledge, as well as prepare for the Navywide advancement-in-rate examination. It contains subject matter about day-to-day occupational knowledge and skill requirements and includes text, tables, and illustrations to help you understand the information. An additional important feature of this course is its reference to useful information in other publications. The well-prepared Sailor will take the time to look up the additional information.

Training series information:

This is Module 15 of a series.

History of the course:

Sep 1998: Original course released.
Jul 2003: Administrative update release. No significant content changes were made.

NAVSUP Logistics Tracking Number
0504-LP-026-8400

TABLE OF CONTENTS

CHAPTER 1

SYNCHROS

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions placed throughout the chapters are based on the objectives. By successfully completing the Nonresident Training Course (NRTC), you indicate that you have met the objectives and have learned the information. The learning objectives for this chapter are listed below.

Upon completing this chapter, you will be able to:

1. Define the term "synchro."
2. State the primary purpose of a synchro.
3. Explain the importance of synchros in naval equipment.
4. Name the two general classifications of synchros.
5. Explain the differences between torque and control synchros.
6. Name the seven functional classes of synchros and list all inputs and outputs.
7. Name the two types of synchro identification codes.
8. Interpret all synchro markings and identify the particular codes used.
9. Draw the five standard schematic symbols for synchros and identify all connections.
10. Describe the general construction and physical appearance of synchro rotors and stators.
11. Name the two common types of synchro rotors, giving an application of each.
12. List the different synchro characteristics and give a brief explanation of each.
13. State the advantage of using 400-Hz synchros over 60-Hz synchros.
14. Explain the operation of a basic synchro transmitter and receiver.
15. State the difference between a synchro transmitter and a synchro receiver.
16. List the basic components that compose a torque synchro system.
17. Explain the operation of a simple synchro transmission system.
18. Define the term "correspondence" and explain how it is used in a simple synchro system.
19. Explain the principle behind reversing the S1 and S3 leads on a synchro receiver and how this action affects receiver operation.

20. Explain what happens when the rotor leads on a synchro transmitter or receiver are reversed.
21. State the purposes of differential synchros.
22. Name the two types of differential synchros and give a brief explanation of each.
23. Explain the difference between the torque differential transmitter and the torque differential receiver.
24. Name the components that make up the TDX and the TDR synchro systems.
25. Explain how the two differential synchro systems add and subtract.
26. State the wiring changes required to convert the differential synchro systems from subtraction to addition.
27. State the purposes and functions of control synchros.
28. Name the different types of control synchros.
29. Explain how the CX and CDX differ from the TX and TDX.
30. Explain the theory and operation of a control transformer.
31. List the basic components that compose a control synchro system.
32. Explain the operation of a control synchro system and how it is used to control a servo system.
33. State the purpose and function of the synchro capacitor.
34. Explain how synchro capacitors improve the accuracy of synchro systems.
35. Explain the method used to connect synchro capacitors in a circuit.
36. Define single and multispeed synchro systems.
37. State the purposes and functions of multispeed synchro systems.
38. Stale the purposes for zeroing synchros.
39. Name three common synchro zeroing methods and give a brief explanation of each.
40. Explain the different troubleshooting techniques used in isolating synchro malfunctions and breakdowns.

SYNCHRO FUNDAMENTALS

Synchros play a very important role in the operation of Navy equipment. Synchros are found in just about every weapon system, communication system, underwater detection system, and navigation system used in the Navy. The importance of synchros is sometimes taken lightly because of their low failure rate. However, the technician who understands the theory of operation and the alignment procedures for synchros is well ahead of the problem when a malfunction does occur. The term "synchro" is an abbreviation of the word "synchronous." It is the name given to a variety of rotary, electromechanical, position-sensing devices. Figure 1-1 shows a phantom view of typical synchro. A synchro resembles a small electrical motor in size and appearance and operates like a variable transformer. The synchro, like the transformer, uses the principle of electromagnetic induction.

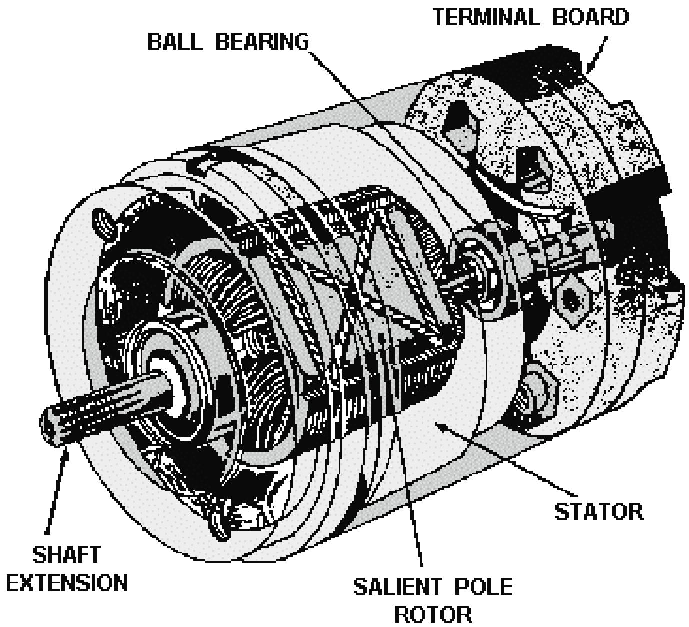

Figure 1-1.—Phantom view of a synchro.

Synchros are used primarily for the rapid and accurate transmission of information between equipment and stations. Examples of such information are changes in course, speed, and range of targets or missiles; angular displacement (position) of the ship's rudder; and changes in the speed and depth of torpedoes. This information must be transmitted quickly and accurately. Synchros can provide this speed and accuracy. They are reliable, adaptable, and compact. Figure 1-2 shows a simple synchro system that can be used to transmit different as of data or information In this system, a single synchro transmitter furnishes information to two synchro receivers located in distant spaces. Operators put information into the system by turning the handwheel. As the handwheel turns, its attached gear rotates the transmitter shaft (which has a dial attached to indicate the value of the transmitted information). As the synchro transmitter shaft turns, it converts the mechanical input into an electrical signal, which is sent through interconnecting wiring to the two synchro receivers. The receiver shafts rotate in response to the electrical signal from the transmitter. When these shafts turn, the dials attached to the shafts indicate the transmitted information.

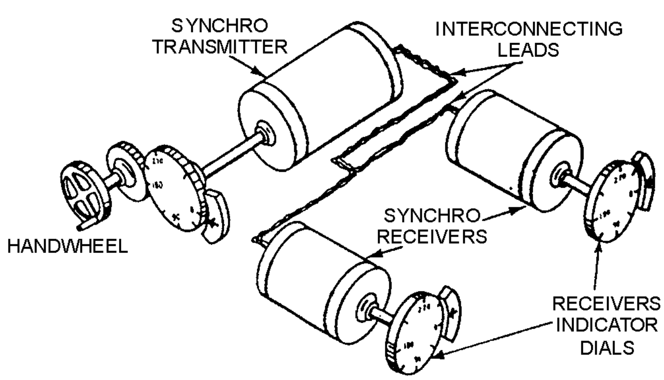

Figure 1-2.—Data transfer with synchros.

By studying the simple synchro system, you can see that information can be transmitted over long distances, from space to space, and from equipment to equipment.

In addition to supplying data by positioning dials and pointers, synchros are also used as control devices in servo systems. When the synchro and the servo are combined, they work as a team to move and position heavy loads. The methods used to accomplish this are covered in detail in the next chapter.

Q-1. What is the name given to a variety of rotary electromechanical, position sensing devices?

Q-2. What is the primary purpose of a synchro system?

SYNCHRO CLASSIFICATION

Synchros work in teams. Two or more synchros interconnected electrically form a synchro system. There are two general classifications of synchro systems—TORQUE SYSTEMS AND CONTROL SYSTEMS. Torque-synchro systems use torque synchros and control-synchro systems use control synchros. The load dictates the type of synchro system, and thus the type of synchro.

Torque-synchro systems are classified "torque" because they are mainly concerned with the torque or turning force required to move light loads such as dials, pointers, or similar indicators. The positioning of these devices requires a relatively low amount of torque. Control synchros are used in systems that are designed to move heavy loads such as gun directors, radar antennas, and missile launchers.

In addition to the two general classifications, synchros are grouped into seven basic functional classes as shown in table 1-1. Four of these are the torque type and three are the control type. Each synchro is described in the table by name, abbreviation, input, output, and the other synchro units that may be connected to it. Generally, torque and control synchros may not be interchanged. The functional operation of each of these seven synchros is covered later in this text.

Table 1-1.—Synchro Information

FUNCTIONAL CLASSIFICATION	ABBREVIATION	INPUT	OUTPUT
Torque transmitter	TX	Mechanical input to rotor (rotor energized from AC source)	Electrical output from stator representing angular position of rotor to TDX, TDR, or TR.
Control transmitter	CX	Same as TX	Same as TX except it is supplied to CDX or CT
Torque differential transmitter	TDX	Mechanical input to rotor, electrical input to stator from TX or another TDX.	Electric output from rotor representing algebraic sum or difference between rotor angle and angle represented by electrical input to TR, TDR, or another TDX.
Control differential transmitter	CDX	Same as TDX except electrical input is from CX or another CDX.	Same as TDX except output to CT or another CDX.
Torque receiver	TR	Electrical input to stator from TX or TDX. (Rotor energized from AC source)	Mechanical output from rotor. Note: Rotor has mechanical inertia damper.
Torque differential receiver	TDR	Electrical input to stator from TX or TDX, another electrical input to rotor from TX or TDX.	Mechanical output from rotor representing algebraic sum or difference between angles represented by electrical inputs. Has inertia damper.
Control transformer	CT	Electric input to stator from CX or CDX, mechanical input to rotor.	Electrical output from rotor proportional to the sine of the angle between rotor position and angle represented by electrical input to stator. Called error signal.
Torque receiver	TRX	Depending on application, same as TX.	Depending on application, same as TX or TR.

Synchros are also classified according to their operating frequency. This classification was brought about by the development of the 400-Hz synchro. Prior to this time, the 60-Hz synchro was the only one in use. Synchro operating frequencies are covered in detail in the section on synchro characteristics.

Q-3. Name the two general classifications of synchro systems.

Q-4. What is the difference between a torque synchro and a control synchro?

Q-5. Using table 1-1, name two synchros that provide a mechanical output.

STANDARD MARKINGS AND SYMBOLS

Synchros used in the Navy can be grouped into two broad categories: MILITARY STANDARD SYNCHROS and PRESTANDARD NAVY SYNCHROS. Military standard synchros conform to specifications that are uniform throughout the armed services. New varieties of equipment use synchros of this type. Prestandard synchros were designed to meet Navy, rather than servicewide, specifications. Each category has its own designation code for identification.

Military Standard Synchro Code

The military standard designation code identifies standard synchros by their physical size, functional purpose, and supply voltage characteristics. The code is alphanumerical and is broken down in the following manner. The first two digits indicate the diameter of the synchro in tenths of an inch, to the next higher tenth. For example, a synchro with a diameter of 1.75 inches has the numeral 18 as its first two digits. The first letter indicates the general function of the synchro and of the synchro system-C for control or T for torque. The next letter indicates the specific function of the synchro, as follows:

LETTER	DEFINITION
D	Differential
R	Receiver
T	Transformer
X	Transmitter

If the letter B follows the specific function designation, the synchro has a rotatable stator. The last number in the designation indicates the operating frequency-6 for 60 Hz and 4 for 400 Hz. The upper-case letter following the frequency indicator is the modification designation. The letter "A" indicates that the synchro design is original. The first modification is indicated by the letter "B." Succeeding modifications are indicated by the letters "C," "D," and so on, except for the unused letters "I," "L," "O," and "Q."

For example, an 18TR6A synchro is an original design, 60-Hz torque receiver with a diameter of between 1.71 and 1.80 inches.

A synchro designated 16CTB4B is the first modification of a 400-Hz control transformer with a rotatable stator and a diameter of between 1.51 and 1.60 inches.

All standard synchros are labeled with such a code. Synchros used in circuits supplied by 26 volts are classified in the same way, except that the symbol 26V is prefixed to the designator (for example, 26V-16CTB4A). Otherwise, a 115 volts source is assumed for the synchro system.

Navy Prestandard Synchro Code

The Navy prestandard designation code identifies prestandard synchros by size and function, using a number and letter combination. Unlike the standard code, the number does not indicate directly the diameter of the synchro. The number merely represents the approximate size of the synchro, increasing as the size increases. The approximate size and weight of the five most common sizes are shown in the following table.

SIZE	APPROX. DIAMETER	APPROX. LENGTH	APPROX WEIGHT
1	2 1/4 in	4 in	2 lb
3	3 1/10 in	5 3/8 in	3 lb
5	3 3/8 to 3 5/8 in	6 1/2 in	5 lb
6	4 1/2 in	7 in	8 lb
7	5 3/4 in	9 in	18 lb

Note that prestandard size 1 is approximately the same size as standard size 23 (2.21 to 2.30 inches in diameter). Prestandard size 3 is approximately the same size as standard size 31. Prestandard size 5 is approximately the same size as standard size 37.

The letters used in the prestandard coding system indicate the function, mounting, or special characteristics of the synchro as shown in the following chart.

LETTER	DEFINITION
G	Transmitter
F	Flange Mounted Receiver (this letter is normally omitted if letters other than H or S occur in type designation)
D	Differential Receiver
DG	Differential Transmitter
CT	Control Transformer
H	High-Speed Unit
B	Bearing Mounted Unit
N	Nozzle Mounted Unit
S	Special Unit

Navy prestandard synchros are rarely used today. They have been replaced by the standard synchro. However, by being familiar with the prestandard coding system, you will be able to identify the older synchros and make correct replacements if necessary.

Q-6. What does the code 26V-11TX4D mean on a synchro nameplate?

Q-7. Which of the two synchro designation codes is indicated by 5DG on a synchro nameplate?

Schematic Symbols

Schematic symbols for synchros are drawn by various manufacturers in many different ways. Only five symbols (as shown in figure 1-3), however, meet the standard military specifications for schematic diagrams of synchros and synchro connections. When a symbol is used on a schematic, it will be accompanied by the military abbreviation of one of the eight synchro functional classifications (TR, TX, TDX, etc.).

The symbols shown in views A and B of figure 1-3 are used when it is necessary to show only the external connections to a synchro, while those shown in views C, D, and E are used when it is important to see the positional relationship between the rotor and stator. The letters R and S, in conjunction with an Arabic number, are used to identify the rotor and stator connections; for example, R1, R2, S1, S2, and S3. The small arrow on the rotor symbol indicates the angular displacement of the rotor; in figure 1-3 the displacement is zero degrees.

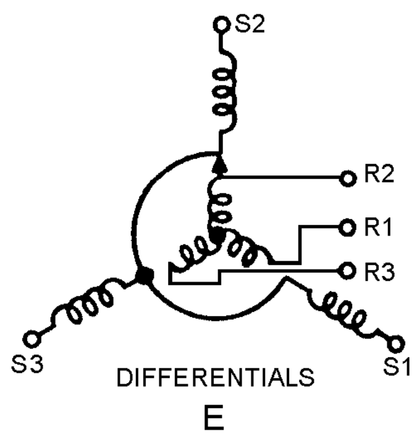

Figure 1-3E.—Schematic symbols for synchros.

Q8. On the synchro schematic symbol, what indicates the angular displacement of the rotor?

SYNCHRO CONSTRUCTION

Figure 1-4 shows a cutaway view of a typical synchro. Having the knowledge of how a synchro is constructed should enable you to better understand how synchros operate.

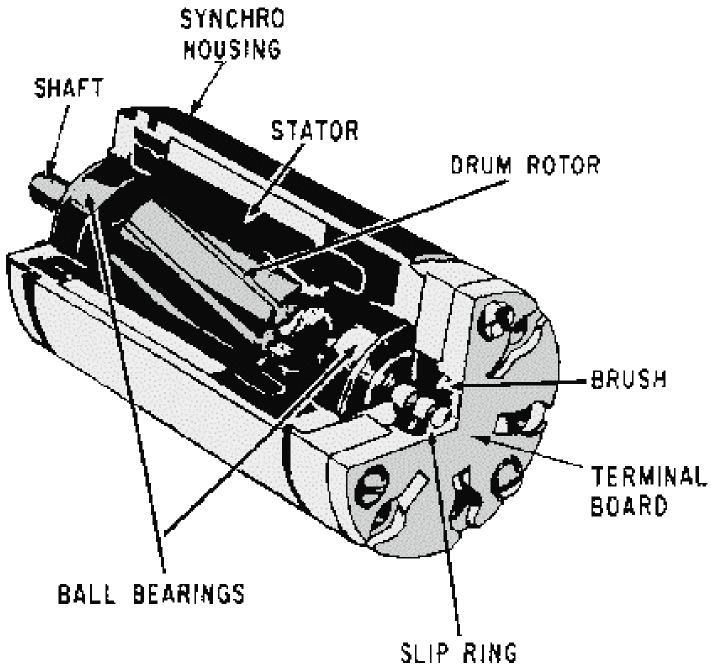

Figure 1-4.—Typical synchro assembly.

In this section we will discuss how rotors and stators are constructed and how the synchro is assembled. Each synchro contains a rotor, similar in appearance to the armature in a motor, and a stator, which corresponds to the field in a motor. The synchro stator is composed of three Y-connected windings (S1, S2, and S3). The rotor is composed of one single winding (R1 and R2). As you can see in the figure, the rotor winding is free to turn inside the stator. The rotor is usually the primary winding and receives its voltage (excitation) from an external voltage source. The stator receives its voltage from the rotor by magnetic coupling.

ROTOR CONSTRUCTION

There are two common types of synchro rotors in use-the SALIENT-POLE ROTOR and the DRUM or WOUND ROTOR. The salient-pole rotor shown in figure 1-5 has a single coil wound on a laminated core. The core is shaped like a "dumb-bell" or the letter "H."

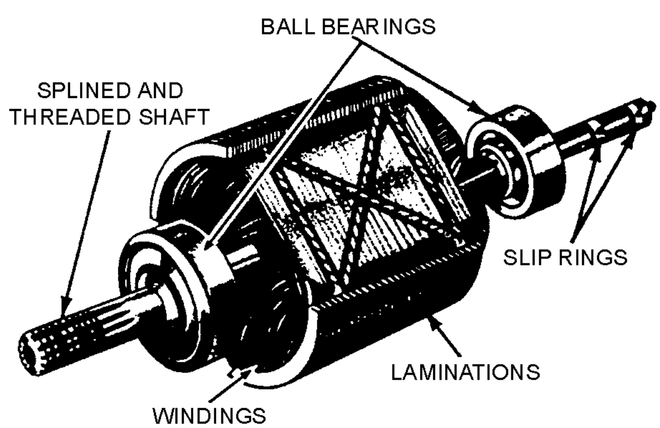

Figure 1-5.—Salient-pole rotor.

This type of winding is frequently used in both transmitters and receivers.

The drum or wound rotor has coils wound in slots in a laminated core as shown in figure 1-6. This type of rotor is used in most synchro control transformers and differential units, and occasionally in torque transmitters. It may be wound continuously with a single length of wire or may have a group of coils connected in series. The single continuous winding provides a distributed winding effect for use in transmitters. When the rotor is wound with a group of coils connected in series, a concentrated winding effect is provided for use in control transformers. When used in differential units, the rotor is wound with three coils so their magnetic axes are 120º apart.

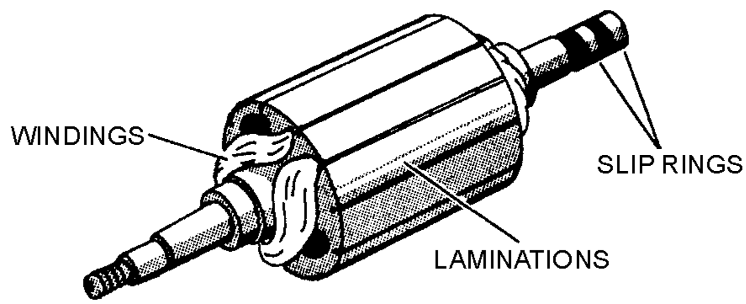

Figure 1-6.—Drum or wound rotor.

Both types of synchro rotors have their coils wound on laminated cores that are rigidly mounted on a shaft. To enable the excitation voltage to be applied to the rotor winding, two slip rings are mounted on one end of the shaft and insulated from the shaft to prevent shorting. An insulated terminal board, mounted on the end of the cylindrical frame, houses the brushes, which ride on the slip rings. These brushes provide continuous electrical contact to the rotor during its rotation. Also mounted on the rotor shaft are low-friction ball bearings, which permit the rotor to turn easily.

STATOR CONSTRUCTION

The stator of a synchro is a cylindrical structure of slotted laminations on which three Y-connected coils are wound with their axes 120º apart. In figure 1-7, view A shows a typical stator assembly consisting of the laminated stator, stator windings, and cylindrical frame; view B shows the stator lamination and the slots in which the windings are placed. Some synchros are constructed so both the stator and the rotor may be turned. Electrical connections to this type of stator are made through slip rings and brushes.

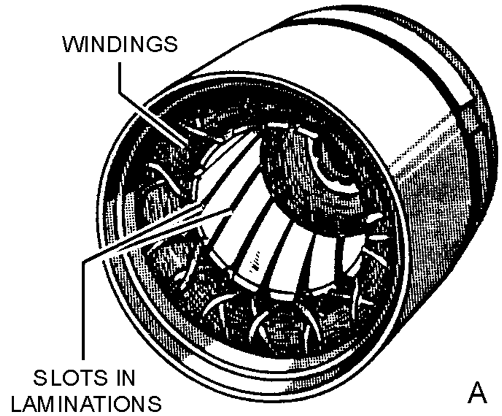

Figure 1-7A.—Typical stator.

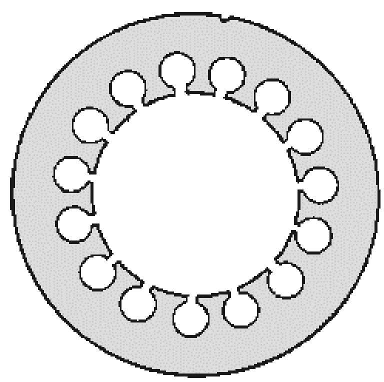

Figure 1-7B.—Stator lamination.

Now, refer to figure 1-4 for a view of a completed synchro assembly. The rotor has been placed in the stator assembly, and a terminal board has been added to provide a point at which internal and external connections can be made.

Q-9. What are the two major components of a synchro?

Q-10. Which of the two main types of rotors can have either a single winding or three Y-connected windings?

Q-11. How does the stator receive its voltage?

Q-12. Where are the external connections made on standard synchros?

SYNCHRO CHARACTERISTICS

Synchro characteristics play a very important part in synchro troubleshooting and maintenance. By closely observing these characteristics, you can generally tell if a synchro or synchro system is working properly. Low torque, overheating, and improper operating voltages are just a few of the abnormal characteristics found in synchro systems. In general, the load capacity of a synchro system is limited by the number and types of receiver units loading the transmitter, the loads on these receiver units, and the operating temperature.

TORQUE

Torque is simply a measure of how much load a machine can turn. In torque synchros, only small loads are turned; therefore, only a small amount of torque is required. The measure of torque is the product of the applied force and the distance between the point of application and the center of rotation. For instance, if a 3 ounce weight is suspended from a synchro pulley having a radius of 2 inches, the torque required to move the weight is 6 ounce-inches. In heavy machinery, torque may be expressed in pound-feet, but torque synchro measurements are in ounce-inches.

NOTE: The unit of torque is the pound-foot or ounce-inch. Do not confuse this with foot-pounds, which is the measurement of work. Many times in referring to torque, tools are marked in foot-pounds. While this use of foot-pounds is technically incorrect, common usage has made it acceptable.

The torque developed in a synchro receiver results from the tendency of two electromagnets to align themselves. Since the rotor can be turned and the stator usually cannot, the stator must exert a force (torque) tending to pull the rotor into a position where the primary and secondary magnetic fields are in line. The strength of the magnetic field produced by the stator determines the torque. The field strength depends on the current through the stator coils. As the current through the stator is increased, the field strength increases and more torque is developed.

Q-13. What major factors determine the load capacity of a torque-synchro transmitter?

Q-14. Define the term "torque."

Q-15. What unit of measurement refers to the torque of a synchro transmitter?

OPERATING VOLTAGES AND FREQUENCIES

Military standard and Navy prestandard synchros are designed to operate on either 115 volts or 26 volts. Synchros used in shipboard equipment are designed predominately for 115 volts, while most aircraft synchros operate on 26 volts.

Synchros are also designed to operate on a 60- or 400-Hz frequency. But like transformers, they are more efficient at the higher frequency. Operating a synchro at a higher frequency also permits it to be made physically smaller. This is because the lines of flux produced by the 400-Hz excitation voltage are much more concentrated than those produced by the 60-Hz excitation voltage. Hence, the core of the 400-Hz synchro can be made smaller than the core of the 60-Hz synchro. However, some 400-Hz synchro units are identical in size to their 60-Hz counterparts. This is done so that 60- and 400-Hz units can be physically interchanged without special mounting provisions. The operating voltage and frequency of each synchro is marked on its nameplate.

The use of the smaller size synchro permits the construction of smaller and more compact equipment. The most widely used frequency for airborne equipment is 400 Hz. It is being used increasingly in shipboard equipment as well. The newer gun and missile fire-control systems use 400-Hz synchros almost exclusively.

A synchro designed for 60-Hz operation may occasionally be used with a 400-Hz supply. There may be considerable loss of accuracy, but the synchro will not be damaged. This should be done only in the case of an emergency when the specified replacement is not available, and system accuracy is not critical.

CAUTION

NEVER connect a 400-Hz synchro to 60-Hz voltage. The reduced impedance results in excessive current flow and the windings quickly burn out.

Q-16. What type of equipment normally uses 26-volt 400-hertz synchros?

OPERATING TEMPERATURES AND SPEEDS

Standard synchros are designed to withstand surrounding temperatures ranging from −67º F to +257º F (-55º C to +125º C) at the terminal board. Prestandard synchros operate in a range of −13º F to +185º F (-25º C to +85º C). When a synchro is energized and not loaded, its temperature should stay within prescribed limits. Loading an energized synchro causes it to generate more heat. Similarly, overloading causes a synchro to generate much more heat than it would under normal loading conditions and could possibly result in permanent synchro damage. To meet military specifications, all standard synchros must be capable of continuous operation for 1,000 hours at 1,200 revolutions per minute (rpm) without a load.

A prestandard synchro has one of two specifications, depending upon its use in a data transmission system. Low-speed prestandard synchros must be capable of continuous operation for 500 hours at 300 rpm without a load. Low-speed prestandard synchros must be capable of continuous operation for 1,500 hours at 1200 rpm without a load.

Q-17. When will a synchro generate more heat than it is designed to handle?

THEORY OF OPERATION

Synchros, as stated earlier, are simply variable transformers. They differ from conventional transformers by having one primary winding (the rotor), which may be rotated through 360º and three stationary secondary windings (the stator) spaced 120º apart. It follows that the magnetic field within the synchro may also be rotated through 360º. If an iron bar or an electromagnet were placed in this field and allowed to turn freely, it would always tend to line up in the direction of the magnetic field. This is the basic principle underlying all synchro operations.

We will begin the discussion of synchro operation with a few basic points on electromagnets. Look at figure 1-8. In this figure, a simple electromagnet is shown with a bar magnet pivoted in the electromagnet's field. In view A, the bar is forced to assume the position shown, since the basic law of magnetism states that like poles of magnets repel and unlike poles attract. Also notice that when the bar is aligned with the field, the magnetic lines of force are shortest. If the bar magnet is turned from this position and held as shown in view B, the flux is distorted and the magnetic lines of force are lengthened. In this condition, a force (torque) is exerted on the bar magnet. When the bar magnet is released, it snaps back to its original position. When the polarity of the electromagnet is reversed, as shown in view C, the field reverses and the bar magnet is rotated 180º from its original position.

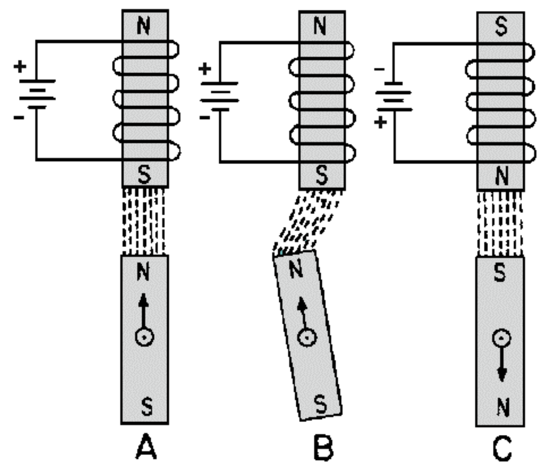

Figure 1-8.—Operation of an electromagnet with a bar-magnet rotor.

Keeping in mind these basic points, consider how the bar magnet reacts to three electromagnets spaced 120º apart as illustrated in figure 1-9. In this figure, stator coils S1 and S3, connected in parallel, together have the same field strength as stator coil S2. The magnetic field is determined by current flow through the coils. The strongest magnetic field is set up by stator coil S2, since it has twice the current and field strength as either S1 or S3 alone. A resultant magnetic field is developed by the combined effects of the three stator fields. Coil S2 has the strongest field, and thus, the greatest effect on the resultant field, causing the field to align in the direction shown by the vector in view B of the figure. The iron-bar rotor aligns itself within the resultant field at the point of greatest flux density. By convention, this position is known as the zero-degree position. The rotor can be turned from this position to any number of positions by applying the proper combination of voltages to the three coils, as illustrated in figure 1-10, view (A), view (B), view (C), view (D), view (E), view (F).

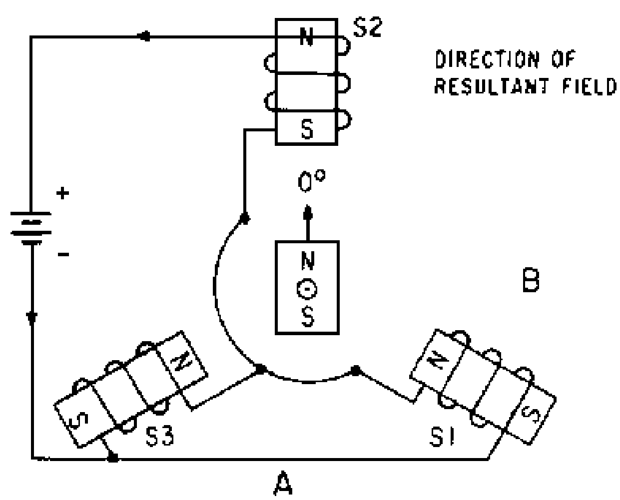

Figure 1-9.—Operation of three electromagnets spaced 120º apart.

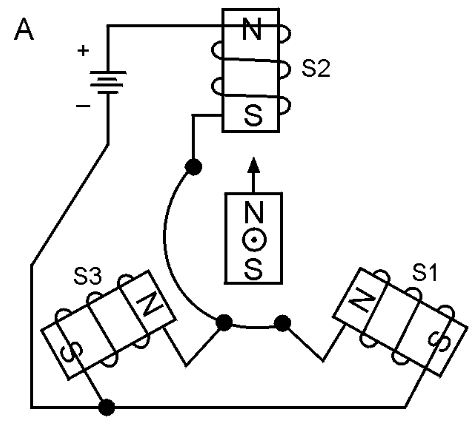

Figure 1-10A.—Positioning of a bar magnet with three electromagnets.

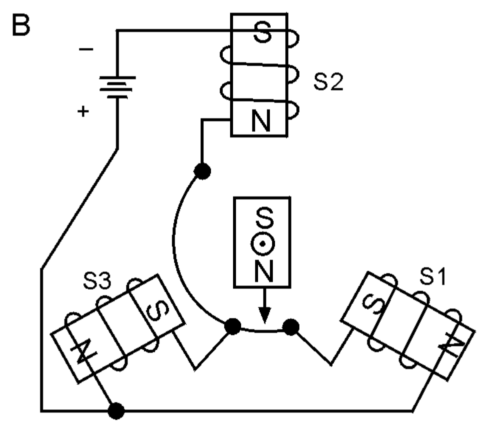

Figure 1-10B.—Positioning of a bar magnet with three electromagnets.

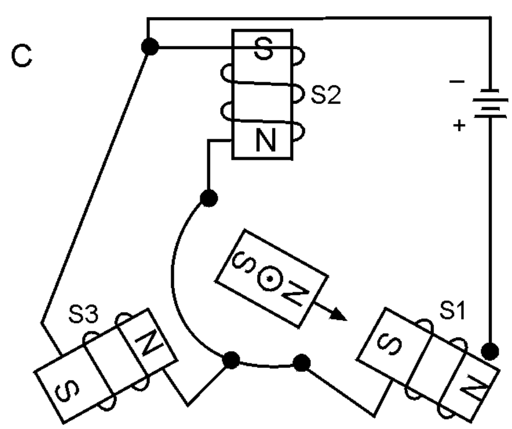

Figure 1-10C.—Positioning of a bar magnet with three electromagnets.

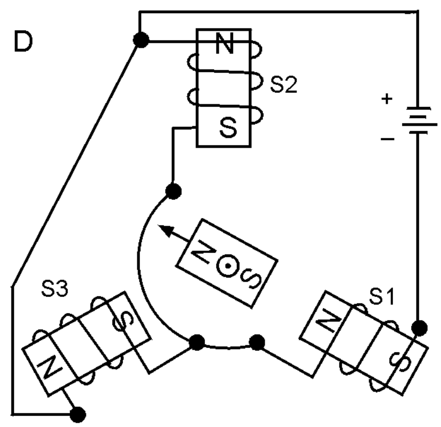

Figure 1-10D.—Positioning of a bar magnet with three electromagnets.

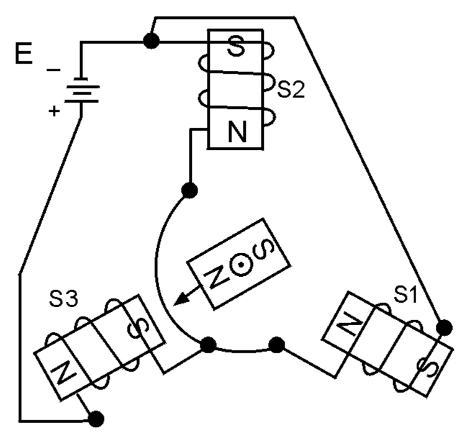

Figure 1-10E.—Positioning of a bar magnet with three electromagnets.

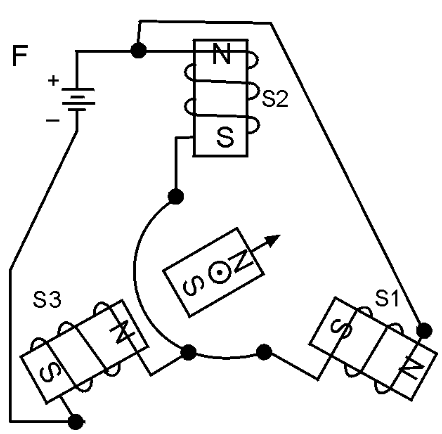

Figure 1-10F.—Positioning of a bar magnet with three electromagnets.

Notice in figure 1-10, in views A C, and E, that the rotor positions are achieved by shifting the total current through different stator windings (S1, S2, and S3). This causes the rotor to move toward the coil with the strongest magnetic field. To obtain the rotor positions in views B, D, and F, it was necessary only to reverse the battery connections. This causes the direction of current flow to reverse and in turn reverses the direction of the magnetic field. Since the rotor follows the magnetic field the rotor also changes direction. By looking closely at these last three rotor positions, you will notice that they are exactly opposite the first three positions we discussed. This is caused by the change in the direction of current flow. You can now see that by varying the voltages to the three stator coils, we can change the current in these coils and cause the rotor to assume any position we desire.

In the previous examples, dc voltages were applied to the coils. Since synchros operate on ac rather than dc, consider what happens when ac is applied to the electromagnet in figure 1-11. During one complete cycle of the alternating current, the polarity reverses twice.

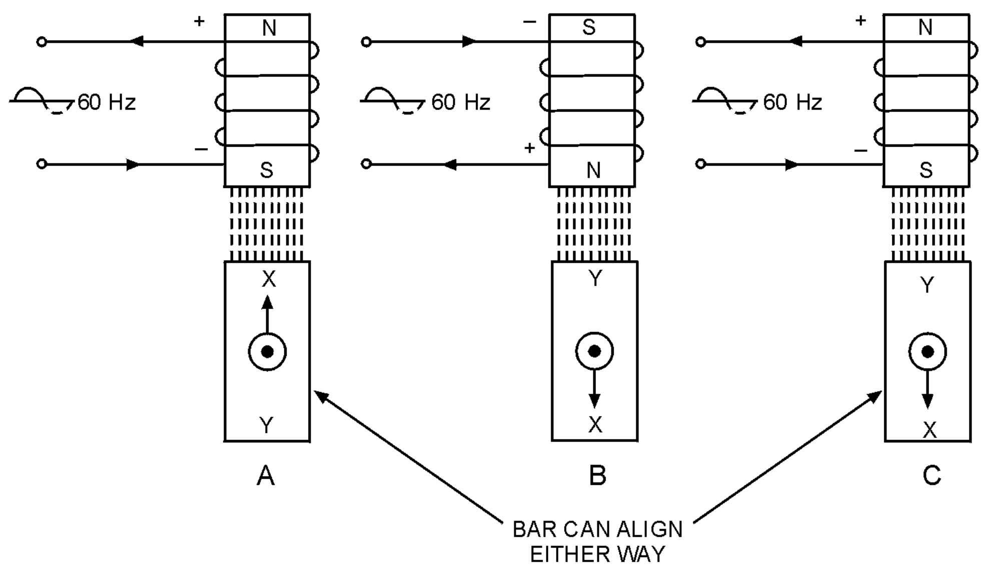

Figure 1-11.—Operation of an electromagnet with ac voltage.

Therefore, the number of times the polarity reverses each second is twice the excitation frequency, or 120 times a second when a 60-Hz frequency is applied. Since the magnetic field of the electromagnet follows this alternating current, the bar magnet is attracted in one direction during one-half cycle (view A) and in the other direction during the next half cycle (view B). Because of its inertia, the bar magnet cannot turn rapidly enough to follow the changing magnetic field and may line up with either end toward the coil (view C). This condition also causes weak rotor torque. For these reasons, the iron-bar rotor is not practical for ac applications. Therefore, it must be replaced by an electromagnetic rotor as illustrated in figure 1-12.

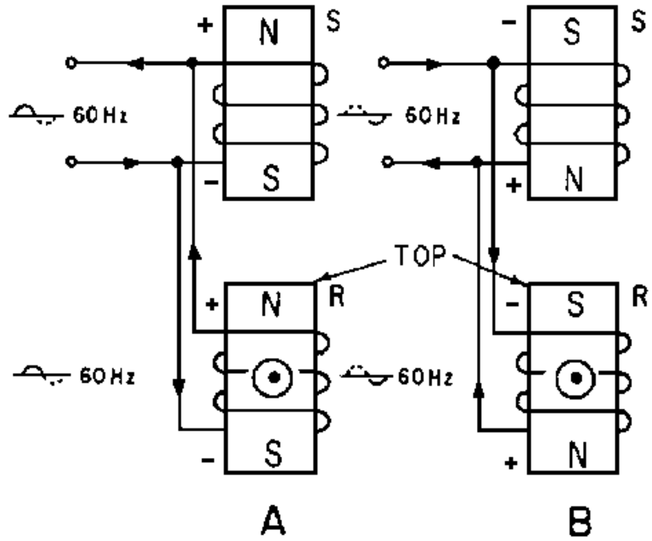

Figure 1-12.—Operation of fixed and moveable electromagnets with ac voltage.

In this figure, both stationary and rotating coils are connected to the same 60-Hz source. During the positive alternation (view A), the polarities are as shown and the top of the rotor is attracted to the bottom of the stationary coil. During the negative alternation (view B), the polarities of both coils reverse, thus keeping the rotor aligned in the same position. In summary, since both magnetic fields change direction at the same time when following the 60-Hz ac supply voltage, the electromagnetic rotor does not change position because it is always aligned with the stationary magnetic field.

Q-18. How do synchros differ from conventional transformers?

Q-19. Describe the zero-position of a synchro transmitter.

SYNCHRO TORQUE TRANSMITTER

The synchro transmitter converts the angular position of its rotor (mechanical input) into an electrical output signal.

When a 115-volt ac excitation voltage is applied to the rotor of a synchro transmitter, such as the one shown in figure 1-13, the resultant current produces an ac magnetic field around the rotor winding. The lines of force cut through the turns of the three stator windings and, by transformer action, induce voltage into the stator coils. The effective voltage induced in any stator coil depends upon the angular position of that coil's axis with respect to the rotor axis. When the maximum effective coil voltage is known, the effective voltage induced into a stator coil at any angular displacement can be determined.

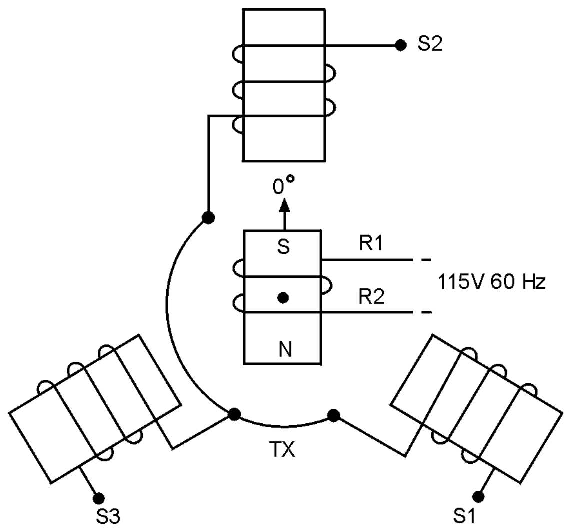

Figure 1-13.—Synchro transmitter.

Figure 1-14 illustrates a cross section of a synchro transmitter and shows the effective voltage induced in one stator coil as the rotor is turned to different positions. The turns ratios in synchros may vary widely, depending upon design and application, but there is commonly a 2.2:1 stepdown between the rotor and a single coil. Thus, when 115 volts is applied to the rotor, the highest value of effective voltage induced in any one stator coil is 52 volts. The maximum induced voltage occurs each time there is maximum magnetic coupling between the rotor and the stator coil (views A, C, and E). The effective voltage induced in the secondary winding is approximately equal to the product of the effective voltage on the primary, the secondary-to-primary turns ratio, and the magnetic coupling between primary and secondary. Therefore, because the primary voltage and the turns ratio are constant, it is commonly said that the secondary voltage varies with the angle between the rotor and the stator.

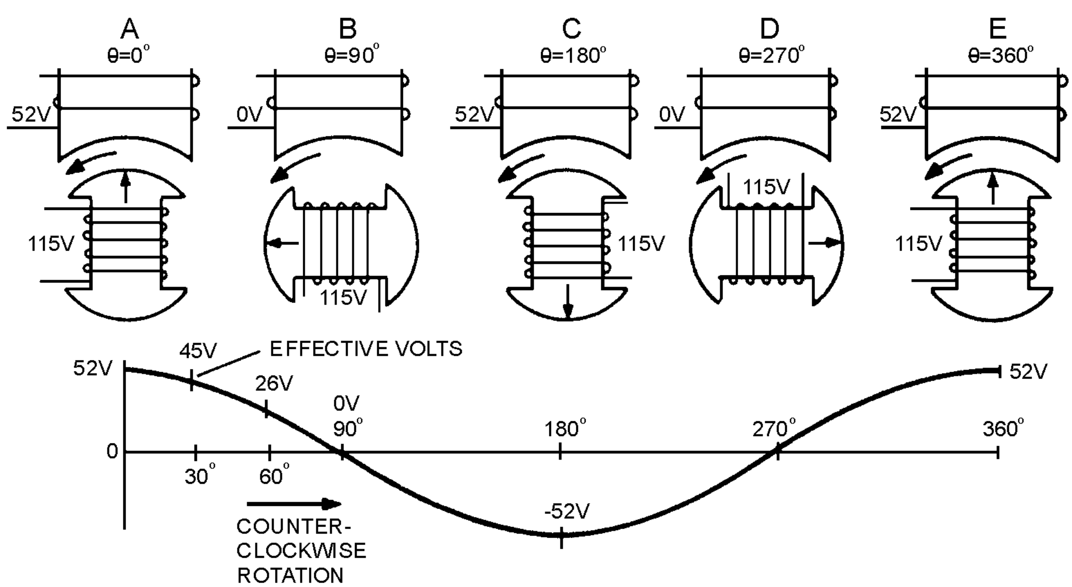

Figure 1-14.—Stator voltage vs rotor position.

When stator voltages are measured, reference is always made to terminal-to-terminal voltages (voltage induced between two stator terminals) instead of to a single coil's voltage. This is because the voltage induced in one stator winding cannot be measured because the common connection between the stator coils is not physically accessible.

In summary, the synchro transmitter converts the angular position of its rotor into electrical stator signals, which are sent through interconnecting wires to other synchro devices.

Q-20. When is the maximum voltage induced into a stator coil?

Q-21. What three factors determine the amplitude of the voltage induced into a stator winding?

SYNCHRO TORQUE RECEIVER

Synchro torque receivers, commonly called synchro receivers, are electrically identical to torque transmitters of the same size except for the addition of some form of damping. In some sizes of 400-Hz synchros, units are designated as torque receivers but may be used as either transmitters or receivers.

Unlike the transmitter, the receiver has an electrical input to its stator and a mechanical output from its rotor. The synchro receiver's function is to convert the electrical data supplied to its stator from the transmitter, back to a mechanical angular position through the movement of its rotor. This function is accomplished when the rotor is connected to the same ac source as the transmitter and assumes a position determined by the interaction of its magnetic field with the magnetic field of the stator. If you recall, this is the same concept discussed earlier under the operation of electromagnets.

Normally, the receiver rotor is unrestrained in movement except for brush and bearing friction. When power is first applied to a system, the transmitter position changes quickly; or if the receiver is switched into the system, the receiver rotor turns to correspond to the position of the transmitter rotor. This sudden motion can cause the rotor to oscillate (swing back and forth) around the synchronous position If the movement of the rotor is great enough, it may even spin. Some method of preventing oscillations or spinning must be used. Any method that accomplishes this task is termed DAMPING.

There are two types of damping methods ELECTRICAL and MECHANICAL. In small synchros the electrical method is used more frequently than the mechanical method. This method uses an additional winding placed in the synchro to retard oscillations. In larger units, a mechanical device, known as an inertia damper, is more effective. Several variations of the inertia damper are in use. One of the more common types consists of a heavy brass flywheel (inertia damper), which is free to rotate around a bushing that is attached to the rotor shaft (fig. 1-15). A tension spring on the bushing rubs against the flywheel so that the bushing and flywheel turn together during normal operation. If the rotor shaft turns or tends to change its speed or direction of rotation suddenly, the inertia of the damper opposes the changing condition.

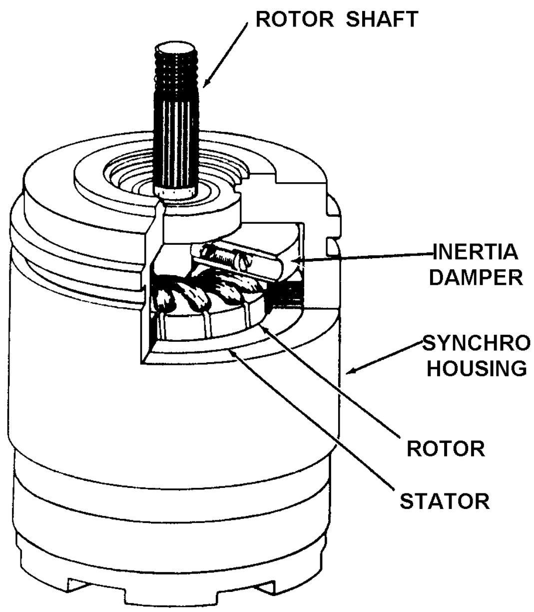

Figure 1-15.—Cutaway view of torque receiver with inertia damper.

Q-22. What is the physical difference between a synchro transmitter and a synchro receiver?

Q-23. What method is used to prevent oscillations in large synchro units?

TORQUE SYNCHRO SYSTEM

A torque transmitter (TX) and a torque receiver (TR) make up a simple torque-synchro system. Basically, the electrical construction of synchro transmitters and receivers is similar, but their intended functions are different. The rotor of a synchro transmitter is usually geared to a manual or mechanical input. This gearing may drive a visual indicator showing the value or quantity being transmitted. The rotor of the receiver synchronizes itself electrically with the position of the rotor of the transmitter and thus responds to the quantity being transmitted.

BASIC SYNCHRO SYSTEM OPERATION

A simple synchro transmission system consisting of a torque transmitter connected to a torque receiver (TX-TR) is illustrated in figure 1-16. As you can see, in this system the rotors are connected in parallel across the ac line. The stators of both synchros have their leads connected S1 to S1, S2 to S2, and S3 to S3, so the voltage in each of the transmitter stator coils opposes the voltage in the corresponding coils of the receiver. The voltage directions are indicated by arrows for the instant of time shown by the dot on the ac line voltage.

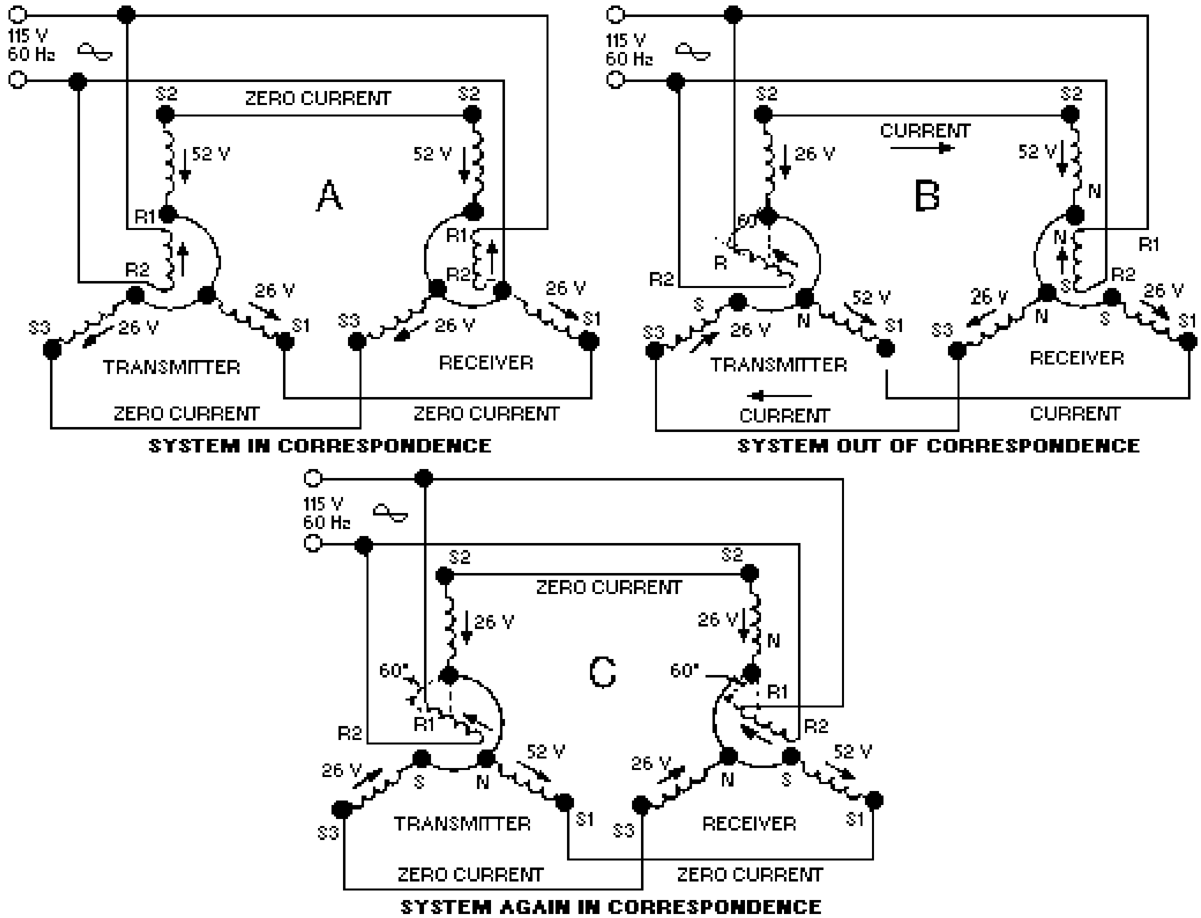

Figure 1-16.—A simple synchro transmission system.

When both transmitter and receiver rotors in a synchro system are on zero or displaced from zero by the same angle, a condition known as CORRESPONDENCE exists. In view A of figure 1-16, the transmitter and receiver are shown in correspondence. In this condition, the rotor of the TR induces voltages in its stator coils (S2 = 52V; S1 and S3 = 26V) that are equal to and opposite the voltages induced into the TX stator coils (S2 = 52V; S1 and S3 = 26V). This causes the voltages to cancel and reduces the stator currents to zero. With zero current through the coils, the receiver torque is zero and the system remains in correspondence.

The angle through which a transmitter rotor is mechanically rotated is called a SIGNAL. In view B of figure 1-16, the signal is 60º. Now, consider what happens to the two synchros in correspondence when this signal is generated

When the transmitter rotor is turned, the rotor field follows and the magnetic coupling between the rotor and stator windings changes. This results in the transmitter S2 coil voltage decreasing to 26 volts, the S3 coil voltage reversing direction, and the S1 coil voltage increasing to 52 volts. This imbalance in voltages, between the transmitter and receiver, causes current to flow in the stator coils in the direction of the stronger voltages. The current flow in the receiver produces a resultant magnetic field in the receiver stator in the same direction as the rotor field in the transmitter. A force (torque) is now exerted on the receiver rotor by the interaction between its resultant stator field and the magnetic field around its rotor. This force causes the rotor to turn through the same angle as the rotor of the transmitter. As the receiver approaches correspondence, the stator voltages of the transmitter and receiver approach equality. This action decreases the stator currents and produces a decreasing torque on the receiver. When the receiver and the transmitter are again in correspondence, as shown in view C, the stator voltages between the two synchros are equal and opposite (S1 = 52V; S2 and S3 = 26V), the rotor torque is zero, and the rotors are displaced from zero by the same angle (60º). This sequence of events causes the transmitter and receiver to stay in correspondence.

In the system we just explained, the receiver reproduced the signal from the transmitter. As you can see, a synchro system such as this could provide a continuous, accurate, visual reproduction of important information to remote locations.

Q-24. What two components make up a simple synchro transmission system?

Q-25. What leads in a simple synchro system are connected to the ac power line?

Q-26. What is the relationship between the transmitter and receiver stator voltages when their rotors are in correspondence?

Q-27. What is the name given to the angle through which a transmitters rotor is mechanically rotated?

Receiver Rotation

When the teeth of two mechanical gears are meshed and a turning force is applied, the gears turn in opposite directions. If a third gear is added, the original second gear turns in the same direction as the first. This is an important concept, because the output of a synchro receiver is often connected to the device it operates through a train of mechanical gears. Whether or not the direction of the force applied to the device and the direction in which the receiver rotor turns are the same depends on whether the number of gears in the train is odd or even. The important thing, of course, is to move the dial or other device in the proper direction. Even when there are no gears involved, the receiver rotor may turn in the direction opposite to the direction you desire. To correct this problem, some method must be used to reverse the receiver's direction of rotation. In the transmitter-receiver system, this is done by reversing the S1 and S3 connections so that SI of the transmitter is connected to S3 of the receiver and vice versa (fig. 1-17), view (A) and view (B).

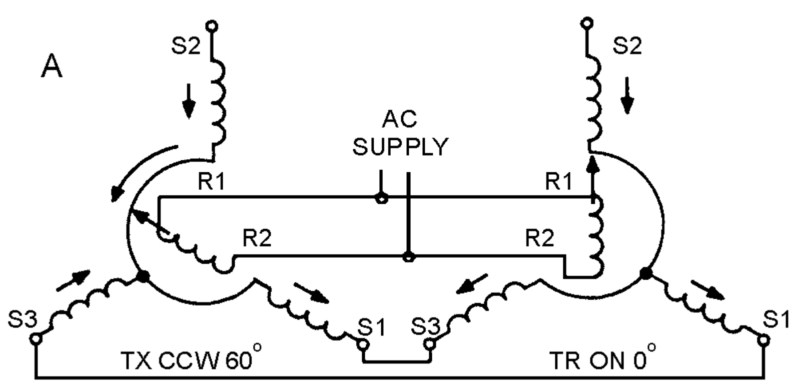

Figure 1-17A.—Effect of reversing the S1 and S3 connections between the transmitter and the receiver.

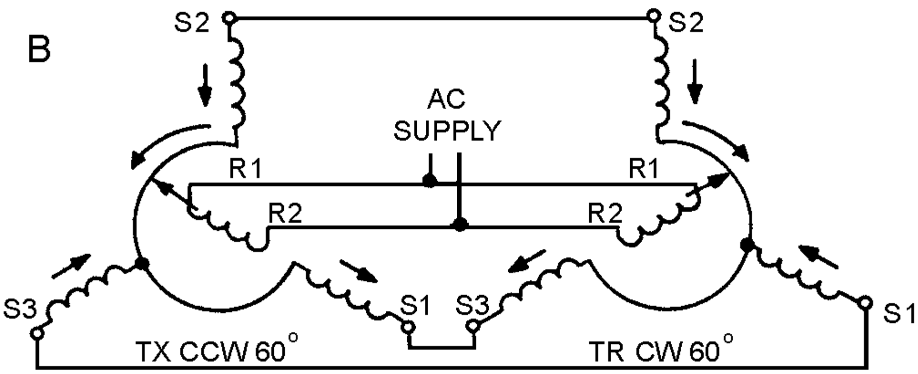

Figure 1-17B.—Effect of reversing the S1 and S3 connections between the transmitter and the receiver.

Even when the S1 and S3 connections are reversed, the system at 0º acts the same as the basic synchro system we previously described at 0º. This is because the voltages induced in the S1 and S3 stator windings are still equal and oppose each other. This causes a canceling effect, which results in zero stator current and no torque. Without the torque required to move the receiver rotor, the system remains in correspondence and the reversing of the stator connections has no noticeable effect on the system at 0º.

Suppose the transmitter rotor is turned counterclockwise 60º, as shown in view A of figure 1-17. The TX rotor is now aligned with S1. This results in maximum magnetic coupling between the TX rotor and the S1 winding. This maximum coupling induces maximum voltage in S1. Because S1 is connected to S3 of the TR, a voltage imbalance occurs between them. As a result of this voltage imbalance, maximum current flows through the S3 winding of the TR causing it to have the strongest magnetic field. Because the other two fields around S2 and S1 decrease proportionately, the S3 field has the greatest effect on the resultant TR stator field. The strong S3 stator field forces the rotor to turn 60º clockwise into alignment with itself, as shown in view B. At this point, the rotor of the TR induces canceling voltages in its own stator coils and causes the rotor to stop. The system is now in correspondence. Notice that by reversing S1 and S3, both synchro rotors turn the same amount, but in OPPOSITE DIRECTIONS.

We must emphasize that the only stator leads ever interchanged, for the purpose of reversing receiver rotation, are S1 and S3. S2 cannot be reversed with any other lead since it represents the electrical zero position of the synchro. As you know, the stator leads in a synchro are 120º apart. Therefore, any change in the S2 lead causes a 120º error in the synchro system and also reverses the direction of rotation.

In new or modified synchro systems, a common problem is the accidental reversal of the R1 and R2 leads on either the transmitter or receiver. This causes a 180º error between the two synchros, but the direction of rotation remains the same.

Q-28. What two receiver leads are reversed to reverse the rotor's direction of rotation?

Q-29. What is the most likely problem if the transmitter shaft reads 0º when the receiver shaft indicates 180º?

TORQUE DIFFERENTIAL SYNCHRO SYSTEMS

The demands on a synchro system are not always as simple as positioning an indicating device in response to information received from a single source (transmitter). For example, an error detector used in checking weapons equipment uses a synchro system to determine the error in a gun's position with respect to the positioning order. To do this, the synchro system must accept two signals, one containing the positioning order and the other corresponding to the actual position of the gun. The system must then compare the two signals and position an indicating dial to show the difference between them, which is the error.

Obviously, the simple synchro transmitter-receiver system discussed so far could not handle a job of this sort. A different type of synchro is needed, one which can accept two signals simultaneously, add or subtract the signals, and furnish an output proportional to their sum or difference. This is where the SYNCHRO DIFFERENTIAL enters the picture. A differential can perform all of these functions.

There are two types of differential units - differential transmitters and differential receivers. The differential transmitter (TDX) accepts one electrical input and one mechanical input and produces one electrical output. The differential receiver (TDR) accepts two electrical inputs and produces one mechanical output. A comparison of the TDX and TDR is shown in figure 1-18. The torque differential transmitter and the torque differential receiver can be used to form a DIFFERENTIAL SYNCHRO SYSTEM. The system can consist either of a torque transmitter (TX), a torque differential transmitter (TDX), and a torque receiver (TR), (TX-TDX-TR); or two torque transmitters (TXs) and one torque differential receiver (TDR), (TX-TDR-TX). Before beginning a discussion of the systems using differentials, we need to provide a brief explanation on the newly introduced synchros, the TDX and the TDR.

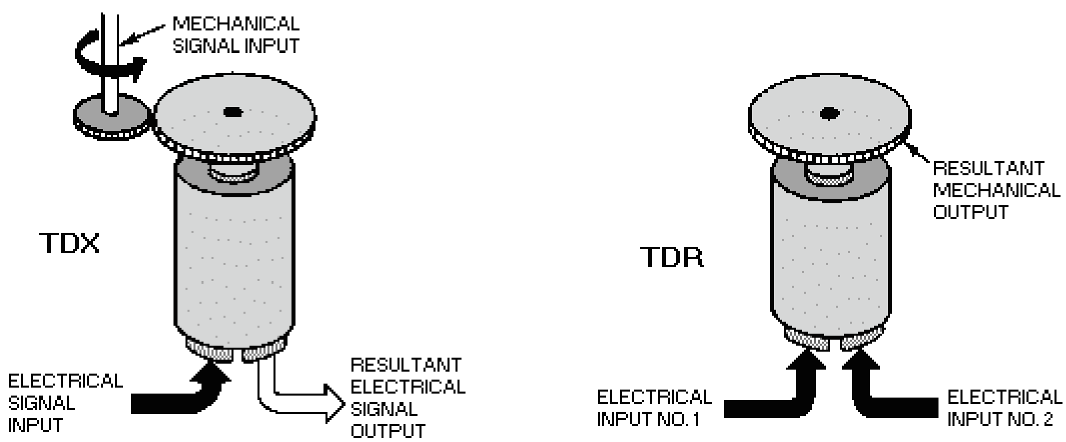

Figure 1-18.—Torque differentials.

Torque Differential Transmitter

In the torque differential transmitter, BOTH the rotor and stator windings consist of three Y-connected coils, as illustrated in view A of figure 1-19. The stator is normally the primary, and receives its input signal from a synchro transmitter. The voltages appearing across the differential's rotor terminals (R1, R2, and R3) are determined by the magnetic field produced by the stator currents, the physical positioning of the rotor, and the step-up turns ratio between the stator and the rotor. The magnetic field, created by the stator currents, assumes an angle corresponding to that of the magnetic field in the transmitter supplying the signal. The position of the rotor controls the amount of magnetic coupling that takes place between the stator magnetic field and the rotor, and therefore, the amount of voltage induced into the rotor windings. If the rotor position changes in response to a mechanical input, then the voltages induced into its windings also change. Therefore, the output voltage of the TDX varies as a result of either a change in the input stator voltage or a change in the mechanical input to the rotor. This electrical output of the TDX may be either the SUM or the DIFFERENCE of the two inputs depending upon how the three units (the TX, the TDX, and the TR) are connected.

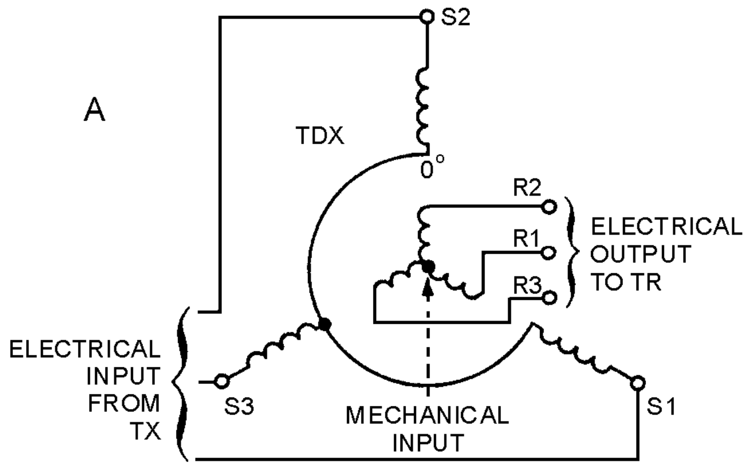

Figure 1-19A.—Torque differential transmitter.

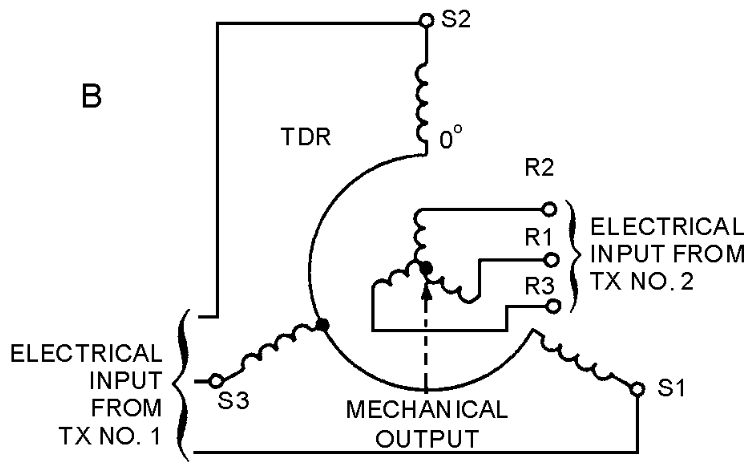

Figure 1-19B.—Torque differential receiver.

Torque Differential Receiver

The torque differential transmitter (TDX) and the torque differential receiver (TDR) are ELECTRICALLY IDENTICAL. The only difference in their construction is that the receiver (TDR) has a damper, which serves the same purposes as the damper in the TR — it prevents the rotor from oscillating. The real difference in the receiver lies in its application. It provides the mechanical output for a differential synchro system usually as the sum or difference of two electrical inputs from synchro transmitters. As in the case with the TDX, the TDR addition or subtraction function depends upon how the units in the system are connected.

Basically, the torque differential receiver operates like the electromagnets we discussed earlier in this chapter. In view B, the rotor and stator of the torque differential receiver receive energizing currents from two torque transmitters. These currents produce two resultant magnetic fields, one in the rotor and the other in the stator. Each magnetic field assumes an angle corresponding to that of the magnetic field in the transmitter supplying the signal. It is the interaction of these two resultant magnetic fields that causes the rotor in the TDR to turn.

Q-30. What is the purpose of using differential synchros instead of regular synchros?

Q-31. What are the two types of differential synchros?

Q-32. Other than their physical differences, what is the major difference between a TDX and a TDR?

Q-33. What determines whether a differential synchro adds or subtracts?

TX-TDX-TR System Operation (Subtraction)

Now that you know how the individual units work, we can continue our discussion with their application in different systems. The following sections explain how the TDX and TDR are used with other synchros to add and subtract.

To understand how a TDX subtracts one input from another, first consider the conditions in a TX-TDX-TR system when all the rotors are on 0º, as in view A of figure 1-20. In this case, the TDX is on electrical zero and merely passes along the voltages applied to its windings without any change. Therefore, the TX stator voltages are felt at the TDX rotor. With the system in perfect balance, the TDX rotor voltages equal and oppose the TR stator voltages so that no current flows in the circuit. Since there is no current to produce the torque required to move the TR rotor, the system will remain in this condition, thus solving the equation 0º – 0º = 0º.

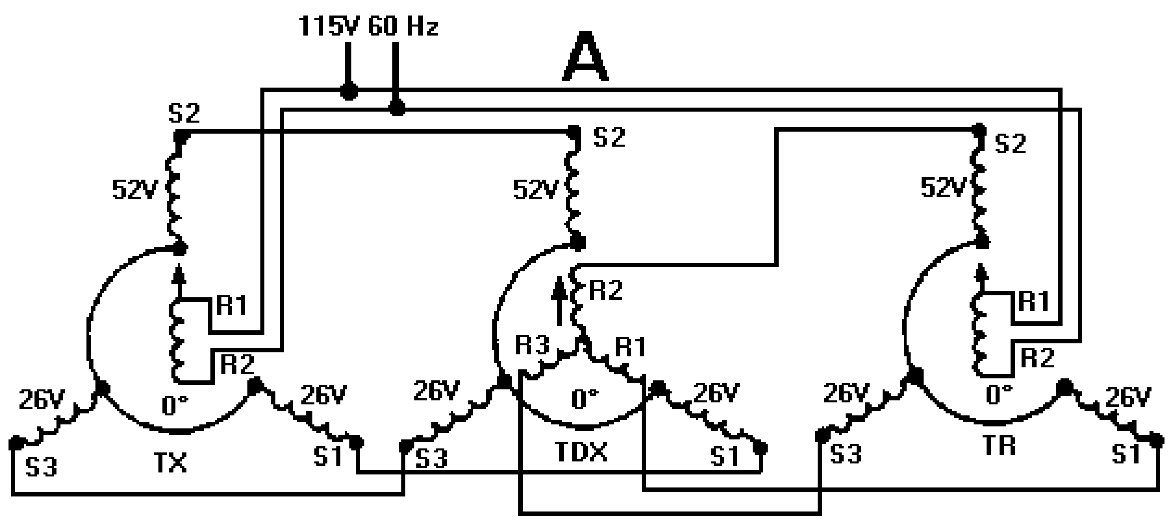

Figure 1-20A.—TX-TDX-TR system operation (subtraction).

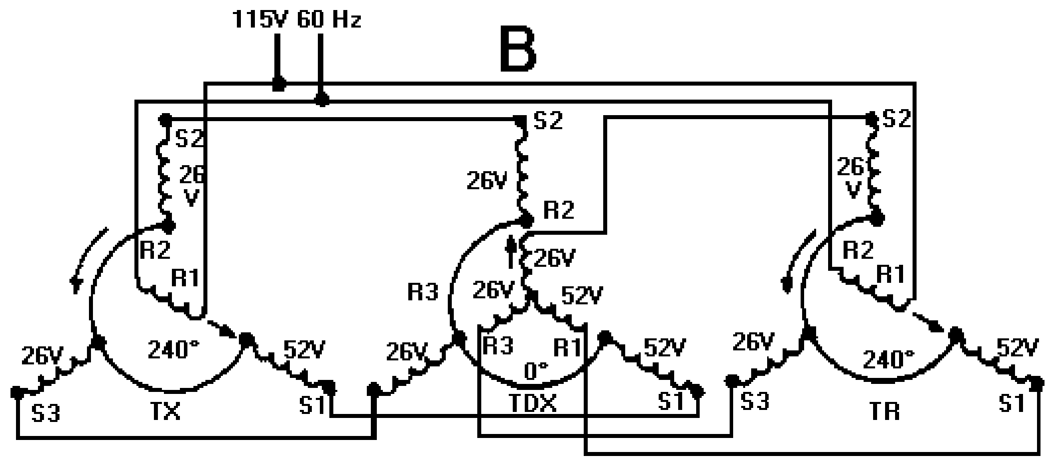

Figure 1-20B.—TX-TDX-TR system operation (subtraction).

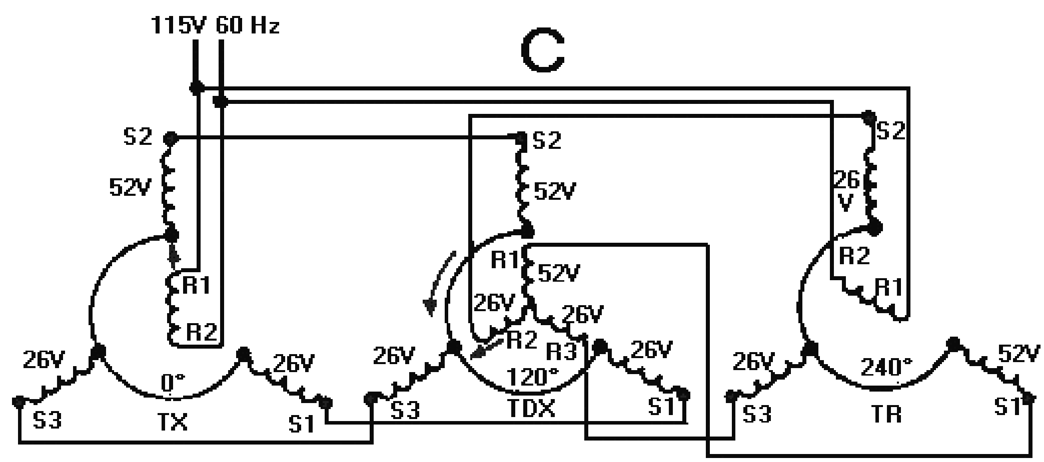

Figure 1-20C.—TX-TDX-TR system operation (subtraction).

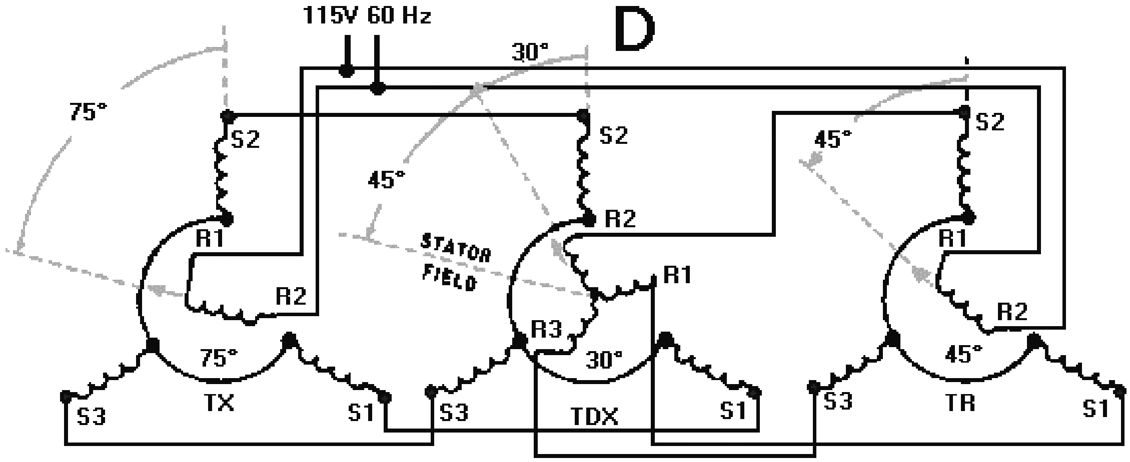

Figure 1-20D.—TX-TDX-TR system operation (subtraction).

Up to this point, we have discussed the number of degrees a rotor is turned. Now, it is important to point out the labeling of synchro positions. Labeling is necessary to determine the actual position of the synchro's rotor. Notice that synchro rotor positions are labeled from 0º, increasing in a counterclockwise direction. It is common practice to refer to a synchro transmitter as being on 120º when its rotor is pointing toward the S3 winding. Do not confuse these positions with the number of degrees a rotor is turned.

Assume that a 240º input is applied to the system, as indicated in view B, by turning the TX rotor to its 240º position. At this position maximum voltage is induced into the S1 winding of the TX and coupled to S1 of the TDX. Since the TDX rotor is on 0º, it passes this maximum voltage (via R1) along to the S1 winding of the TR. The stator magnetic field in the receiver now lines up in the direction of the S1 winding and causes the rotor to turn counterclockwise to the 240º position. This illustrates an important point:

Whenever the TDX rotor is at 0º, the TR rotor follows the TX rotor exactly. In the present case, the system has just solved the equation 240º – 0º = 240º.

Before we go to another example, you need to understand that when you subtract a higher value of degrees from a lower value of degrees, you add 360º to the lower value and subtract directly.

For example: 10º - 260º

Add 360º to lower value: 10º + 360º = 370º

Subtract: 370º – 260º = 110º

In the next example, hold the TX rotor on 0º and turn the TDX rotor to 120º, as illustrated in view C of figure 1-20. In this situation, R1 of the TDX has maximum voltage induced in its winding since it is in line with S2. With R1 of the TDX connected to S1 of the TR, the TR stator magnetic field lines up in the direction of S1 and causes the TR rotor to turn clockwise to the 240º position. Given, then, that the TX is on 360º (or the 0º position), and subtracting the 120º displacement of the TDX rotor, the difference is 240º. This is the position at which the TR rotor comes to rest. Therefore, the system has solved the equation 360º – 120º = 240º. The actual subtraction operation of the TDX is a little more apparent in the next example.

Now, consider what happens in view D when the TX rotor is turned manually to 75º and the TDX rotor is set manually on 30º. When the TX rotor is turned to 75º, magnetic coupling increases between the rotor and S1. This, in turn, increases the voltage in S1 and, therefore, the magnetic field surrounding it. At the same time, the field in S2 and S3 decreases proportionately. This causes the resultant TX stator field to line up in the direction of its rotor. The increased voltage in S1 of the TX also causes an increase in current flow through S1 in the TDX, while decreased currents flow through S2 and S3. Therefore, a strong magnetic field is established around the S1 winding in the TDX. This field has the greatest effect on the resultant TDX stator field and causes it to line up in the same relative direction as the TX stator field (75º). The TDX stator field does not move from this 75º position because it is controlled by the position of the TX rotor. However, its angular position with respect to the R2 winding decreases by 30 when the TDX rotor is turned. Therefore, the signal induced into the TDX rotor and transmitted to the TR is 45º. The TR rotor responds to the transmitted signal and turns counterclockwise to 45º. This system has just solved the equation 75º – 30º = 45º.

TX-TDX-TR System Operation (Addition)

Frequently it is necessary to set up a TX-TDX-TR system for addition. This is done by reversing the S1 and S3 leads between the TX and the TDX, and the R1 and R3 leads between the TDX and the TR. With these connections, the system behaves as illustrated in figure 1-21. Consider what happens when the TX rotor is turned to 75º, while the TDX is set at 0º view A. In the TX, with the rotor at 75º, increased coupling between the rotor and S1 increases the current in, and consequently the magnetic field around, that coil. At the same time, the field strengths of S2 and S3 decrease proportionately. This causes the resultant field of the TX stator to rotate counterclockwise and align itself with its rotor field. The system is now connected so the increased current in S1 of the TX flows through S3 of the TDX, while decreased currents flow through S1 and S2. Therefore, in the TDX, the resultant stator field is shifted 75º clockwise because of the stronger field around S3. Since the rotor of the TDX is on 0º, the voltage in the rotor is not changed but simply passed on to the TR. Remember, the R1 and R3 leads between the TDX and the TR have also been reversed. Just as in the simple TX-TR system with S1 and S3 leads interchanged, torque is developed in the TR, which turns the rotor in a direction opposite to the rotation of the TDX stator field. Therefore, the TR rotor rotates 75º counterclockwise and aligns itself with the TX rotor. Thus, the TX-TDX-TR system connected for addition behaves in the same way as the system connected for subtraction as long as the TDX rotor remains on 0º. When this condition exists, the TR rotor follows the TX rotor exactly. As you can see, the system in view. A just solved the equation 75º + 0º = 75º.

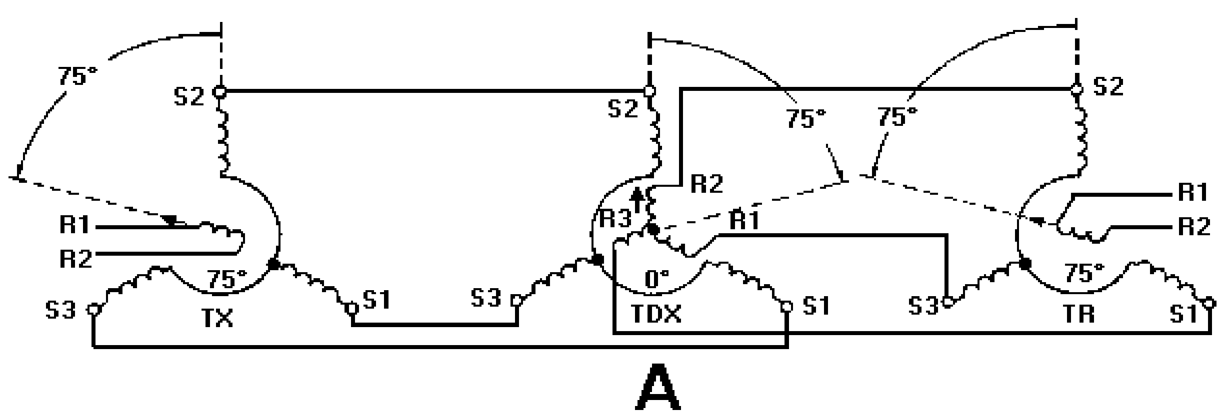

Figure 1-21A.—TX-TR system operation (addition).

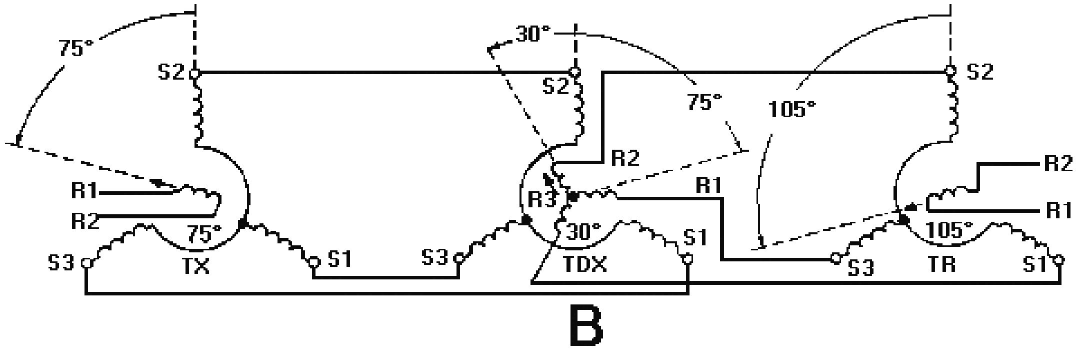

Figure 1-21B.—TX-TR system operation (addition).

Now, with the TX in the same position (75º), the TDX rotor is turned to 30º (view B). The angle between the TDX stator field and R2 is then increased by 30º. This appears to the TR as an additional rotation of the TDX stator field. In transmitting the TX signal to the TR, the TDX adds the amount its own rotor has turned. The TR rotor now turns to 105º. Thus, the equation 75º + 30º = 105º is solved.

Q-34. In a TDX system when does the TR rotor follow the TX rotor exactly?

Q-35. What is the angular position of a TX rotor when it is pointing toward the S1 winding? (Hint. Remember synchros are labeled counter clockwise from 0º.)

Q-36. In a TDX system with standard synchro connections, the TX rotor is at 120º and the TDX rotor is at 40º. What position will the TR indicate?

Q-37. What connections in a TDX system are reversed to set up the system for addition?

TX-TDR-TX System Operation (Subtraction)

As we previously explained, the differential receiver differs chiefly from the differential transmitter in its application. The TDX in each of the previous examples combined its own input with the signal from a synchro transmitter (TX) and transmitted the sum or difference to a synchro receiver (TR). The synchro receiver then provided the system's mechanical output. When the differential receiver (TDR) is used, the TDR itself provides the system's mechanical output. This output is usually the sum or difference of the electrical signals received from two synchro transmitters. Figure 1-22 shows a system consisting of two TXs (No. 1 and No. 2) and a TDR connected for subtraction.

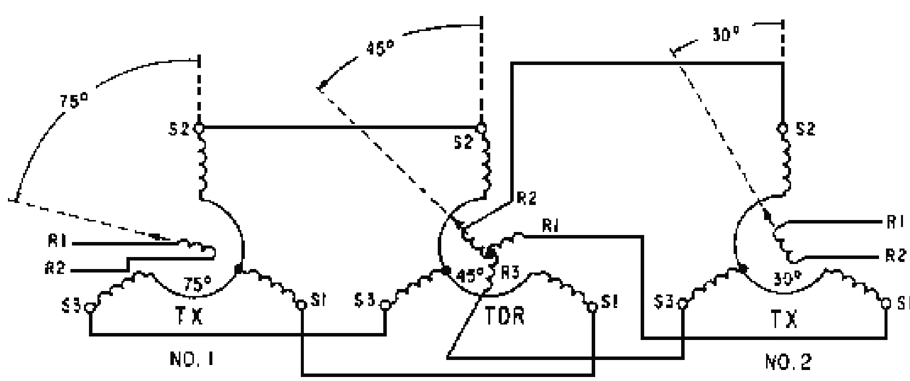

Figure 1-22.—TX-TDR-TX system operation (subtraction).

In this figure the signal from TX No. 1 rotates the resultant TDR stator field 75º counterclockwise. In a similar manner, the signal from TX No. 2 rotates the resultant TDR rotor field counterclockwise 30º. Since the two resultant fields are not rotated by equal amounts, a torque is exerted on the rotor to bring the two fields into alignment. This torque causes the rotor to turn to 45º, the point at which the two fields are aligned. To bring the two fields into alignment, the TDR rotor need turn only through an angle equal to the difference between the signals supplied by the two TXs.

TX-TDR-TX System Operation (Addition)

To set up the previous system for addition, it is necessary to reverse only the R1 and R3 leads between the TDR rotor and TX No. 2. With these connections reversed, the system operates as shown in figure 1-23.

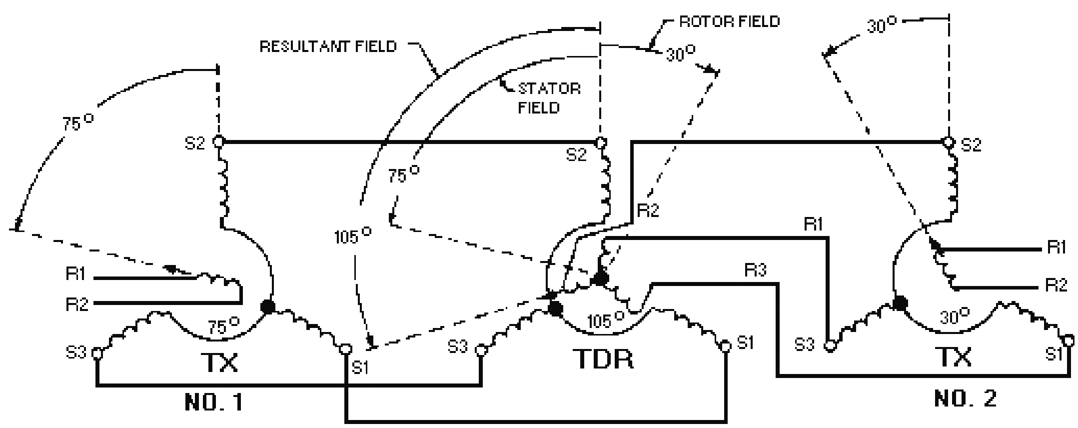

Figure 1-23.—TX-TDR-TX system operation (addition).

Assume the TDR rotor is initially at 0º. TX No. 1 is turned to 75º, and TX rotor No. 2 is turned to 30º. The TDR stator field still rotates counterclockwise 75º, but because R1 and R3 on the TDR rotor are reversed, its rotor field rotates 30º clockwise. The angular displacement of the two fields then, with respect to each other, is the sum of the signals transmitted by the two TXs. The magnetic force pulling the TDR rotor field into alignment with that of the stator turns the TDR rotor to 105º. Therefore, the system solves the equation 75º + 30º = 105º.

Q-38. What connections in a TDR system are reversed to set up the system for addition?

Q-39. In a TDR system connected for addition in what direction will the TDR rotor field turn when the TX rotor to which it is connected turns counterclockwise?

CONTROL SYNCHRO SYSTEMS

It should be clear to you from our discussion of torque synchro systems that, since they produce a relatively small mechanical output, they are suitable only for very light loads. Even when the torque system is moderately loaded, it is never entirely accurate because the receiver rotor requires a slight amount of torque to overcome its static friction.

When large amounts of power and a higher degree of accuracy are required, as in the movement of heavy radar antennas and gun turrets, torque synchro systems give way to the use of CONTROL

SYNCHROS. Control synchros by themselves cannot move heavy loads. However, they are used to "control" servo systems, which in turn do the actual movement. Servo systems are covered in depth in the next chapter in this module.

There are three types of control synchros: the CONTROL TRANSMITTER (CX), the CONTROL TRANSFORMER (CT), and the CONTROL DIFFERENTIAL TRANSMITTER (CDX). The control transmitter (CX) and the control differential transmitter (CDX) are identical to the TX and the TDX we discussed previously except for higher impedance windings in the CX and CDX. The higher impedance windings are necessary because control systems are based on having an internal voltage provide an output voltage to drive a large load. Torque systems, on the other hand, are based on having an internal current provide the driving torque needed to position an indicator. Since we discussed the theory and operation of the TX and the TDX earlier, we will not discuss their counterparts, the CX and CDX. However, we will cover the third control synchro, the CT, in depth during this discussion.

CONTROL TRANSFORMERS

A control transformer is just what its name implies-a control synchro device accurately governing some type of power amplifying device used for moving heavy equipment. Figure 1-24 shows a phantom view of a typical CT and its schematic symbols.

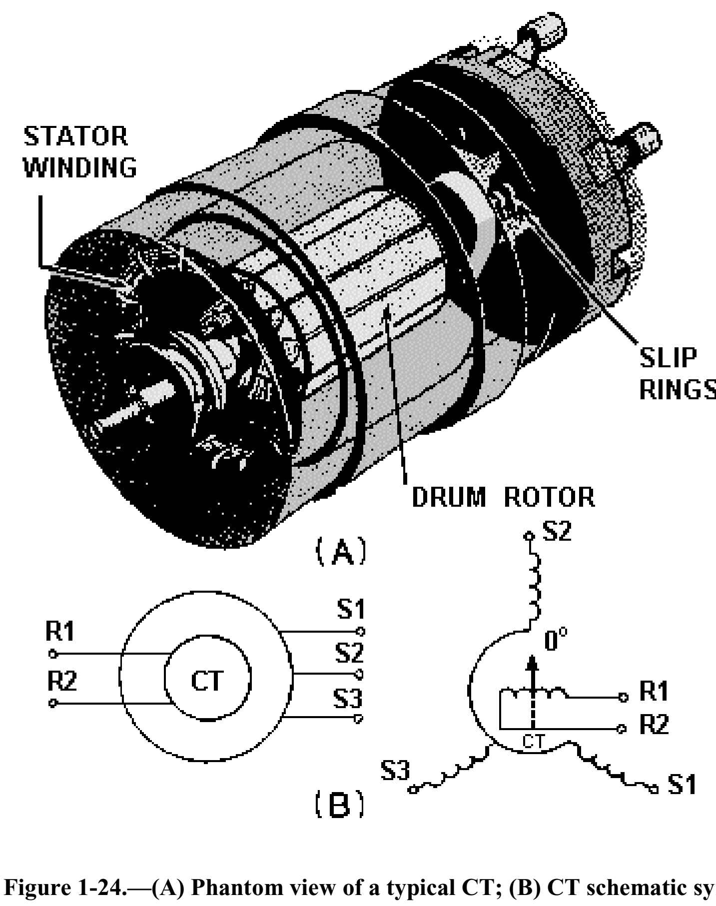

Figure 1-24.—(A) Phantom view of a typical CT; (B) CT schematic symbols.

The CT compares two signals, the electrical signal applied to its stator and the mechanical signal applied to its rotor. Its output is a difference signal that controls a power amplifying device and thus the movement of heavy equipment.

The unit construction and physical characteristics of a control transformer are similar to those of a control transmitter or torque receiver, except that there is no damper and the rotor is a drum or wound rotor rather than a salient-pole rotor.

An interesting point about the rotor is that it is never connected to an ac supply and, therefore, induces no voltages in the stator coils. As a result, the CT stator currents are determined solely by the voltages applied to the high-impedance stator windings. The rotor itself is wound so that its position has very little effect on the stator currents. Also, there is never any appreciable current flowing in the rotor because its output voltage is always applied to a high-impedance load. As a result, the CT rotor does not try to follow the magnetic field of its stator and must be turned by some external force.

The stator windings of the CT are considered to be the primary windings, and the rotor windings the secondary windings. The output, which is taken off the R1 and R2 rotor leads, is the voltage induced in the rotor windings. The phase and amplitude of the output voltage depend on the angular position of the rotor with respect to the magnetic field of the stator.

Q-40. What type of synchro is used in systems requiring large amounts of power and a high degree of accuracy?

Q-41. What are the three types of control synchros?

Q-42. How do the CX and CDX differ from the TX and TDX?

Q-43. What three things prevent a CT rotor from turning when voltages are applied to its stator windings?

CONTROL SYNCHRO SYSTEM OPERATION

A control synchro system consisting of a control transmitter and a control transformer is illustrated in figure 1-25. The stator windings of the CX are connected to the stator windings of the CT and both synchros are shown on 0º. Notice, that at 0º, the CT rotor is perpendicular to its S2 winding. This is contrary to what we have learned so far about synchros, but it is just another peculiarity of the CT. When the rotor of the CX is on 0º, the rotor's magnetic field points straight up as shown (the black arrow). The voltages induced in the CX stator windings, as a result of this field, are impressed on the CT stator windings through the three leads connecting the S1, S2, and S3 terminals. Exciting currents proportional to these voltages flow in the CT stator windings and establish a magnetic field in the CT in the same direction (white arrow) as the magnetic field (black arrow) in the CX. Observe that the rotor of the CT is perpendicular to the stator magnetic field and, therefore, the induced voltage in the rotor is zero, as indicated by the straight line on the oscilloscope presentation.

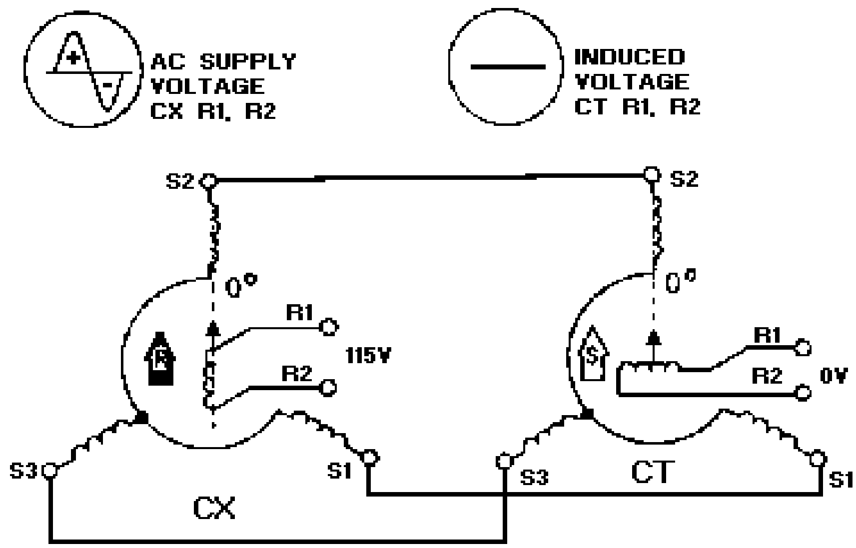

Figure 1-25.—CX-CT system operation with rotor in correspondence.

When the CT rotor is rotated 90º, as shown in figure 1-26, the rotor is parallel to the resultant stator field Maximum magnetic coupling occurs between the rotor and stator fields at this point. As a result of this coupling, the stator windings induce a maximum of 55 volts into the rotor winding. The phase of this voltage depends upon the direction in which the CT rotor is turned. The rotor of the CT is wound so that clockwise rotation of the stator magnetic field induces a voltage across the rotor which is proportional to the amount of rotation and in phase with the ac supply voltage. Counterclockwise rotation of the stator magnetic field produces a voltage that is still proportional to the amount of rotation, but 180º out of phase with the supply voltage. Keep in mind that the clockwise rotation of the CT stator magnetic field is the same as the counterclockwise rotation of the CT rotor. This phase relationship between the ac supply voltage and the CT output voltage becomes more apparent in figure 1-27.

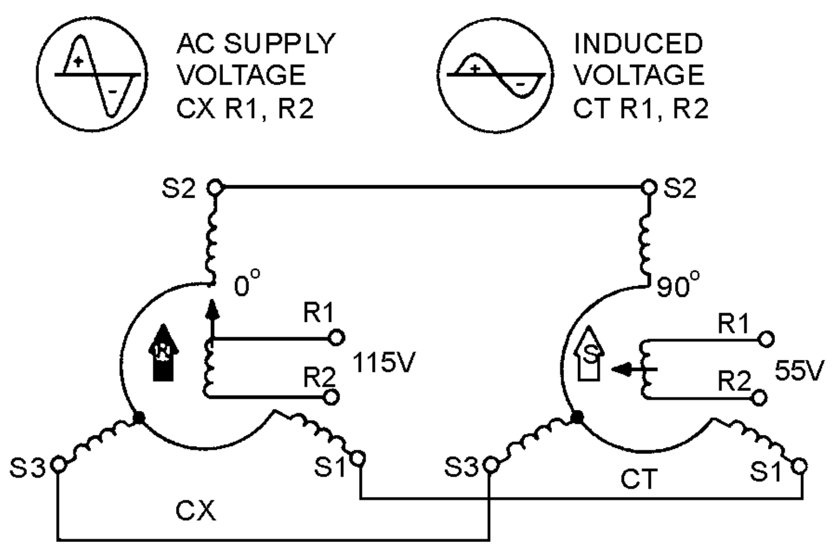

Figure 1-26.—CX-CT system operation with the CX rotor at 0º and the CT rotor at 90º.

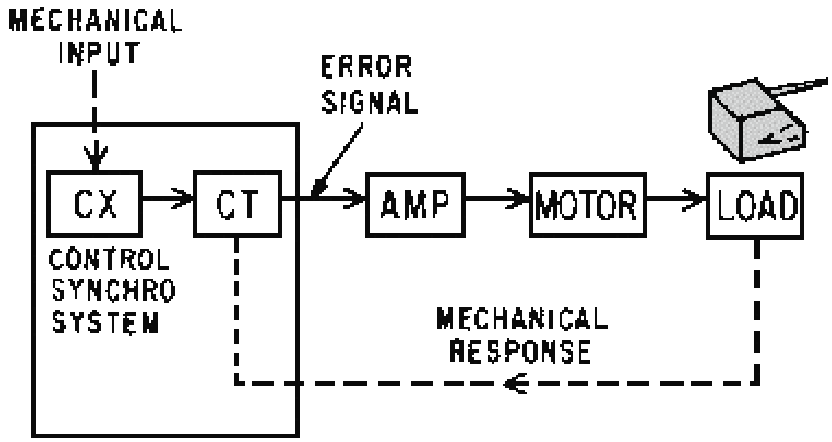

Figure 1-27A.—Control synchro system operation.

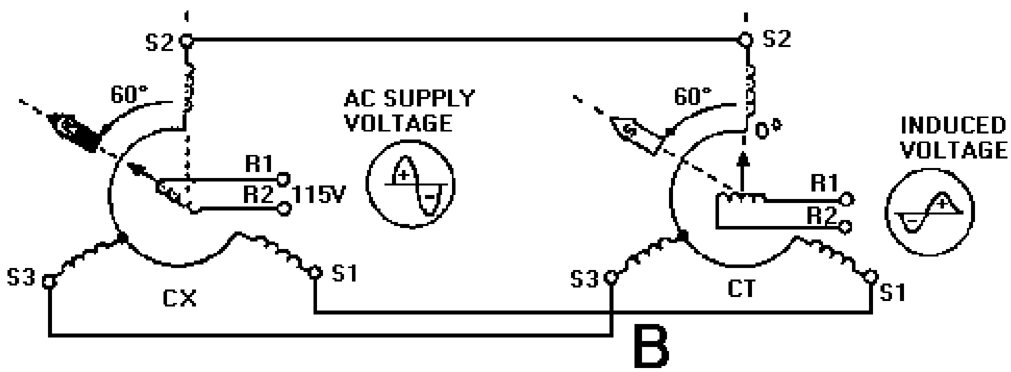

Figure 1-27B.—Control synchro system operation.

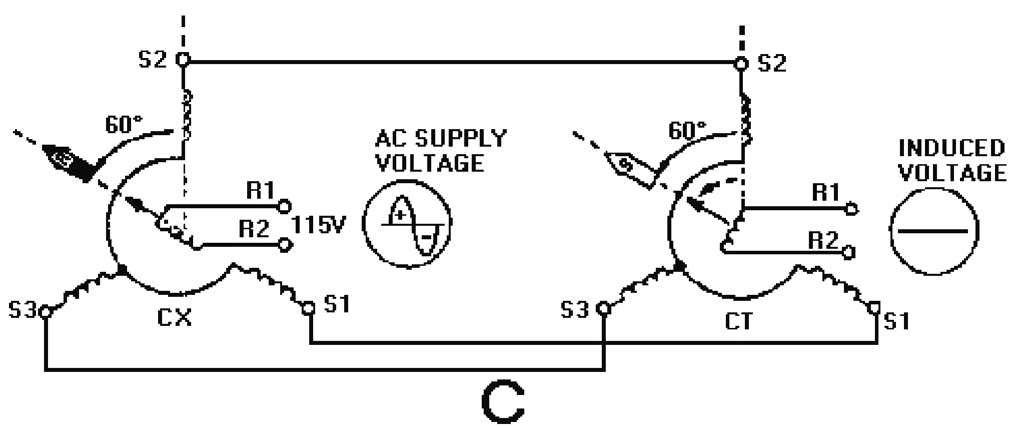

Figure 1-27C.—Control synchro system operation.

When the rotor of the CX in view A of figure 1-27 is turned 60º clockwise, the magnetic field in the CX (black arrow) and the magnetic field in the CT (white arrow) also rotate 60º clockwise. This action induces a voltage in the CT rotor that is in phase with the ac supply, as indicated by the oscilloscope presentation. If the rotor of the CX in view B is turned 60º in a counterclockwise direction from its 0º position, the magnetic field (white arrow) in the CT also rotates counterclockwise through the same number of degrees as the CX. Since the magnetic field in the stator of the CT cuts through the rotor in the opposite direction, the induced voltage in the rotor is now out of phase with the ac supply to the CX, as shown in the oscilloscope presentation.

At times it is necessary, because the CT is used to control servo systems, to have the CT output reduced to zero volts to prevent any further movement of a load. To accomplish this, it is necessary to turn the rotor of the CT through the same number of degrees and in the same direction as the rotor of the CX. This places the CT rotor perpendicular to its own stator field and reduces its output to zero volts as illustrated in view C.

The CT output voltage discussed throughout this section is commonly referred to as an ERROR SIGNAL. This is because the voltage represents the amount and direction that the CX and CT rotors are out of correspondence. It is this error signal that eventually is used in moving the load in a typical servo system.

Now that we have covered the basic operation of the control synchro system, let us see how this system works with a servo system to move heavy equipment. Figure 1-28 shows a block diagram of a typical servo system that uses a control synchro system. Assume the shaft of the CX in this system is turned by some mechanical input. This causes an error signal to be generated by the CT because the CX and the CT rotors are now out of correspondence. The error signal is amplified by the servoamplifier and applied to the servomotor. The servomotor turns the load, and through a mechanical linkage called RESPONSE, also turns the rotor of the CT. The servomotor turns the rotor of the CT so that it is once again in correspondence with the rotor of the CX, the error signal drops to zero volts, and the system comes to a stop.

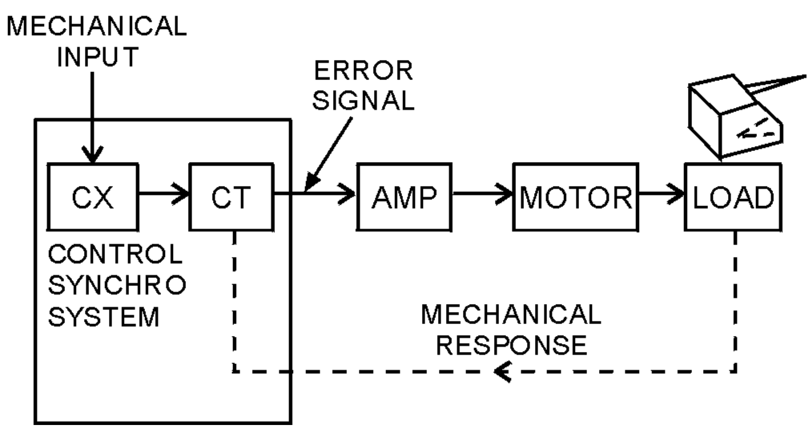

Figure 1-28.—A positioning servo system using a control synchro system.

Q-44. When a CT is on electrical zero, what is the relationship between its rotor and the S2 winding?

Q-45. What is the amplitude and voltage induced into the rotor when the CX is turned 90º while the CT remains on electrical zero?

Q-46. What is the name given to the electrical output of a CT?

Q-47. In a control synchro system, when is the output of the CT reduced to zero?

SYNCHRO CAPACITORS

As we stated earlier, the speed and accuracy of data transmission are most important. With the use of more complex synchros, like the differential and the control transformer, the accuracy of the synchro systems may be affected. The following discussion will deal with how complex synchros affect the accuracy of synchro systems and what can be done to keep this accuracy as high as possible. Synchro capacitors play a major role in maintaining a high degree of accuracy in synchro systems.

When a torque transmitter is connected to a torque receiver (TX-TR), very little, if any, current flows in the stators when the rotors are in correspondence. This is because the voltages induced in the TR windings almost exactly balance out the voltages induced in the TX windings. As a result, the TR is very sensitive to small changes in the position of the TX rotor, causing the TR to follow the TX with a high degree of accuracy.

When a synchro system contains differential synchros (TDX or CDX), the stator currents at correspondence are greater than they are in a single TX-TR system. The reason is the step-up turns ratio between the stator and rotor in the differential synchro.

In a synchro system that uses a CT, stator current at correspondence is also greater than in a TX-TR system. In this case, however, this reason is that the CT rotor is not energized and as a result no voltage is induced in the stator to oppose the voltage in the transmitter stator. The overall effect of this increase in stator current is to reduce the accuracy of the system. To maintain high accuracy in a synchro system containing either differential units or CTs, the stator currents must be kept to a minimum. This is done by connecting synchro capacitors in the circuit.

To understand the operation of a synchro capacitor and how it reduces current drain on the transmitter requires a recollection of the voltage and current relationships in inductive and capacitive circuits. As you learned in module 2 of this series, current lags voltage by 90º in a purely inductive circuit. You also know that an ideal inductor is impossible to make because there is always resistance present. Therefore, an inductor has a combination of inductive reactance and resistance. Since current and voltage are always in phase in a resistive circuit and 90º out of phase in an inductive circuit, we can say that there are two currents in an inductor-the loss current, which is the resistive (in-phase) current, and the magnetizing current, which is the inductive (out-of-phase) current. It is this magnetizing current that we would like to eliminate in the stator coils of the TDX, CDX, and CT because it makes up most of the line current.

Keeping in mind that current leads voltage by 90º in a capacitive circuit, let's see what happens to magnetizing current when a capacitor is added to the circuit.

Suppose a capacitor is hooked up across one of the stator coils of a TDX and its capacitance is adjusted so that its reactance equals the reactance of the coil. Since the two reactances are equal, the current they draw from the line must also be equal. However, these currents are going to be 180º out of phase, because the current in the coil lags the line voltage, while the capacitor's current leads it. Since the two currents are equal in magnitude but opposite in phase, they cancel. The total line current is reduced by this effect and, if a capacitor is placed across each coil in the TDX, the line current decreases even further. This, in effect, increases torque in synchro systems near the point of correspondence and, therefore, increases overall system accuracy.

Connecting capacitors across individual stator windings is impractical because it requires that the stator winding's common connection be outside the synchro. Since this is not done with synchros, another method has been devised to connect up the capacitors which works just as well. This method is shown in figure 1-29.

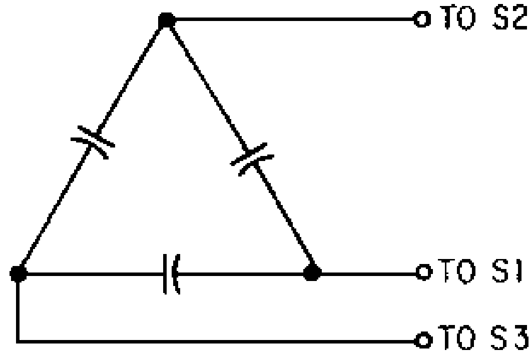

Figure 1-29.—The synchro capacitor.

The three delta-connected capacitors, shown in figure 1-29, usually come as a unit mounted in a case with three external connections. The entire unit is called a SYNCHRO CAPACITOR. The synchro capacitor is made in many sizes to meet the requirements of all sizes of standard differentials and control transformers. The synchro capacitor is rated by its total capacity, which is the sum of the individual capacities in the unit.

Figure 1-30 shows how a synchro capacitor affects the operation of a control synchro system. In this figure, the capacitor is placed between the CX and the CT. Two current meters are also placed in the circuit to show the effect the capacitor has on stator current. The meter connected between the capacitor and the CT reads normal stator current, 32 milliamperes (mA). This current would normally flow in the stator of the CX if the synchro capacitor were not connected. The other meter reads 10 mA, which is what is left of the original stator current after the magnetizing current has been canceled by the synchro capacitor. By reducing the current drain on the transmitter, the sensitivity and accuracy of the system increase.

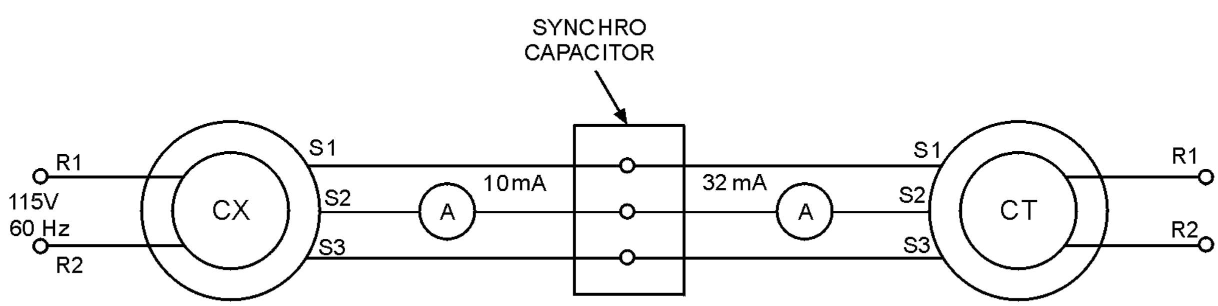

Figure 1-30.—The use of a synchro capacitor with a CT.

Figure 1-31 shows another application of a synchro capacitor; this time in a differential system in this circuit the capacitor is placed between a TX and a TDX. The meter readings show the same comparison between currents as in the previous paragraph. The only significant difference between this circuit and the one in figure 1-30 is that the differential draws more stator current than the CT.

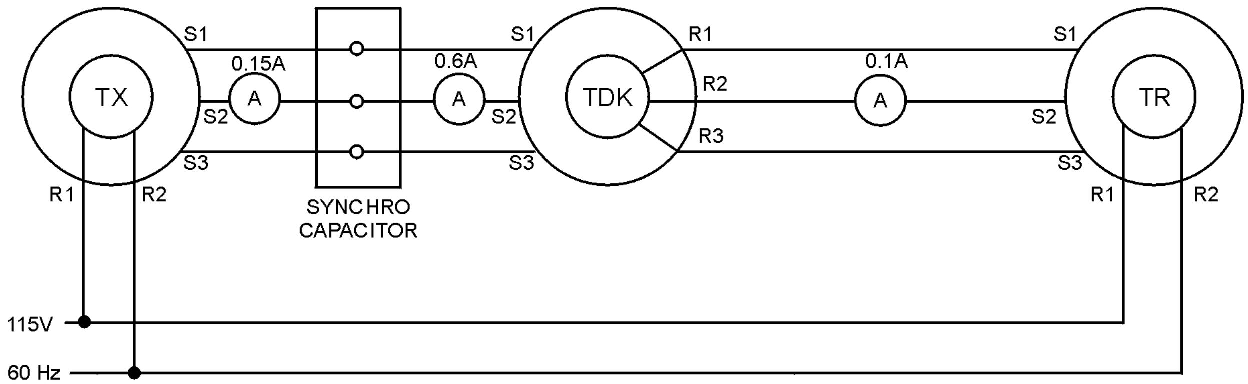

Figure 1-31.—The use of a synchro capacitor with a TDX.

Some synchro systems contain a differential and a control transformer, as illustrated in figure 1-32. In this figure, there are large stator currents flowing in the CX, since it supplies all the losses as well as the magnetizing current for both synchros. Two meters are placed in the circuit to show the value of stator current for the CDX and CT. Another meter is placed in series with the ac excitation voltage to show the amount of current being drawn from the ac line is 0.9 ampere.

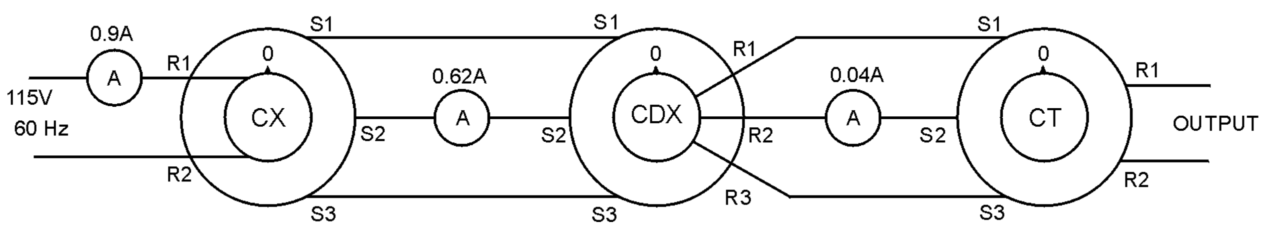

Figure 1-32.—Synchro current in a control synchro system using a CDX and a CT.

Adding synchro capacitors to this system, as shown in figure 1-33, greatly reduces the stator currents and improves the efficiency of the system. Also, notice that the line current is reduced from 0.9 ampere in figure 1-32 to 0.65 ampere in figure 1-33.

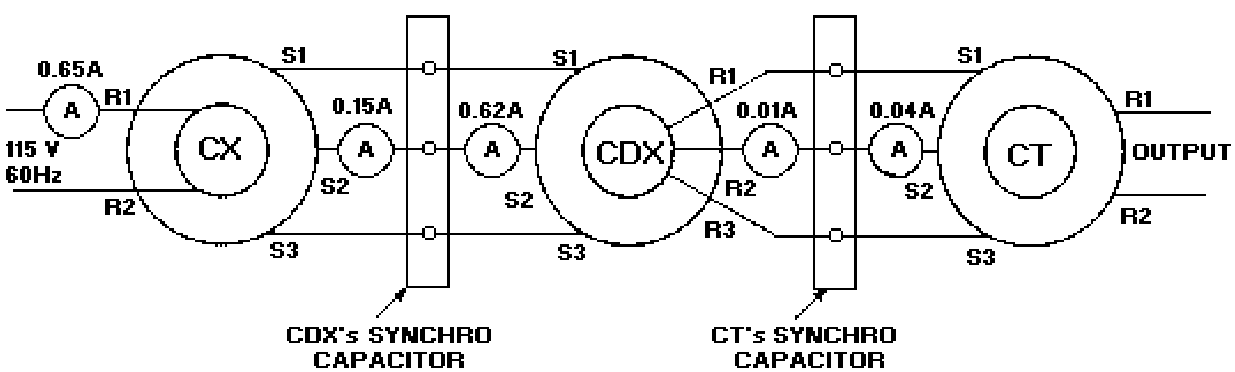

Figure 1-33.—The effects of synchro capacitors in a control synchro system using a CDX and a CT.

When a synchro capacitor is used, it is always placed physically close to the differential or control transformer whose current it corrects. This is done to keep the connections as short as possible, because high currents in long leads increase the transmitter load and reduce the accuracy of the system.

We must stress that the synchro capacitor should never be used in a simple transmitter-receiver system. This is because stator currents in this system are zero at correspondence and the addition of a synchro capacitor would only increase the stator current and throw the system out of balance.

Q-48. What is the purpose of the synchro capacitor?

Q-49. What type of synchros usually require the use of synchro capacitors?

Q-50. What type of current is eliminated by synchro capacitors?

Q-51. How are synchro capacitors connected in a circuit?

Q-52. Why are synchro capacitors placed physically close to differentials transmitters and CTs?

MULTISPEED SYNCHRO SYSTEMS

The data to be transmitted is another important factor that we must consider when we discuss the accuracy of a synchro system. If this data covers a wide range of values, the basic synchro system is unable to detect any small changes in the data. When this happens, the accuracy of the system decreases. Because of this difficulty, multispeed synchro systems were developed. They handle this type of data very effectively and still maintain a high degree of accuracy.

Multispeed synchro systems use more than one speed of data transmission. The speed of data transmission is, simply, the number of times a synchro transmitter rotor must turn to transmit a full range of values. For example, a system in which the rotors of synchro devices turn in unison with their input and output shafts is commonly called a 1-speed data transmission system. In this system, the transmitter's rotor is geared so that 1 revolution of the rotor corresponds to 1 revolution of the input. Until now, the discussion of synchro systems has dealt exclusively with this 1-speed system.

In a 36-speed data transmission system, the rotor of the synchro transmitter is geared to turn through 36 revolutions for 1 revolution of its input. Units transmitting data at one speed are frequently called 1-speed synchros; a unit transmitting data at 36-speed would be a 36-speed synchro, and so forth.

It is quite common in synchro systems to transmit the same data at two different speeds. For example, ship's course information is usually transmitted to other locations on a ship at 1-speed and 36-speed. A system in which data is transmitted at two different speeds is called a dual- or double-speed system. Sometimes a dual-speed system will be referred to by the speeds involved, for example a 1- and 36-speed system.

In summary, the speed of data transmission is referred to as 1-speed, 2-speed, 36-speed, or some other definite numerical ratio. To indicate the number of different speeds at which data is transmitted, refer to the system as being a single-speed, dual-speed, or tri-speed synchro system.

SINGLE-SPEED SYNCHRO SYSTEM

If the data to be transmitted covers only a small range of values, a single-speed system is normally accurate enough. However, in applications where the data covers a wide range of values and the accuracy of the system is most important, the 1-speed system is not adequate enough and must be replaced by a more suitable system. Increasing the speed of a single-speed system from 1-speed to 36-speed provides greater accuracy, but the self-synchronous feature of the 1-speed system is lost. If primary power is interrupted in a 36-speed system and the transmitter is turned before power is reapplied, the synchros could realign themselves in an erroneous position. The number of positions in which the transmitter and receiver rotors can correspond is the same as the transmission speed. Thus, in the 36-speed system, there are 35 incorrect positions and only 1 correct position of correspondence.

For accurate transmission of data over a wide range of values without the loss of self-synchronous operation, multispeed synchro systems must be used. Multispeed synchro systems use more than one speed of data transmission and, therefore, require more than one output shaft.

DUAL-SPEED SYNCHRO SYSTEM

A basic dual-speed synchro system consists of two transmitters and two receivers, as shown in figure 1-34. One transmitter receives the external input to the system and, through a network of gears, passes the effects of the external input to the second transmitter. The gear ratio between these two transmitters determines the two specific speeds the system will use to transmit the input data. The two speeds of this system are often referred to as fast and slow, high and low, or more often as fine and coarse.

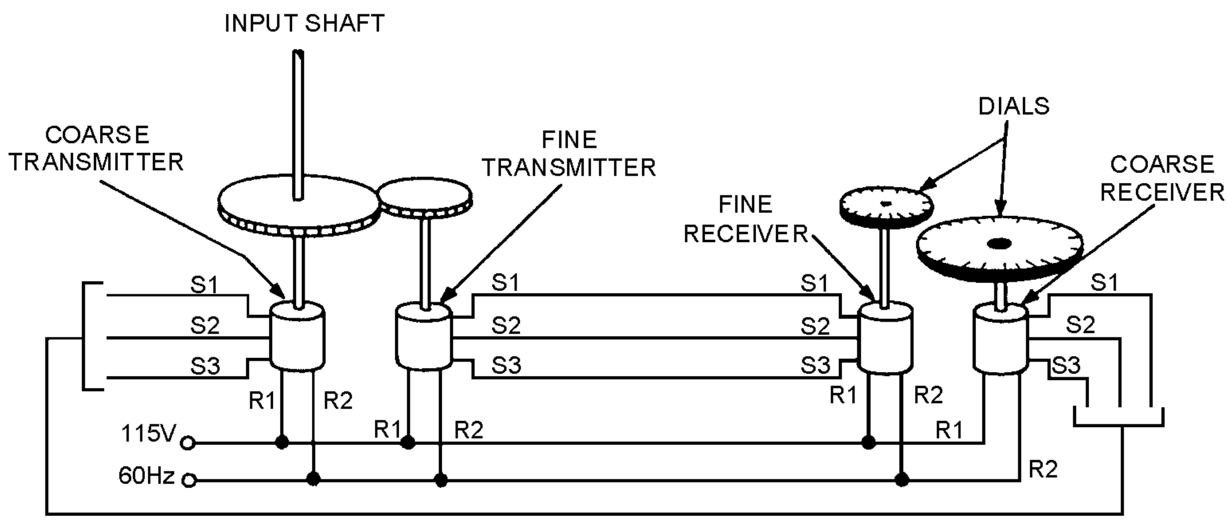

Figure 1-34.—Dual-speed synchro system.

If, for example, the gear ratio between the two transmitters is 36 to 1, 1 revolution of the rotor of the first transmitter causes 36 revolutions of the rotor of the second transmitter. The first transmitter-the one that accepts the external input-can be called the coarse transmitter, and the second one can be called the fine transmitter. Representative speeds include 1 and 36, 2 and 36, and 2 and 72.

The output of each transmitter is passed through standard synchro connections to a receiver. One receiver receives the coarse signal and the other one receives the fine signal. The two receivers may or may not be connected by a network of gears similar to the network between the two transmitters. In some dual-speed applications, a double receiver is used instead of two individual receivers.

The double receiver (fig. 1-35) consists of a coarse and a fine receiver enclosed in a common housing. It has a two-shaft output one inside the other. The coarse and fine receivers may be likened to the hour and minute hands of a clock. The coarse receiver corresponds to the hour hand, and the fine receiver corresponds to the minute hand. This double receiver has the advantage of requiring less space than two single receivers. However, it also has a disadvantage — when one receiver goes bad, both must be replaced.

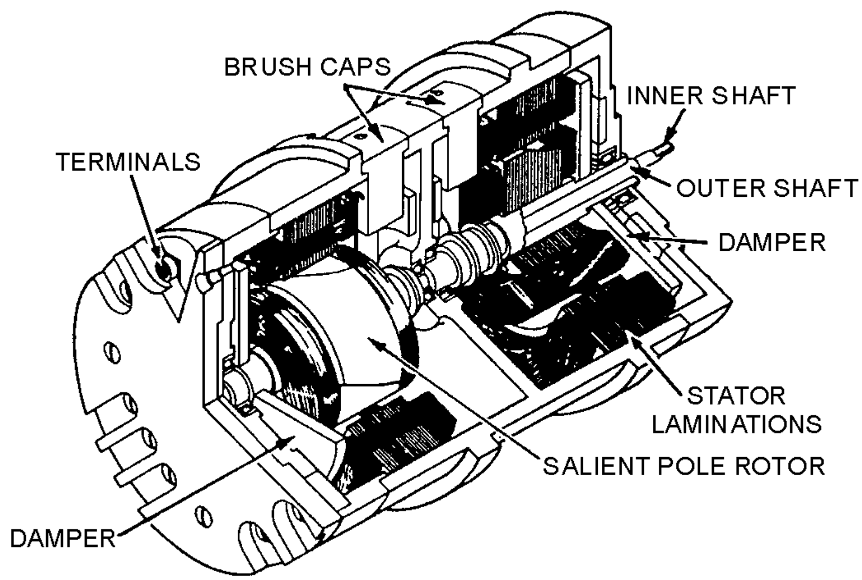

Figure 1-35.—Cutaway view of a double receiver.

In the dual-speed synchro system, data is transmitted by the coarse transmitter, while the system is far out of correspondence and then is shifted to the fine transmitter as the system approaches correspondence. This shifting from coarse to fine control is done automatically when the fine error signal exceeds the coarse error signal. The fine synchro transmitter then drives the system to the point of correspondence.

When the dual-speed synchro system includes control transformers, there is always the possibility of a 180º error being present in the system. The reason is the rotor of the CT is not energized and its error-voltage output is zero both at its proper position and also at a point 180º away from that position. To prevent the CT from locking 180º out of phase with the rest of the system, a low voltage is applied across the rotor terminals of the coarse CT as shown in figure 1-36.

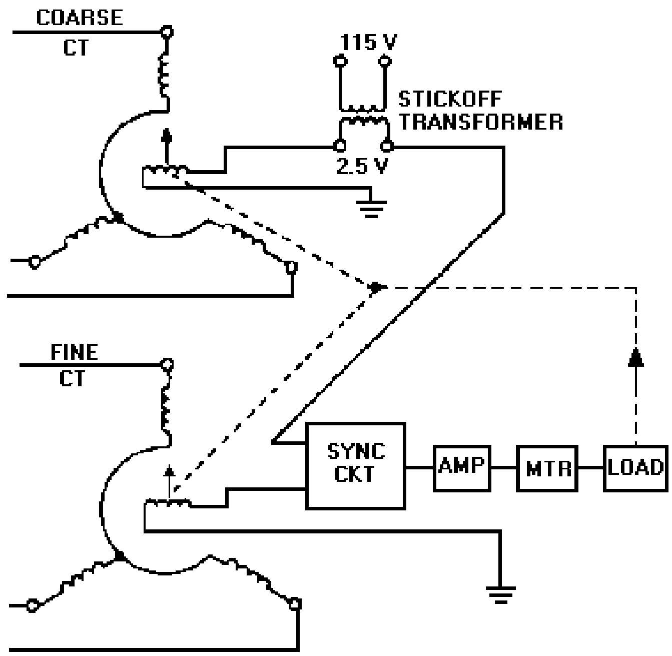

Figure 1-36.—Dual-speed synchro system using a stickoff transformer.

This voltage is normally about 2.5 volts and is commonly termed "stickoff" voltage. It is obtained from the secondary of a small transformer. The voltage induced in the secondary of the transformer shifts the 0º position of the coarse CT To reestablish a new 0º position, the stator of the coarse CT must be turned through an angle that induces an opposing 2.5 volts in the rotor to cancel the stickoff voltage. Therefore, at 0º the two voltages cancel and no input exists to drive the servo amplifier. Should the rotor of the CT stop at 180º, the same 2.5 volts would be induced in the rotor. However, it would be in phase with the stickoff voltage and no cancellation would occur. The end result is an error signal at 180º that drives the dual-speed synchro system out of any false synchronizations.

TRI-SPEED SYNCHRO SYSTEM

The advent of long-range missiles and high-speed aircraft has brought about the need for accurately transmitting very large quantities. This is best done by a tri-speed synchro system, which transmits data at three different speeds. These speeds are sometimes referred to as coarse, medium or intermediate, and fine. A typical weapons systems, for example, might transmit range in miles, thousands of yards, and hundreds of yards. By providing this range in three different scales, greater accuracy is obtained than would be possible with a dual-speed system. Representative speeds for tri-speed systems include 1, 36, and 180; 1, 36, and 360; and 1, 18, and 648.

Q-53. What is the name given to the synchro system that transmits data at two different speeds?

Q-54. What is the main reason for using a multispeed synchro system instead of a single-speed synchro system?

Q-55. In a dual-speed synchro system what determines the two specific speeds at which the data will be transmitted?

Q-56. What type of synchro system is used to transmit very large quantities?

Q-57. What is the disadvantage of using a double receiver instead of two individual receivers?

Q-58. What is the purpose of "stickoff voltage"?

ZEROING SYNCHROS

If synchros are to work properly in a system, they must be connected and aligned correctly with respect to each other and to the other devices with which they are used. The reference point for alignment of all synchro units is ELECTRICAL ZERO. The mechanical reference point for the units connected to the synchros depends upon the particular application of the synchro system. Whatever the application, the electrical and mechanical reference points must be aligned with each other. The mechanical position is usually set first, and then the synchro device is aligned to electrical zero.

There are various methods for zeroing synchros. Some of the more common zeroing methods are the voltmeter, the electrical-lock, and the synchro-tester methods. The method used depends upon the facilities and tools available and how the synchros are connected in the system. Also, the method for zeroing a unit whose rotor or stator is not free to turn may differ from the procedure for zeroing a similar unit whose rotor or stator is free to turn.

VOLTMETER METHOD

The most accurate method of zeroing a synchro is the ac voltmeter method. The procedure and the test circuit configuration for this method vary somewhat, depending upon which type of synchro is to be zeroed. Transmitters and receivers, differentials, and control transformers each require different test circuit configurations.

Regardless of the synchro to be zeroed, there are two major steps in each procedure. The first step is the coarse or approximate setting. The second step is the fine setting. The coarse setting ensures the device is zeroed on the 0º position rather than the 180º position. Many synchro units are marked in such a manner that the coarse setting may be approximated physically by aligning two marks on the synchro. On standard synchros, this setting is indicated by an arrow stamped on the frame and a line marked on the shaft, as shown in figure 1-37. The fine setting is where the synchro is precisely set on 0º.

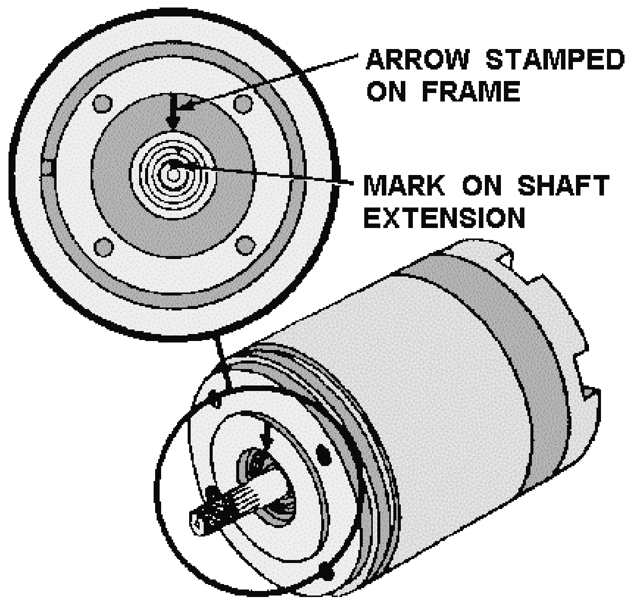

Figure 1-37.—Coarse electrical zero markings.

For the ac voltmeter method to be as accurate as possible, an electronic or precision voltmeter having 0- to 250-volt and a 0- to 5-volt ranges should be used. On the low scale this meter should also be able to measure voltages as low as 0.1 volt.

Q-59. What is the reference point for alignment of all synchro units?

Q-60. What is the most accurate method of zeroing a synchro?

Q-61. What is the purpose of the coarse setting of a synchro?

Zeroing Transmitters and Receivers (Voltmeter Method)

Since the TX, CX, and TR are functionally and physically similar, they can be zeroed in the same manner. For the TX and CX to be properly zeroed, electrical zero voltages (S2 = 52V; S1 and S3 = 26V) must exist across the stator winding when the rotor of the transmitter is set to 0º or its mechanical reference position. The synchro receiver (TR) is properly zeroed when the device it actuates assumes its zero or mechanical reference position while electrical zero voltages (S2 = 52V; S1 and S3 = 26V) exist across its stator windings. The following is a step-by-step procedure used to zero the TX, CX, and TR.

1. Carefully set the unit (antenna, gun mount, director, etc.) whose position the CX or TX transmits, accurately on 0º or on its reference position. In the case of the TR, deenergize the circuit and disconnect the stator leads before setting its rotor on zero or to its reference position. The rotor may need to be secured in this position; taping the dial to the frame is usually sufficient.

2. Deenergize the synchro circuit and disconnect the stator leads. NOTE: Many synchro systems are energized by individual switches. Therefore, be sure that the synchro power is off before working on the connections.Set the voltmeter to its 0- to 250-volt scale and connect it into the circuit as shown in view A of figure 1-38.

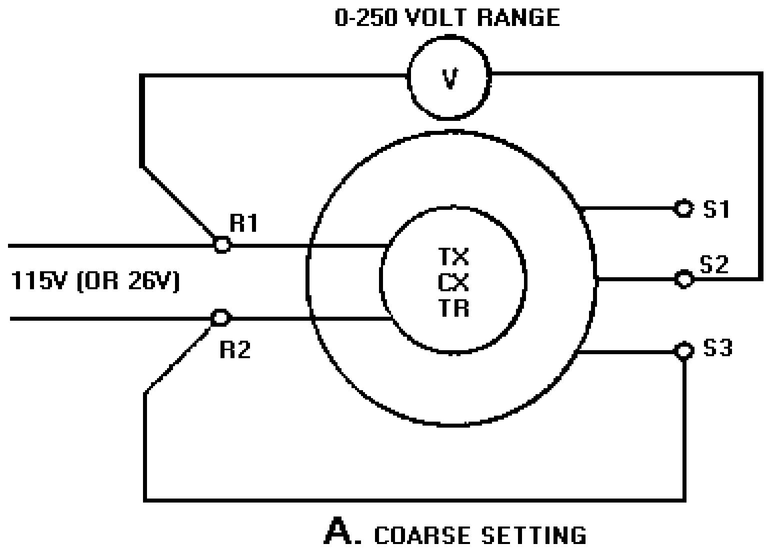

Figure 1-38A.—Zeroing a transmitter or receiver by the voltmeter method.

3. Energize the synchro circuit and turn the stator until the meter reads about 37 volts (15 volts for a 26-volt synchro). Should the voltmeter read approximately 193 volts (115 volts + 78 volts = 193 volts), the rotor is at 180º. Turn it through a half revolution to bring it back to 0º. If you cannot obtain the desired 37 (or 15) volts, use the lowest reading you can take with the meter. This is the coarse setting and places the synchro approximately on electrical zero.

4. Deenergize the synchro circuit and connect the meter as shown in view B. Start with a high scale on the meter and work down to the 0- to 5-volt scale to protect the meter movement.

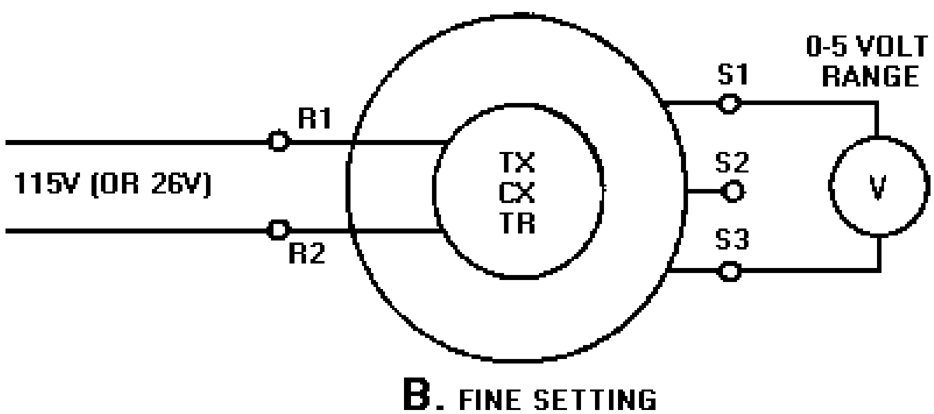

Figure 1-38B.—Zeroing a transmitter or receiver by the voltmeter method.

5. Reenergize the synchro circuit and adjust the stator for a zero or minimum voltage reading. This is the fine electrical zero position of the synchro.

When you have reconnected a TX and a TR into a system after zeroing them, you can perform a simple check on the system to see if they are accurately on electrical zero. First, place the transmitter on 0º. When the system reaches the point of correspondence, the induced voltages in the S1 and S3 stator windings of both synchros should be equal. Since the terminals of S1 and S3 are at equal potential, a jumper between these terminals at the TR should not affect the circuit. If, however, the TR rotor moves when you connect a jumper, there is a slight voltage difference between S1 and S3. This voltage difference indicates that the transmitter is not on electrical zero. If this is the case, recheck the transmitter for electrical zero.

Zeroing Differential Synchros (Voltmeter Method)

A differential synchro is zeroed when it can be inserted into a system without introducing any change. If a differential synchro requires zeroing, use the following voltmeter method:

1. Carefully and accurately set the unit whose position the CDX or TDX transmits on zero or on its reference position. In the case of the TDR, deenergize the circuit and disconnect all leads before setting its rotor to 0º or to its reference position. You may need to secure the rotor in this position; taping the dial to the frame is usually sufficient.

2. Deenergize the circuit and disconnect all leads on the differential except leads S2 and S3 when you use the 78-volt (10.2 volts for 26-volt units) supply from the transmitting unit to zero the differential. Set the voltmeter to its 0- to 250-volt scale and connect it as shown in view A of figure 1-39. If the 78-volts is not available from the transmitter or from an auto transformer, you may use a 115-volt source instead. If you use 115 volts instead of 78 volts, do not leave the synchro connected for more than 2 minutes or it will overheat and may become permanently damaged.

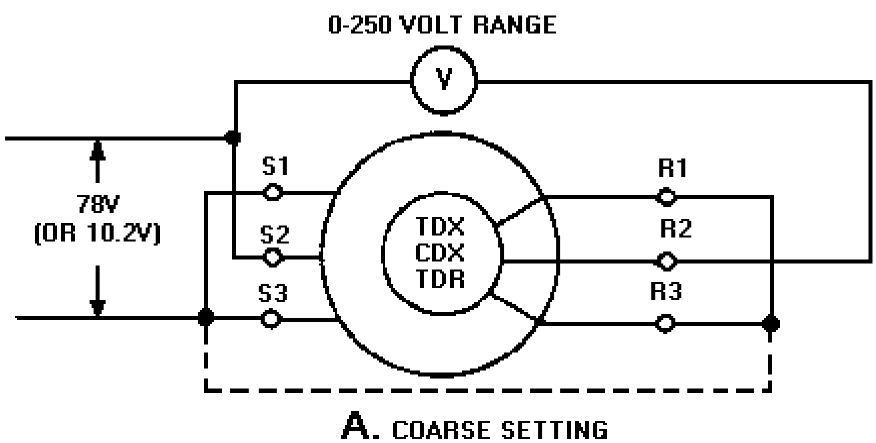

Figure 1-39A.—Zeroing differential synchros by the voltmeter method.

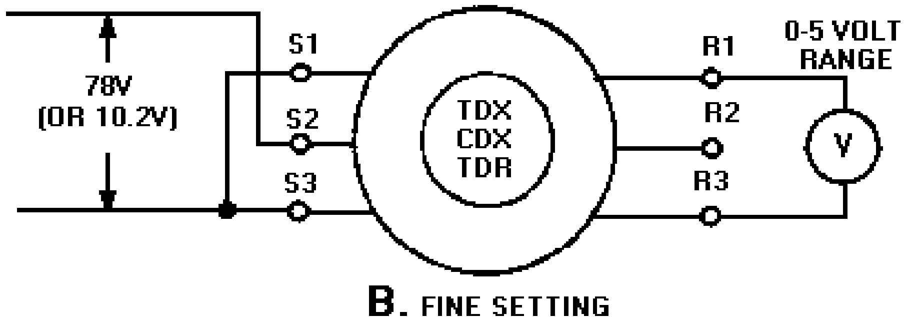

Figure 1-39B.—Zeroing differential synchros by the voltmeter method.

3. Energize the circuit, unclamp the differential's stator, and turn it until the meter reads minimum. The differential is now approximately on electrical zero. Deenergize the circuit and reconnect it as shown in view B.

4. Reenergize the circuit. Start with a high scale on the meter and work down to the 0- to 5-volt scale to protect the meter movement. At the same time, turn the differential's stator until you obtain a zero or minimum voltage reading. Clamp the differential stator in position, ensuring the voltage reading does not change. This is the fine electrical zero position of the differential.

Zeroing a Control Transformer (Voltmeter Method)

Two conditions must exist for a control transformer (CT) to be on electrical zero. First, its rotor voltage must be minimum when electrical zero voltages (S2 = 52 volts; S1 and S3 = 26 volts) are applied to its stator. Second, turning the shaft of the CT slightly counterclockwise should produce a voltage across its rotor in phase with the rotor voltage of the CX or TX supplying excitation to its stator. To zero a CT (using 78 volts from its transmitter) by the voltmeter method, use the following procedure:

1. Set the mechanism that drives the CT rotor to zero or to its reference position. Also, set the transmitter (CX or TX) that is connected to the CT to zero or its reference position.

2. Check to ensure there is zero volts between S1 and S3 and 78 volts between S2 and S3. If you cannot obtain these voltages, you will need to rezero the transmitter. NOTE: If you cannot use the 78 volts from the transmitter circuit and, an auto transformer is not available, you may use a 115-volt source. <u>If you use 115 volts instead of 78 volts, do not energize the CT for more than 2 minutes because it will overheat and may become permanently damaged.</u>

3. Deenergize the circuit and connect the circuit as shown in view A of figure 1-40. To obtain the 78 volts required to zero the CT, leave the S1 lead on, disconnect the S3 lead on the CT, and put the S2 lead (from the CX) on S3. This is necessary since 78 volts exists only between S1 and S2 or S2 and S3 on a properly zeroed CX. Now energize the circuit and turn the stator of the CT to obtain a minimum reading on the 250-volt scale. This is the coarse or approximate zero setting of the CT.

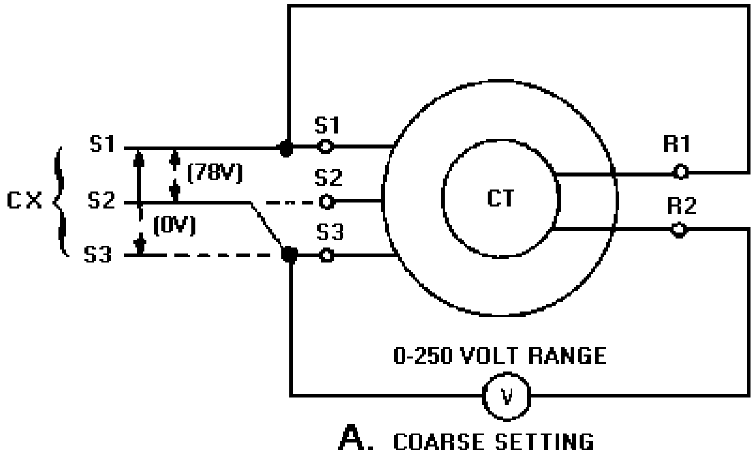

Figure 1-40A.—Zeroing a control transformer by the voltmeter method.

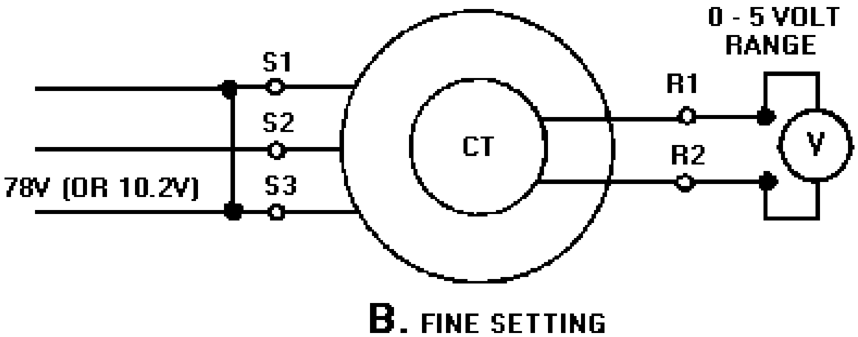

Figure 1-40B.—Zeroing a control transformer by the voltmeter method.

4. Deenergize the circuit, reconnect the S1, S2, and S3 leads back to their original positions, and then connect the circuit as shown in view B.

5. Reenergize the circuit. Start with a high scale on the meter and work down to the 0- to 5-volts scale to protect the meter movement. At the same time, turn the stator of the CT to obtain a zero or minimum reading on the meter. Clamp down the CT stator, ensuring the reading does not change. This is the fine electrical zero position of the CT.

Zeroing Multispeed Synchro Systems.

If multispeed synchro systems are used to accurately transmit data, the synchros within the systems must be zeroed together. This is necessary because these synchros require a common electrical zero to function properly in the system.

First, establish the zero or reference position for the unit whose position the system transmits. Then, zero the most significant synchro in the system first, working down to the least significant. For example, zero the coarse synchro, then the medium synchro, and finally the fine synchro. When you zero those synchros, consider each synchro as an individual unit and zero it accordingly.

Q-62. When is a synchro receiver (TR) properly zeroed?

Q-63. What should a voltmeter read when a TX is set on coarse zero?

Q-64. What precaution should you take when you use 115 volts to zero a differential?

Q-65. Why should a synchro be rechecked for zero after it is clamped down?

Q-66. What is the output voltage of a CT when it is set on electrical zero?

Q-67. When you zero a multispeed synchro system which synchro should you zero first?

ELECTRICAL LOCK METHOD

The electrical lock method, although not as accurate as the voltmeter method, is perhaps tile fastest method of zeroing synchros. However, this method can be used only if the rotors of the units to be zeroed are free to turn and the lead connections are accessible. For this reason, this method is usually used on the TR because, unlike transmitters, the TR shaft is free to turn.

To zero a synchro by the electrical lock method, deenergize the unit, connect the leads as shown in figure 1-41, and apply power. The synchro rotor will then quickly snap to the electrical zero position and lock. If the indicating device connected to the synchro shaft does not point to zero, loosen the synchro in its mounting and rotate it until the zero position of the indicator corresponds with the electrical zero of the synchro. As we stated previously, <u>you may use 115 volts as the power source instead of 78 volts, provided you do not leave the unit connected for more than 2 minutes.</u>

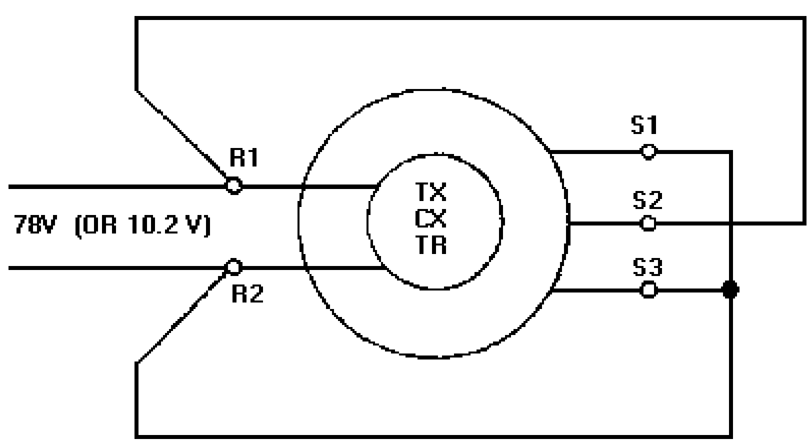

Figure 1-41.—Zeroing a synchro by the electrical lock method.

SYNCHRO TESTERS

Two types of synchro testers are shown in figure 1-42, view (A) and view (B). Each is nothing more than a synchro receiver on which a calibrated dial is mounted.

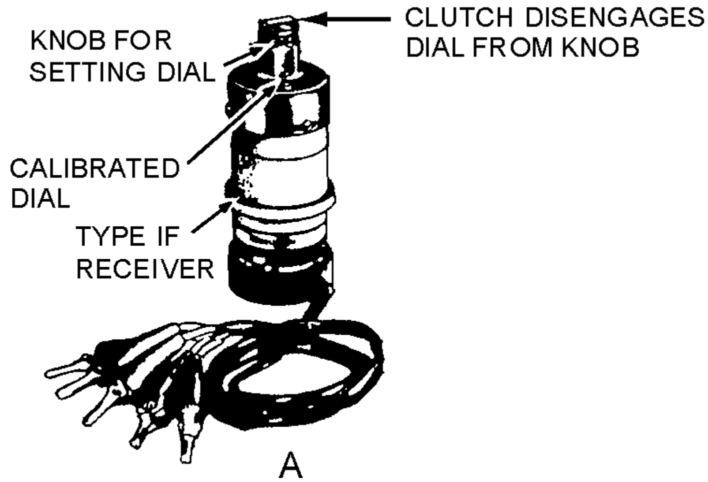

Figure 1-42A.—Synchro Testers.

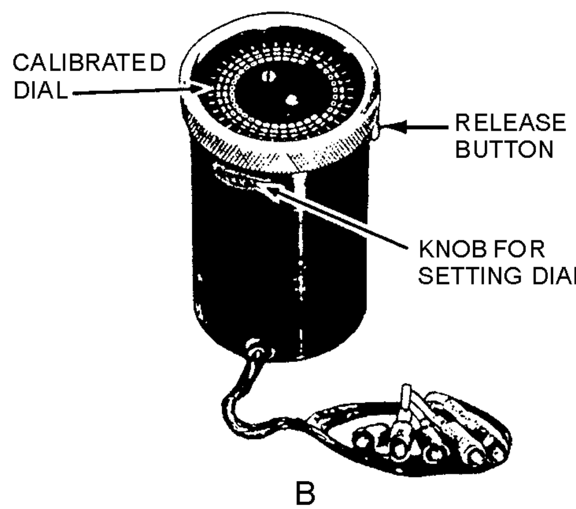

Figure 1-42B.—Synchro Testers.

These testers are used primarily for locating defective synchros. Although they do provide a method for zeroing synchros, they should not be relied on without question. It is possible for the calibrated dial to slip from its proper position, and since the dial is graduated only every 10º, it is difficult to read small angles with accuracy. Therefore, the synchro tester method of zeroing synchros is potentially less accurate than those previously described. To zero a TX, CX or TR using a synchro tester, use the following procedure:

1. Connect the synchro tester as shown in figure 1-43.

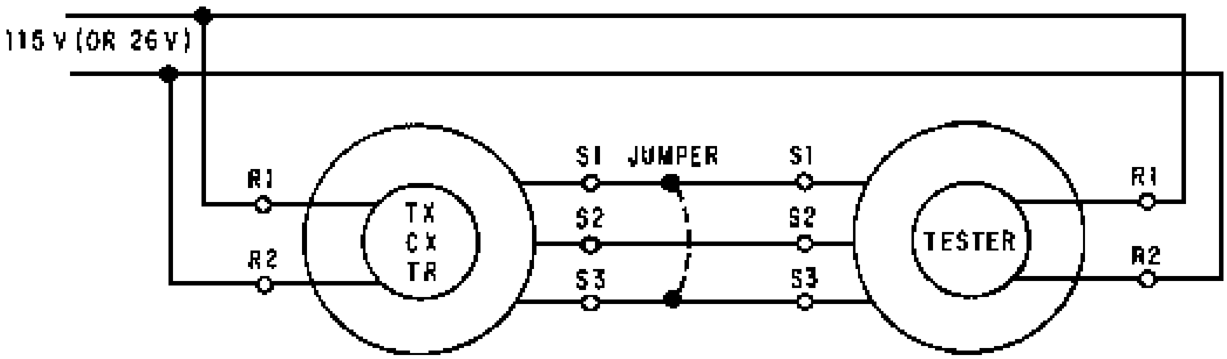

Figure 1-43.—Zeroing a synchro using a synchro tester.

2. Set the unit whose position the TX or CX transmits accurately on zero or on its reference position. In the case of the TR, set its rotor to zero or to its reference position.

3. Turn the stator of the synchro being zeroed until the synchro tester dial reads 0º. The synchro is now approximately on electrically zero.

4. Momentarily short S1 to S3 as shown. If the synchro tester dial moves when S1 is shorted to S3, the synchro is not zeroed. Check the tester dial to ensure it has not slipped. If the tester dial has not slipped, move the synchro stator until there is no movement when S1 and S3 are shorted. This is the electrical zero position of the synchro being aligned.

Q-68. What method of zeroing a synchro is perhaps the fastest but NOT necessarily the most accurate?

Q-69. What restrictions are placed on the use of the electrical lock method?

Q-70. When you zero a synchro with a synchro tester, what is indicated by a jump in the synchro tester's dial when the S1 and S3 leads are momentarily shorted?

TROUBLESHOOTING SYNCHRO SYSTEMS

One of your duties in the Navy is to keep the synchro systems in your equipment in good working order. Therefore, it is essential that you become familiar with the details of synchro maintenance and repair.

First, let's consider some of the more common problem areas you should avoid when working with synchros. As with any piece of electrical or electronic equipment, if it works—leave it alone. Do not attempt to zero a synchro system that is already zeroed just because you want to practice. More often than not, the system will end up more out of alignment than it was before you attempted to rezero it. Do not attempt to take a synchro apart, even if it is defective. A synchro is a piece of precision equipment that requires special equipment and techniques for disassembly. Disassembly should be done only by qualified technicians in authorized repair shops. A synchro, unlike an electric motor, does not require periodic lubrication. Therefore, never attempt to lubricate a synchro. Synchros also require careful handling. Never force a synchro into place, never use pliers on the threaded shaft, and never force a gear or dial onto the shaft. Finally, never connect equipment that is not related to the synchro system to the primary excitation bus. This will cause the system to show all the symptoms of a shorted rotor when the equipment is turned on; but, the system will check out good when the equipment is off.

Trouble in a synchro system that has been in operation for some time is usually one of two types. First, the interconnecting synchro wiring often passes through a number of switches; at these points opens, shorts, or grounds may occur. You will be expected to trace down these troubles with an ohmmeter. You can find an open easily by checking for continuity between two points. Similarly, you can find a ground by checking the resistance between the suspected point and ground. A reading of zero ohms means that the point in question is grounded. Secondly, the synchro itself may become defective, due to opens and shorts in the windings, bad bearings, worn slip rings, or dirty brushes. You can do nothing about these defects except replace the synchro.

Troubles in new and modified synchro systems are most often because of (1) improper wiring and (2) misalignment caused by synchros not being zeroed. You are responsible for finding and correcting these troubles. You can check for improper wiring with an ohmmeter by making a point-to-point continuity and resistance check. You can correct misalignment of a synchro system by rezeroing the entire system.

TROUBLE INDICATORS

When trouble occurs in an electronic installation that contains a large number of synchro systems, it may be very difficult to isolate the trouble to one particular system. Since it is vital that maintenance personnel locate the point of trouble and fix it in as short a time as possible, indicators, which aid in locating the trouble quickly, are included in the equipment. These indicators are usually signal lights, mounted on a central control board and connected to the different synchro systems. When trouble occurs in a synchro system, the signal light connected to it may either light or flash. Maintenance personnel identify the defective system by reading the name or number adjacent to the light.

Signal lights indicate either overload conditions or blown fuses. Overload indicators are usually placed in the stator circuit of a torque synchro system because the stator circuit gives a better indication of mechanical loading than does the current in the rotor circuit. One version of this type of indicator, as shown in figure 1-44, consists of a neon lamp connected across the stator leads of a synchro system by two transformers. The primaries, consisting of a few turns of heavy wire, are in series with two of the stator leads; the secondaries, consisting of many turns of fine wire, are in series with the lamp. The turns ratios are designed so that when excess current flows through the stator windings, the neon lamp lights. For example, when the difference in rotor positions exceeds about 18º, the lamp lights, indicating that the load on the motor shaft is excessive.

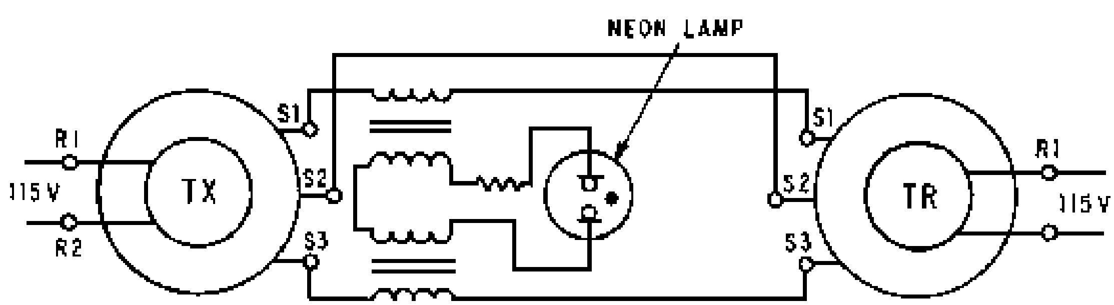

Figure 1-44.—Overload stator current indicator.

Blown fuse indicators are front panel lights which light when a protective fuse in series with the rotor blows. Figure 1-45 shows a typical blown fuse indicator. If excessive current flows in the rotor windings of this circuit because of a short or severe mechanical overload, one of the fuses will blow and the neon lamp across the fuse will light.

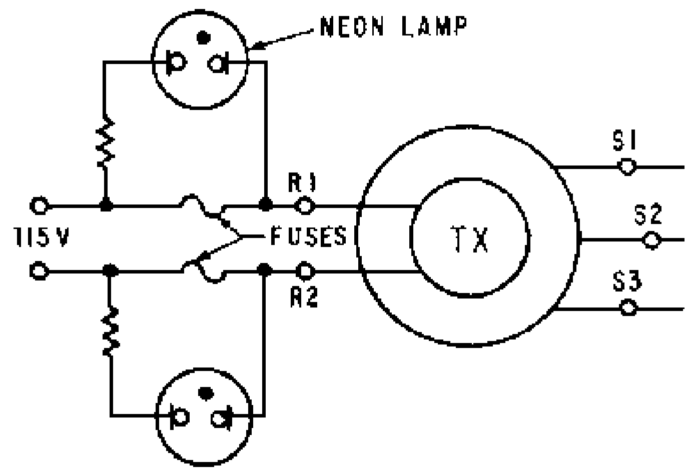

Figure 1-45.—Simple blown fuse indicator.

Another type of blown fuse indicator uses a small transformer having two identical primaries and a secondary connected, as shown in figure 1-46. With both fuses closed, equal currents flow through the primaries. This induces mutually canceling voltages in the secondary. If a fuse blows, the induced voltage from just one primary is present in the secondary, and the lamp lights.

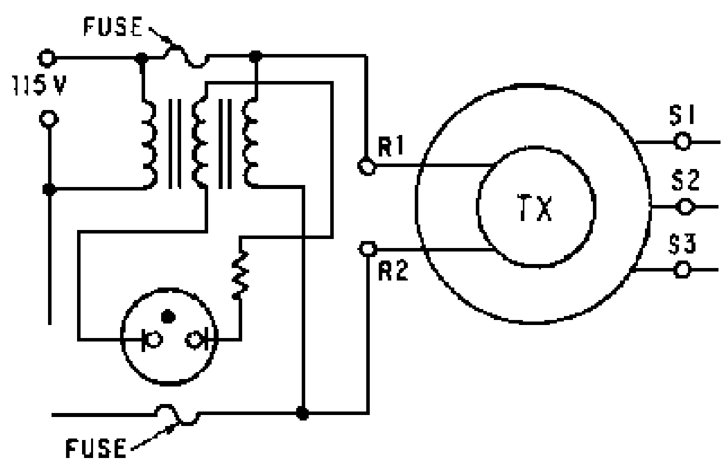

Figure 1-46.—Blown fuse indicator requiring only one lamp.

SYMPTOMS AND CAUSES

To help the technician further isolate synchro problems, many manufacturers furnish tables of trouble symptoms and probable causes with their equipment. These tables are a valuable aid in isolating trouble areas quickly. Tables 1-2 through 1-7 summarize, for a simple TX-TR system, some typical trouble symptoms and their probable causes. Keep in mind, if two or more receivers are connected to one transmitter, similar symptoms occur. However, if all the receivers act up, the trouble is usually in the transmitter or main bus. If the trouble appears in one receiver only, check the unit and its connections.

The angles shown in these tables do not apply to systems using differentials, or to systems whose units are incorrectly zeroed.

Table 1-2.—General Symptoms

<table>
<tr><td colspan="2">Preliminary Actions: Be sure TR is not jammed physically. Turn TX slowly in one direction and observe TR.</td></tr>
<tr><th>SYMPTOMS</th><th>TROUBLE</th></tr>
<tr><td>Overload Indicator lights Units hum at all TX settings One unit overheats TR follows smoothly but reads wrong</td><td>Rotor circuit open or shorted. See table 1-3.</td></tr>
<tr><td>Overload Indicator lights Units hum at all except two opposite TX settings Both units overheat TR stays on one reading half the time, then swings abruptly to the opposite one. TR may oscillate or spin.</td><td>Stator circuit shorted. See table 1-4.</td></tr>
<tr><td>Overload Indicator lights Units hum on two opposite TX settings Both units get warm TR turns smoothly on one direction, then reverses</td><td>Stator circuit open. See table 1-5.</td></tr>
<tr><td>TR reads wrong or turns backward, follows TX smoothly</td><td>Unit interconnections wrong. Unit not zeroed. See tables 1-6 and 1-7.</td></tr>
</table>

Table 1-3.—Open or Shorted Rotor

<table>
<tr><td colspan="2">Preliminary Action: Set TX to 0° and turn rotor smoothly counterclockwise.</td></tr>
<tr><th>SYMPTOMS</th><th>TROUBLE</th></tr>
<tr><td>TR turns counterclockwise from 0° in a jerky or erratic manner, and gets hot.</td><td>TX rotor open</td></tr>
<tr><td>TR turns counterclockwise from 0° or 180° in a jerky or erratic manner. TX gets hot.</td><td>TR rotor open</td></tr>
<tr><td>TR turns counterclockwise from 90° or 270°, torque is about normal, motor gets hot, and TX fuses blow.</td><td>TX rotor shorted</td></tr>
<tr><td>TR turns counterclockwise from 90° or 270°, torque is about normal, TX gets hot, and TR fuses blow.</td><td>TR rotor shorted</td></tr>

SETTINGS OR CONDITIONS	INDICATION	TROUBLE
When TX is on 150º or 330º and When TX is held on 0º	TR reverses or stalls and Overload Indicator lights TR moves between 300º and 0º in a jerky or erratic manner	S1 stator circuit open
When TX is on 90º or 270º and When TX is held on 0º	TR reverses or stalls and Overload Indicator lights TR moves to 0º or 180º , with fairly normal torque	S2 Stator circuit open
When TX is on 30º or 210º and When TX is held on 0º	TR reverses or stalls and Overload Indicator lights TR moves between 0º and 60º in a jerky or erratic manner	S3 stator circuit open
When TX is set at 0˚, and then moved smoothly counterclockwise		

Table 1-6.—Wrong Stator Connections, Rotor Wiring Correct

SETTING OR CONDITIONS	INDICATION	TROUBLE
TX set to 0º and rotor turned smoothly counterclockwise	TR indication is wrong, turns clockwise from 240º	S1 and S2 stator connections are reversed
	TR indication is wrong, turns clockwise from 120º	S2 and S3 stator connections are reversed
	TR indication is wrong, turns clockwise from 0º	S1 and S3 stator connections are reversed
	TR indication is wrong, turns counterclockwise from 120º	S1 is connected to S2, S2 is connected to S3, and S3 is connected to S1
	TR indication is wrong, turns counterclockwise from 240º	S1 is connected to S3, S2 is connected to S1, and S3 is connected to S2

Table 1-7.—Wrong Stator and/or Reversed Rotor Connections

SETTINGS OR CONDITIONS	INDICATION	TROUBLE
TX set to 0º and rotor turned smoothly counterclockwise	TR indication is wrong, turns counterclockwise from 180º	Stator connects are correct, but rotor connections are reversed
	TR indication is wrong, turns clockwise from 60º	Stator connections S1 and S2 are reversed, and rotor connections are reversed
	TR indication is wrong, turns clockwise from 300º	Stator connections S2 and S3 are reversed, and rotor connections are reversed
	TR indication is wrong, turns clockwise from 180º	Stator connections S1 and S3 are reversed, and rotor connections are reversed
	TR indication is wrong, turns counterclockwise from 300º	S1 is connected to S2, S2 is connected to S3, S3 is connected to S1, and rotor connections are reversed
	TR indication is wrong, turns counterclockwise from 60º	S1 is connected to S3, S2 is connected to S1, S3 is connected to S2, and rotor connections are reversed

In a control system, the trouble may be slightly more difficult to isolate. However, the existence of trouble is readily indicated when the system does not properly respond to an input order. For control systems, it is easier to locate the trouble by using a synchro tester or by checking the operating voltages.

VOLTAGE TESTING

Another good way to isolate the trouble in an operating synchro system is to use known operating voltages as references for faulty operation. Since the proper operation of a system is indicated by specific rotor and stator voltages, an ac voltmeter can be used to locate the trouble. When an ac voltmeter is connected between any two stator leads, the voltage should vary from 0 to 90 volts (0 to 11.8 volts for 26-volt systems) as the transmitter rotates. The zero and maximum voltage values should occur at the following headings:

Meter Connected Between	Zero Voltage Headings	Maximum Voltage Headings
S1 and S2	120º, 300º	30º, 210º
S2 and S3	60º, 240º	150º, 330º
S1 and S3	0˚, 180˚	90˚, 270˚

The rotor voltage should remain constant at all times, either 115 volts or 26 volts. In a system where the units are close enough to permit checking, the voltage between the R1 and R2 terminal of any unit energized by the primary ac source and the corresponding R1 or R2 terminal of any other unit energized by the primary ac source should be zero. When the excitation voltage (115 volts or 26 volts) is above or below the nominal value, the maximum stator voltages will also be above or below normal.

SYNCHRO TESTERS

Synchro testers, as stated earlier, are used primarily for quickly locating a defective synchro. These testers are capable of functioning as either transmitter or receiver.

When a transmitter is suspected of being defective, a synchro tester is usually substituted in its place to simulate its actions. When the tester is used in this manner, a braking arrangement on the tester applies the necessary friction to hold its shaft in different positions so you can determine whether the transmitter is good or bad. When using the tester as a transmitter, it is usually a good idea to use only one receiver so as not to overload the tester. If the tester is connected in place of a TR or used to check the output of a transmitter, the brake is released, allowing the rotor to turn and indicate the transmitter's position. By observing the tester's response to the transmitted signal, you can determine if the TR is defective or if the transmitter's output is incorrect.

Q-71. What should you do with a synchro that has a bad set of bearings?

Q-72. Name two types of trouble you would expect to find in a newly installed synchro system.

Q-73. What type of indicator is usually placed in the stator circuit of a torque synchro system?

Q-74. What is the most probable cause of trouble in a synchro system that has all of its receivers reading incorrectly?

Q-75. If an ac voltmeter is connected between the S2 and S3 windings on a TX, at what two rotor positions should the voltmeter read maximum voltage?

Q-76. What precaution should you take when substituting a synchro tester in a circuit for a transmitter?

You should now have a good working knowledge of synchro systems. For further study and assistance in applying this knowledge to synchro troubleshooting and alignment, consult the following references:

Pertinent PMS sources:

1. Applicable maintenance instruction manuals.

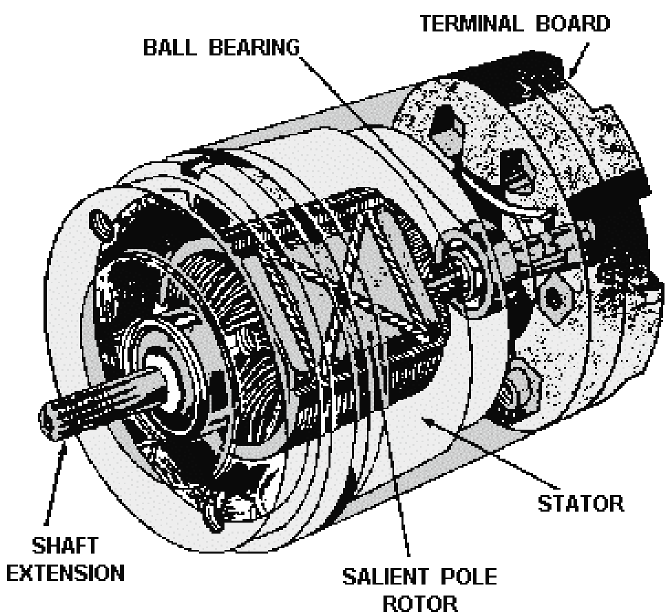
2. Military Handbook, *Synchros, Description and Operation*, MIL-HDBK-225A (March 91).

SUMMARY

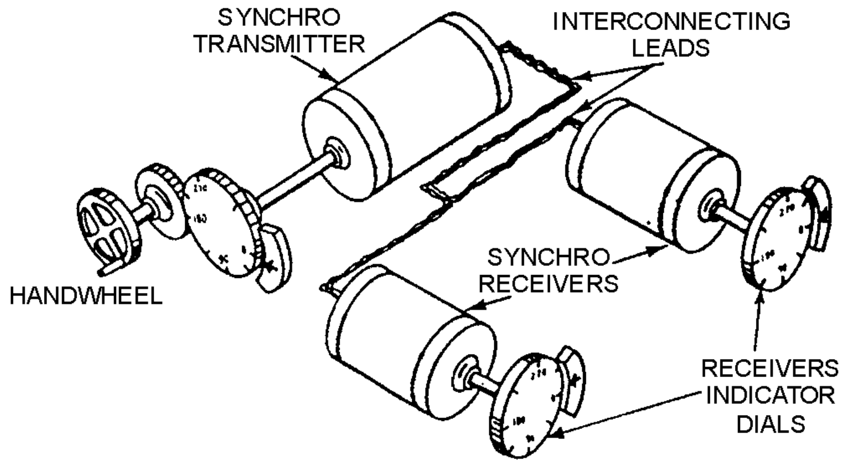
Now that you have completed this chapter, a short review is in order. The following review will refresh your memory of synchros, their principles of operation, and how they are tied together to form synchro systems.

A **SYNCHRO** resembles a small electric motor in size and appearance and operates like a variable transformer.

Synchros are used primarily for the rapid and accurate transmission of data. They are also used as control devices in servo systems.



A **SYNCHRO SYSTEM** consists of two or more synchros interconnected electrically.



TORQUE SYNCHRO SYSTEMS are systems that use torque synchros to move light loads, such as dials and pointers.

CONTROL SYNCHRO SYSTEMS are systems that use control synchros to control servo systems. The servo system, in conjunction with the control synchro system, is used to move heavy loads such as gun directors, radar antennas, and missile launchers.

MILITARY STANDARD SYNCHROS are synchros that conform to specifications that are uniform throughout the Armed Services. They replace the prestandard Navy synchros. A typical example of a military standard synchro designation code is 18TR6A. This code has the following interpretation:

18—Synchro diameter of 1.71 to 1.80 inches

T—Torque

R—Receiver

6—60-Hz frequency

A—Original design

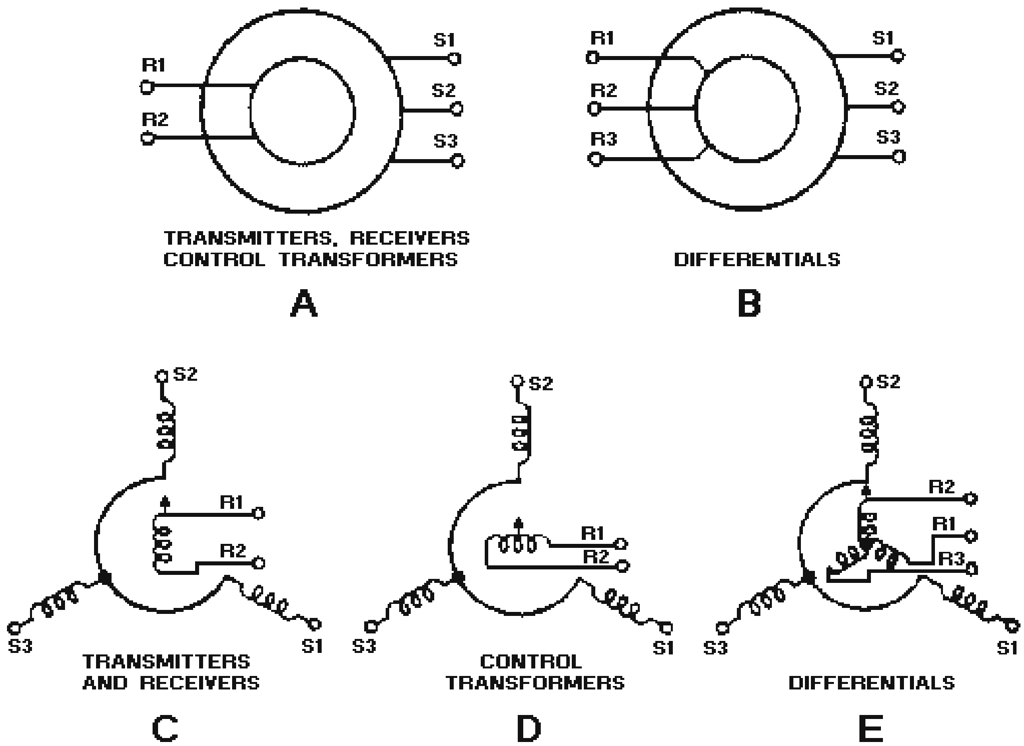
PRESTANDARD NAVY SYNCHROS are synchros designed to meet Navy, rather than service-wide, specifications. A typical example of a prestandard Navy synchro designation code is 5DG. This code has the following interpretation:

5—Synchro diameter of 3 3/8 to 3 5/8 inches, length

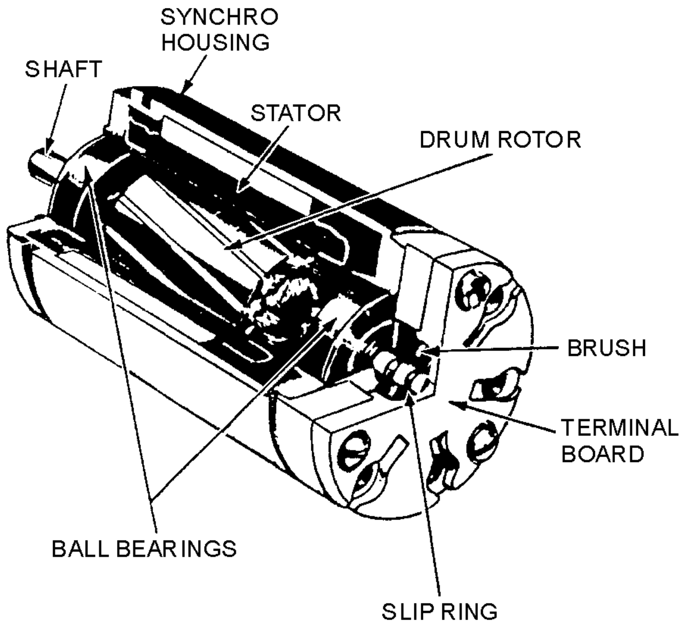
1/2 inches, weight 5 lbs.

DG—Differential transmitter

SCHEMATIC SYMBOLS for synchros are drawn in two different forms. Two of the five standard military symbols are drawn to show only the external connections to the synchro. The other three symbols are drawn to show both the external connections and the internal relationship between the rotor and the stator.

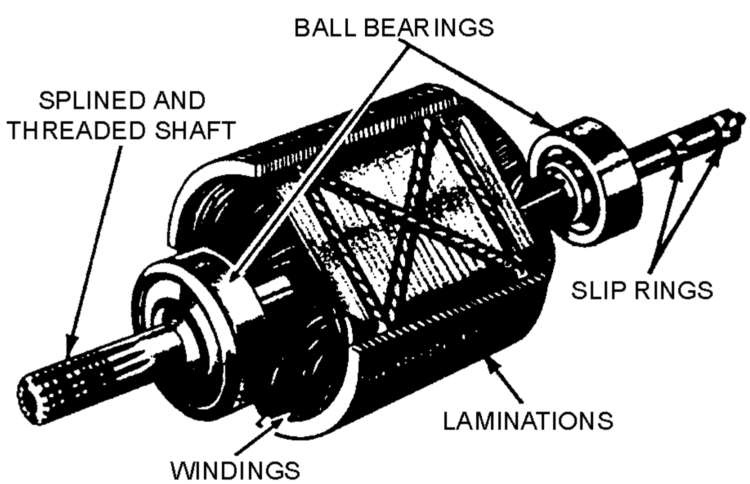


SYNCHROS ARE CONSTRUCTED like motors. Each contains a rotor, similar in appearance to the armature in a motor, and a stator which corresponds to the field in a motor.

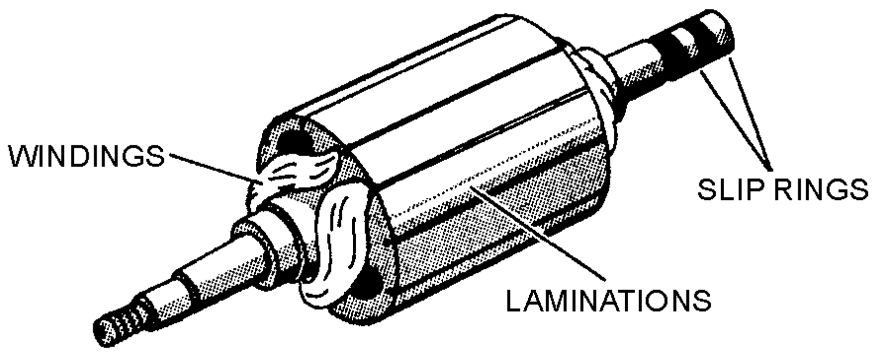


A **SYNCHRO ROTOR** is composed of either a single coil of wire wound on a laminated core or a group of coils wound in slots in a laminated core. The laminated core is rigidly mounted on a shaft that is free to turn inside the stator. Two slip rings are mounted on one end of the shaft to supply excitation voltage to the rotor. There are two common types of synchro rotors - the salient-pole rotor and the drum or wound rotor.

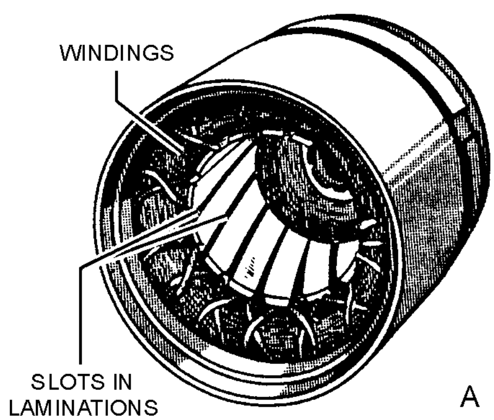
The **SALIENT-POLE ROTOR** has a single coil of wire wound on a laminated core, shaped like a dumbbell or the letter "H." This type of rotor is frequently used in transmitters and receivers.



The **DRUM OR WOUND ROTOR** may be wound continuously with a single length of wire or may have a group of coils connected in series. This type of rotor is used in most synchro control transformers and differential units, and occasionally in torque transmitters. When used in differential units, the rotor is wound with three coils so their magnetic axes are 120 degrees apart.



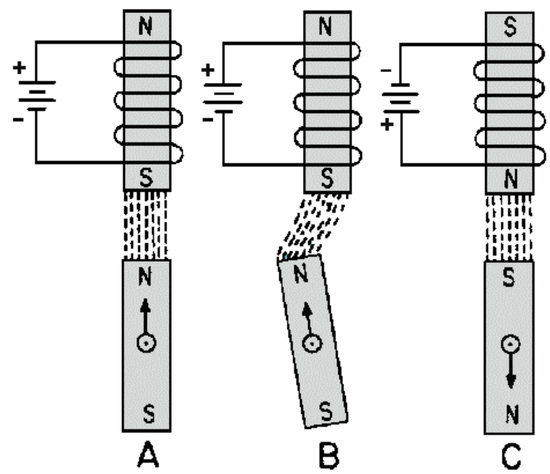
A **SYNCHRO STATOR** is a cylindrical structure of slotted lamination on which three Y-connected coils are wound with their axes 120º apart.



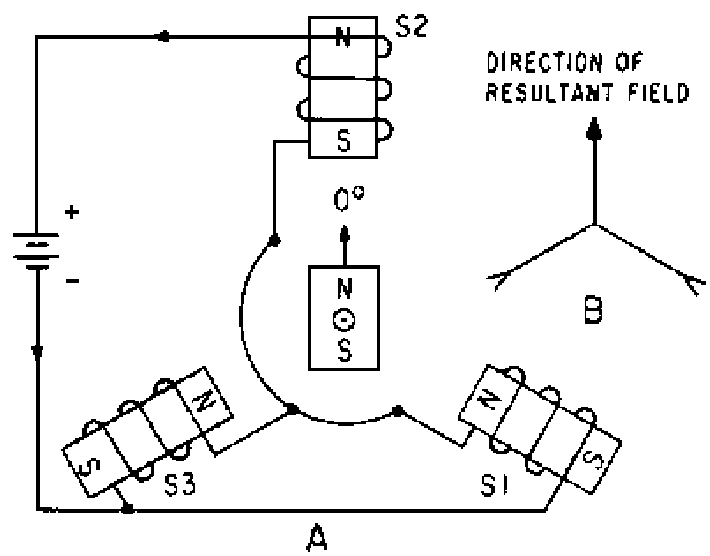
TORQUE is simply a measure of how much load a machine can turn. In heavy machinery, it is expressed in pound-feet and in torque synchro systems, it is expressed in ounce-inches.

SYNCHRO OPERATING VOLTAGES AND FREQUENCIES vary with different equipment. Synchros are designed for use on either a 115-volt or a 26-volt power source. They also operate on either a 60- or 400-Hz frequency.

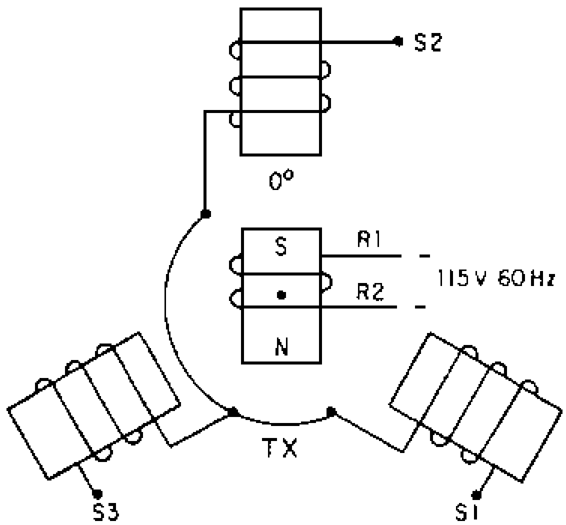
ELECTROMAGNETIC THEORY forms the basis for understanding all synchro operations.



The **RESULTANT MAGNETIC FIELD** in a synchro is the result of the combined effects of three stator fields spaced 120º apart. The stator coil with the strongest field has the greatest effect on the position of the resultant field.

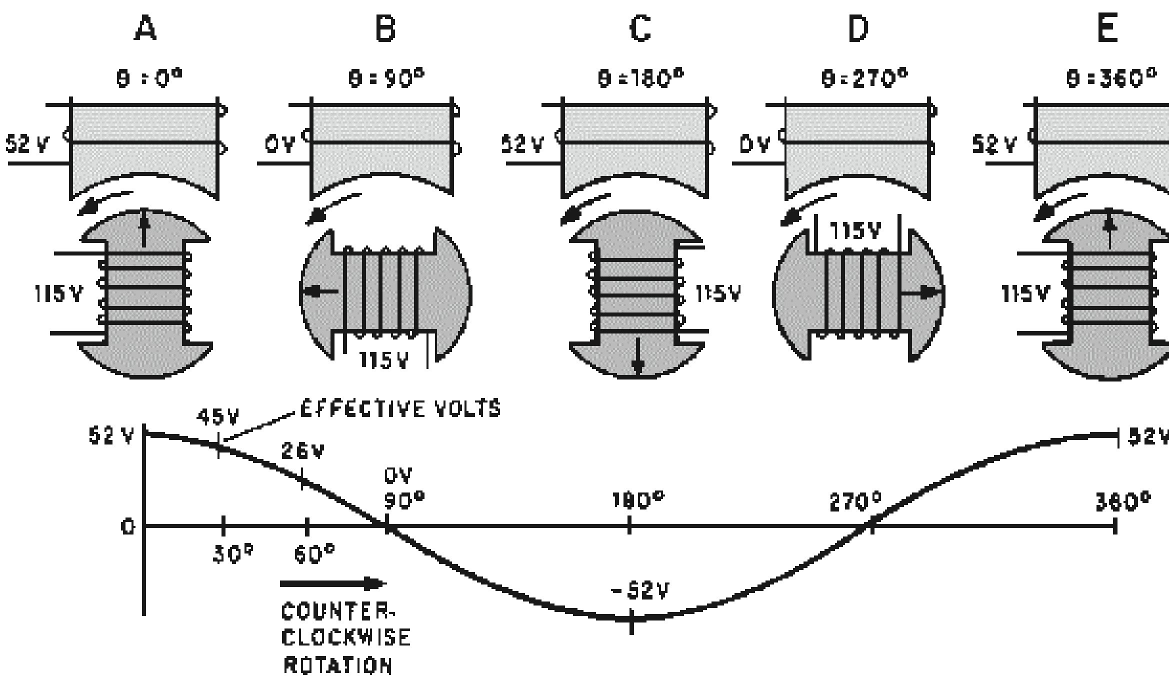


The **ZERO-DEGREE POSITION** of a synchro, transmitter is the position where the rotor and the S2 stator winding are parallel.



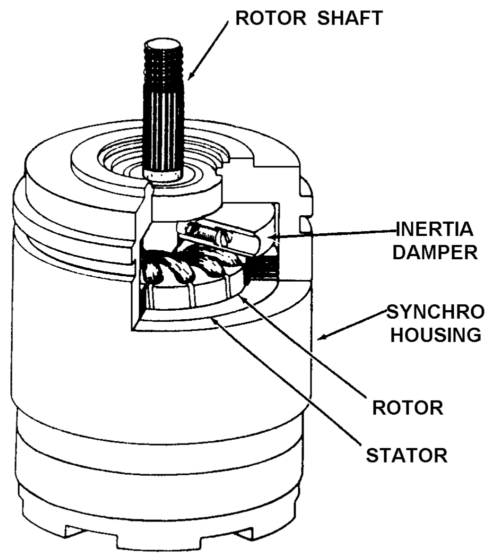
The **SYNCHRO TRANSMITTER (TX)** converts a mechanical input, which is the angular position of the rotor, into an electrical output signal. The output is taken from the stator windings and is used by a TDX, a TDR, or a TR to move light loads, such as dials and pointers.

MAXIMUM INDUCED STATOR VOLTAGE occurs in a single synchro stator coil each time there is maximum magnetic coupling between the rotor and the stator coil. This voltage is approximately equal to the product of the effective voltage on the primary, the secondary-to-primary turns ratio, and the magnetic coupling between the rotor and the stator coil.



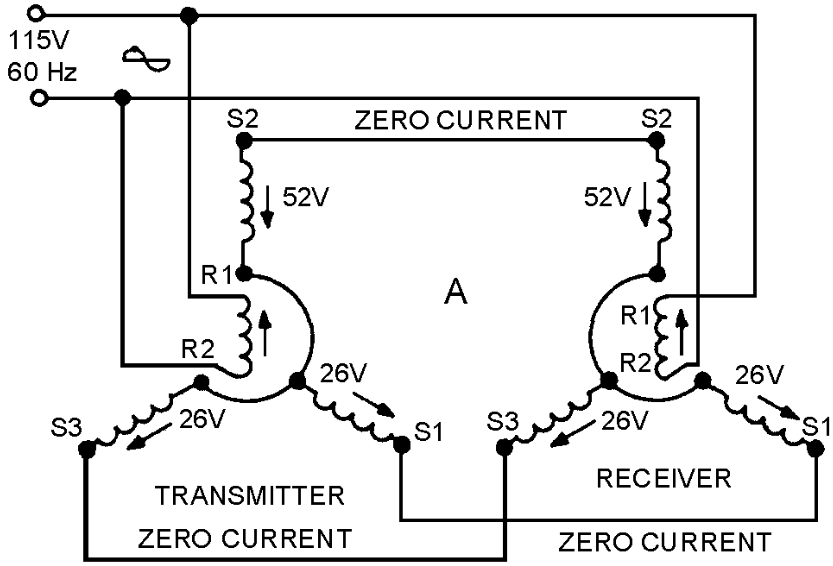
The **SYNCHRO RECEIVER (TR)** is electrically identical to the synchro transmitter. The receiver, however, uses some form of rotor damping that is not present in the transmitter. This real difference between a synchro transmitter and a synchro receiver lies in their applications. The receiver converts the electrical data, supplied to its stator from the transmitter, back to a mechanical angular output through the movement of its rotor.

DAMPING is a method used in synchro receivers to prevent the rotor from oscillating or spinning. There are two types of damping methods - ELECTRICAL and MECHANICAL. The electrical method is commonly used in small synchros, while the mechanical method is more effective in larger synchros.



A **TORQUE SYNCHRO SYSTEM** consists of a torque transmitter (TX) electrically connected to a torque receiver (TR). In this system, the mechanical input to the TX is transmitted electrically to the TR. The TR reproduces the signal from the TX and positions either a dial or a pointer to indicate the transmitted information.

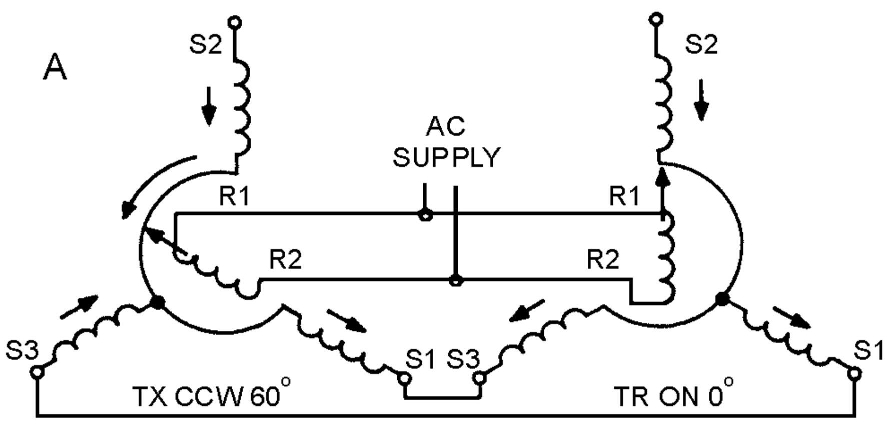
CORRESPONDENCE is the term given to the positions of the rotors of a synchro transmitter and a synchro receiver when both rotors are on 0º or displaced from 0º by the same angle.



SYSTEM IN CORRESPONDENCE

SIGNAL is defined as the angle through which a transmitter rotor is mechanically turned. This term has the same meaning as "transmitter's mechanical input."

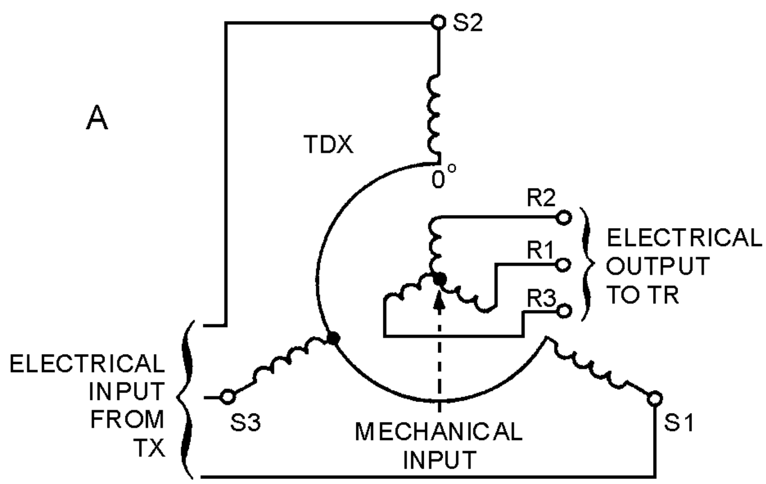
RECEIVER ROTATION may be in a direction opposite to that desired. When it is necessary to reverse receiver rotation, reverse the S1 and S3 connections on either the synchro transmitter or the synchro receiver. The causes both synchro rotors to turn through the same angle but in opposite directions.



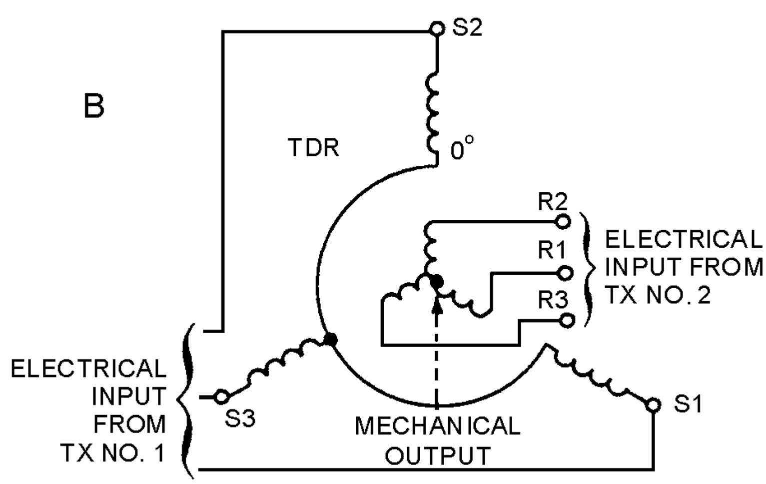
REVERSED ROTOR CONNECTIONS are common problems in new or modified synchro systems and should not be confused with the deliberate reversal of the stator connections. The reversal of the R1 and R2 connections on a synchro rotor causes a 180º error between the synchro transmitter and the synchro receiver, but the direction of rotor rotation still remains the same.

A **TORQUE DIFFERENTIAL SYNCHRO SYSTEM** consists either of a TX, a TDX, (torque differential transmitter), and a TR; or two TXs and one TDR (torque differential receiver). The system is used in applications where it is necessary to compare two signals, add or subtract the signals, and finish an output proportional to the sum of or difference between the two signals.

The **TORQUE DIFFERENTIAL TRANSMITTER (TDX)** has one electrical input to the stator and one mechanical input to the rotor. The TDX either adds or subtracts these inputs, depending upon how it is connected in the system, and provides an electrical output from its rotor proportional to the sum of or difference between the two signals.



The **TORQUE DIFFERENTIAL RECEIVER (TDR)** is electrically identical to the TDX. The only difference in their construction is that the TDR has some form of damping. The real difference between the two differentials lies in their applications. The TDR has two electrical inputs, one to the rotor and the other to the stator. The output is the mechanical position of the rotor. As is the case with the TDX, the addition or subtraction function of the TDR depends upon how it is connected in the system.



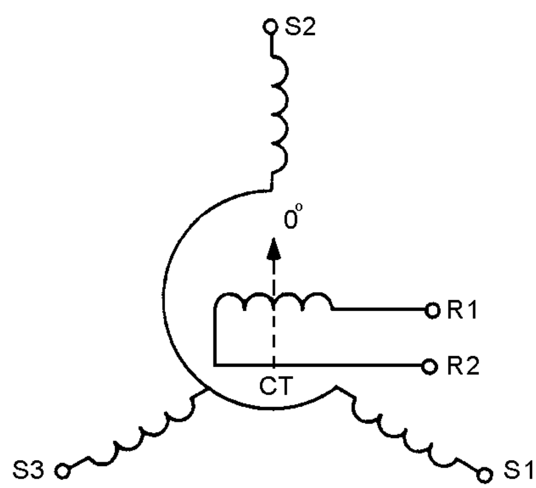
The **TX-TDX-TR SYSTEM** performs subtraction when the system contains standard synchro connections. Addition can also be performed with this system by reversing the S1 and S3 leads between the TX and the TDX, and the R1 and R3 leads between the TDX and the TR. Remember, this system works like a basic synchro system when the rotor of the TDX is on 0º; in this condition the TR rotor follows the TX rotor exactly.

The **TX-TDR-TX SYSTEM** performs subtraction when the system contains standard synchro connections. Addition can also be performed with this system when the R1 and R3 leads between the TDR rotor and TX No. 2 are reversed.

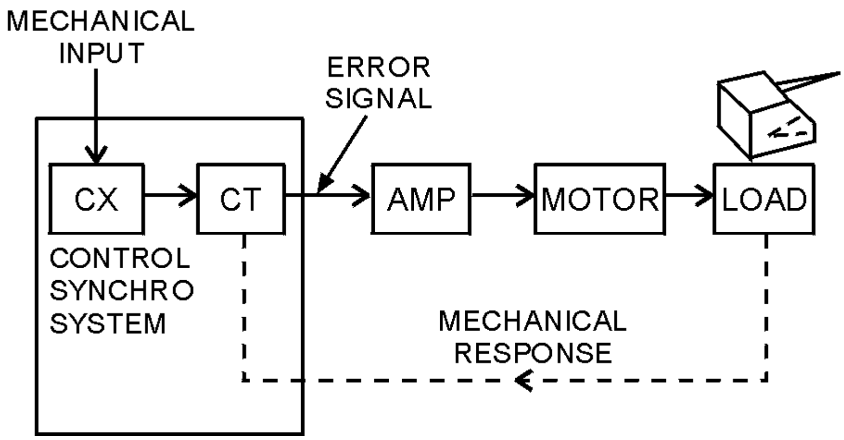
CONTROL SYNCHRO SYSTEMS contain control synchros and are used to control large amounts of power with a high degree of accuracy. These synchro systems control servos that generate the required power to move heavy loads.

CONTROL SYNCHROS are of three different types: the control transmitter (CX), the control transformer (CT), and the control differential transmitter (CDX). The CX and the CDX are identical to the TX and the TDX except for higher impedance windings. In theory, the CX and CDX are the same as the TX and TDX, respectively.

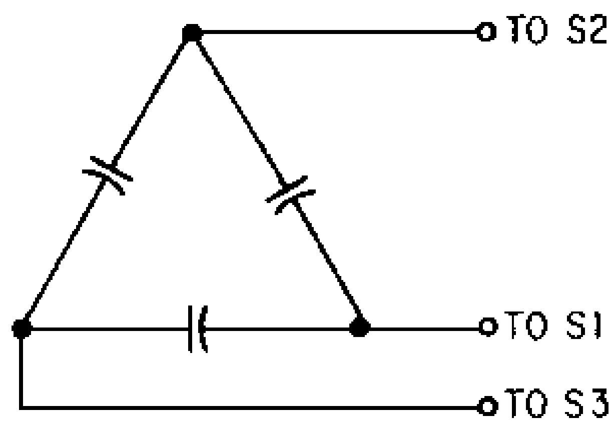
The **CONTROL TRANSFORMER (CT)** is a synchro device that compares two signals, the electrical signal applied to its stator, and the mechanical signal applied to its rotor. The output is an electrical voltage, which is taken from the rotor winding and used to control some form of power amplifying device. The phase and amplitude of the output voltage depend on the angular position of the rotor with respect to the magnetic field of the stator.



ERROR SIGNAL is the name given to the electrical output of a CT. The reason is that the electrical output voltage represents the amount and direction that the CX and CT rotors are out of correspondence. It is this error signal that eventually is used in moving the load in a typical servo system.



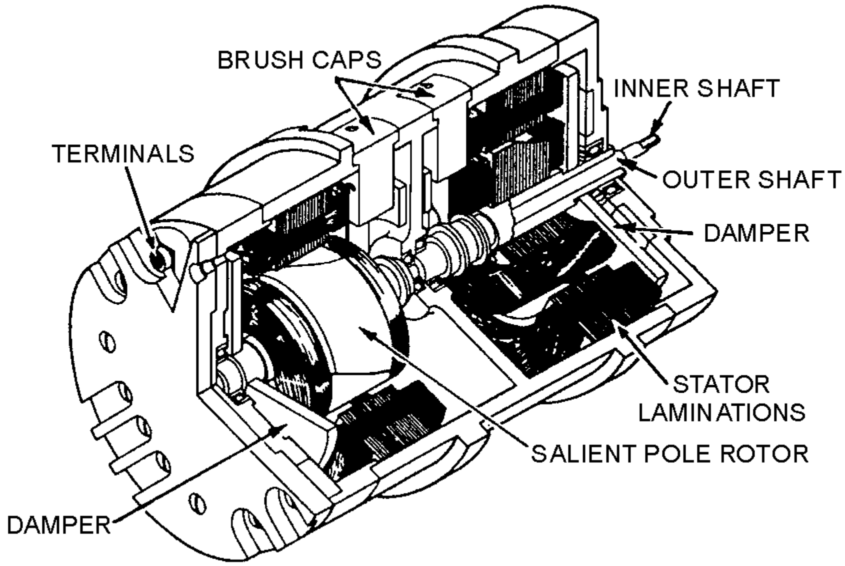
The **SYNCHRO CAPACITOR** is a unit containing three delta-connected capacitors. It is used in synchro systems containing either differential transmitters or CTs. The addition of the synchro capacitor to these systems greatly reduces the stator current and therefore increases the accuracy of the systems.



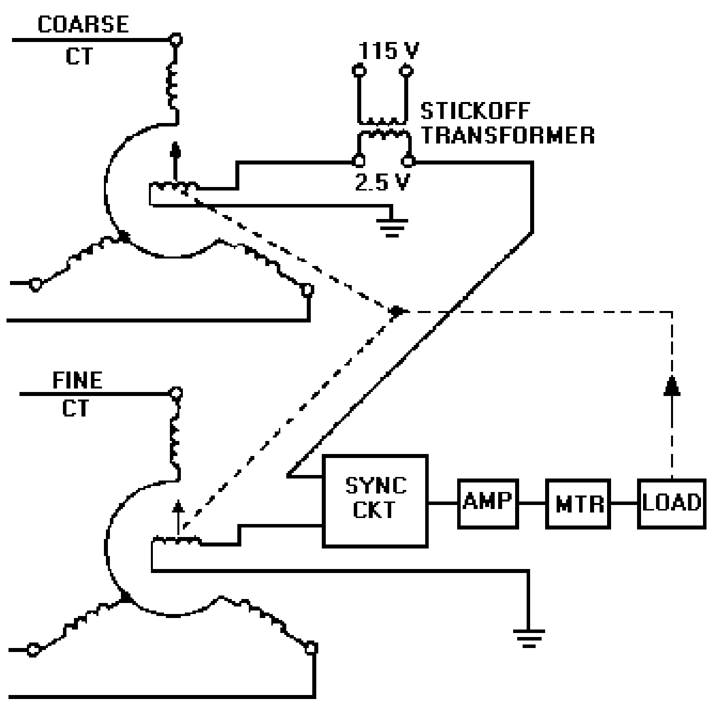
The **SPEED OF DATA TRANSMISSION** is simply the number of times a synchro transmitter rotor must turn to transmit a full range of values. You refer to the speed of data transmission as being 1-speed, 2-speed, 36-speed, or some other definite numerical ratio.

MULTISPEED SYNCHRO SYSTEMS transmit a wide range of data at different speeds and still maintain a high degree of accuracy. To indicate the number of different speeds at which data is transmitted, refer to the system as being a single-speed, dual-speed, or tri-speed synchro system.

A **DOUBLE RECEIVER** consists of a fine and a coarse receiver enclosed in a common housing. It has a two-shaft output (one inside the other), and its operation may be likened to the hour and minute hands of a clock.



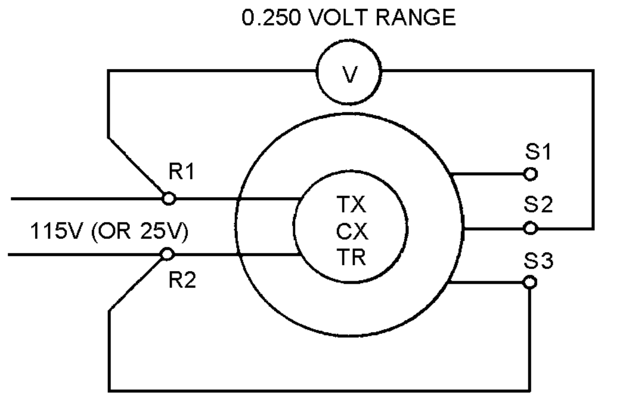
STICKOFF VOLTAGE is a low voltage used in multispeed synchro systems that contain CTs to prevent false synchronizations. The voltage is usually obtained from a small transformer and applied across the rotor terminals of the coarse CT.



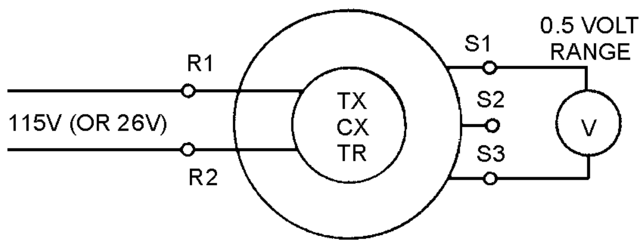
ELECTRICAL ZERO is the reference point for alignment of all synchro units.

SYNCHRO ZEROING METHODS are various and depend upon the facilities and tools available, and how the synchros are connected in the system. Some of the more common zeroing methods are the voltmeter, the electric-lock, and the synchro-tester methods.

The **VOLTMETER ZEROING METHOD** is the most accurate and requires a precision voltmeter. This method has two major steps-the coarse or approximate setting and the fine setting. The coarse setting ensures the synchro is not zeroed 180º away from its reference. This setting may be approximated physically by aligning two marks on the synchro. The fine setting is where the synchro is precisely set on 0º .

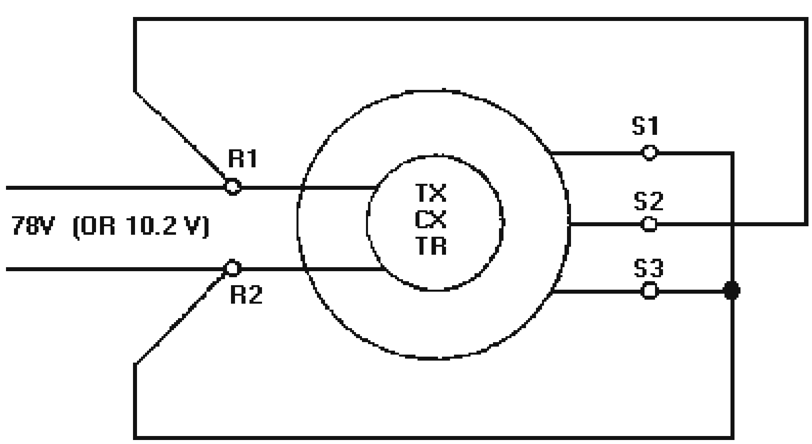


COARSE SETTING



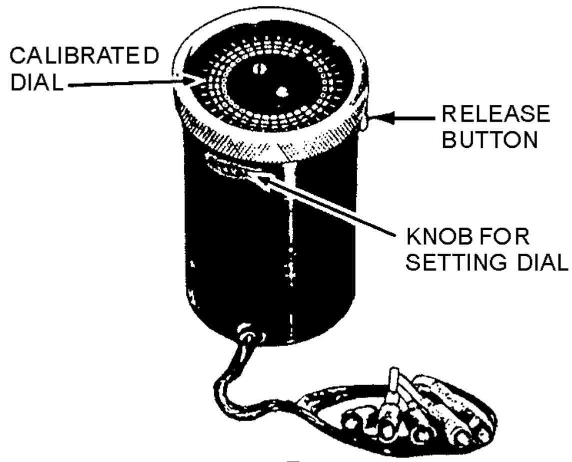
FINE SETTING

ELECTRICAL-LOCK ZEROING METHOD is perhaps the fastest. However, this method can be used only if the rotors of the synchros are free to turn and the leads are accessible. For this reason, this method is usually used on TRs.



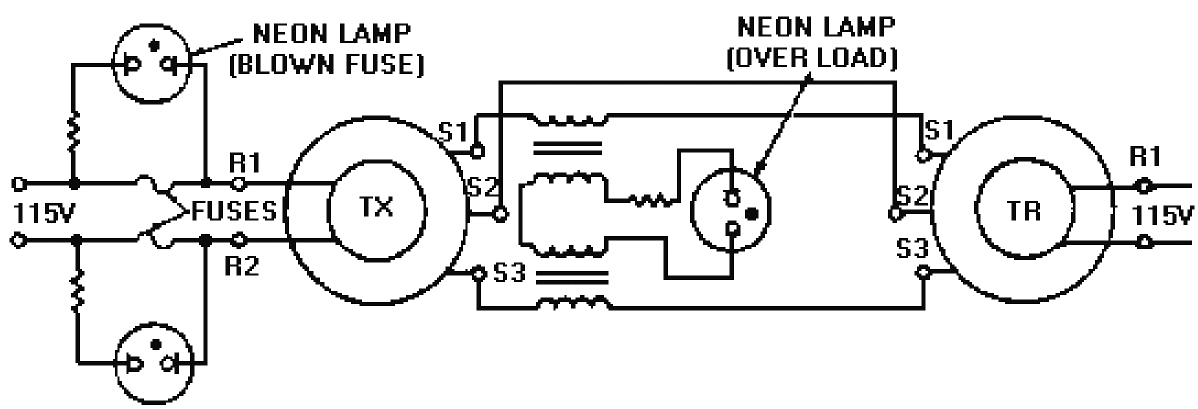
The **SYNCHRO-TESTER ZEROING METHOD** is potentially less accurate than the voltmeter or electric lock methods. This is because the dial on the tester is difficult to read and may slip from its locked position.

The synchro tester is nothing more than a synchro receiver on which a calibrated dial is mounted. The tester is used primarily for locating defective synchros but does provide a method for zeroing synchros.



B

TROUBLE INDICATORS are signal lights used to aid maintenance personnel in locating synchro trouble quickly. These lights are usually mounted on a central control board and connected to different synchro systems. The lights indicate either overload conditions or blown fuses.



SYNCHRO TROUBLESHOOTING is the locating or diagnosing of synchro malfunctions or breakdown by means of systematic checking or analysis. This is done by using trouble indicators, trouble tables furnished by manufacturers, known operating voltages as references, and synchro testers.

ANSWERS TO QUESTIONS Q1. THROUGH Q76.

A-1. The synchro.

A-2. Precise and rapid transmission of data between equipment and stations.

A-3. Torque and control.

A-4. A torque synchro is used for light loads and a control synchro is used in systems desired to move heavy loads.

A-5. The torque receiver (TR) and the torque differential receiver (TDR).

A-6. It is the third modification of a 26-volt 400-hertz (torque) synchro transmitter whose body diameter is between 1.01 and 1.10 inches.

A-7. The Navy prestandard designation code.

A-8. The position of the arrow.

A-9. The rotor and the stator.

A-10. The drum or wound rotor.

A-11. By the magnetic coupling from the rotor.

A-12. At the terminal board.

A-13. The number and type of synchro receivers, the mechanical loads on these receivers and the operating temperatures of both the transmitter and receivers.

A-14. A measure of how much load a machine can turn.

A-15. Ounce-inches.

A-16. Aircraft.

A-17. When it is overloaded.

A-18. Synchros have one primary winding that can be turned through 360º and three secondary windings spaced 120º apart.

A-19. The transmitter is in its zero-position when the rotor is aligned with the S2 stator winding.

A-20. When the rotor coil is aligned with the stator coil.

A-21. The amplitude of the primary voltage, the turns ratio, and the angular displacement between the rotor and the stator winding.

A-22. A synchro receiver uses some form of damping to retard excessive oscillations or spinning.

A-23. Mechanical damping.

A-24. A synchro transmitter and a synchro receiver.

A-25. The rotor leads.

A-26. The voltages are equal and oppose each other.

A-27. Signal.

A-28. 1 and S3.

A-29. The rotor leads on either the transmitter or the receiver are reversed.

A-30. Differential synchros can handle more signals than regular synchros and also perform addition and subtraction functions.

A-31. The TDX and the TDR.

A-32. Their application: a TDX has one electrical and one mechanical input with an electrical output.

A-33. The way the differential synchro is connected in a system is the deciding factor on whether the unit adds or subtracts its inputs.

A-34. When the TDX rotor is on 0º.

A-35. 240º.

A-36. 80º.

A-37. The S1 and S3 leads are reversed between the TX and the TDX, and the R1 and R3 leads are reversed between the TDX rotor and the TR.

A-38. The R1 and R3 leads between the TDR rotor and the TX to which it is connected.

A-39. Clockwise.

A-40. A control synchro.

A-41. CX, CT, and CDX.

A-42. The CX and CDX have higher impedance windings.

A-43. The rotor is specially wound, it is never connected to an ac supply, and its output is always applied to a high-impedance load.

A-44. They are perpendicular to each other.

A-45. The voltage is maximum and in phase with the ac excitation voltage to the CX.

A-46. Error signal.

A-47. When the CX and CT rotors are in correspondence.

A-48. To improve overall synchro system accuracy by reducing stator currents.

A-49. TDXs, CDXs, and Cts.

A-50. Magnetizing current.

A-51. They are delta-connected across the stator windings.

A-52. To keep the connections as short as possible in order to maintain system.

A-53. A dual or double-speed synchro system.

A-54. Greater accuracy without the loss of self-synchronous operation.

A-55. The gear ratio between the two transmitters.

A-56. A tri-speed synchro system.

A-57. If one of the receivers goes bad the entire unit must be replaced.

A-58. It is used in synchro systems to prevent false synchronizations.

A-59. Electrical zero.

A-60. The voltmeter method.

A-61. A61.It ensures the synchro is on 0º, not 180º.

A-62. A TR is zeroed when electrical zero voltages exist across its stator windings at the same time its rotor is on zero or on its mechanical reference position.

A-63. Approximately 37 volts.

A-64. Never leave the circuit energized for more than 2 minutes.

A-65. To ensure that it did not move off zero while it was being clamped.

A-66. Zero or minimum voltage.

A-67. The coarse synchro.

A-68. The electrical lock method.

A-69. It can be used only if the leads of the synchro are accessible and the rotor is free to turn.

A-70. The synchro under test is not on electrical zero.

A-71. Replace it.

A-72. Improper wiring and misalignment.

A-73. An overload indicator.

A-74. The transmitter or main bus.

A-75. 150º and 330º

A-76. Use only one receiver so as not to overload the tester.

CHAPTER 2

SERVOS

LEARNING OBJECTIVES

Upon completion of this chapter you will be able to:

1. Define the term "servo system" and the terms associated with servo systems, including open-loop and closed-loop control systems.
2. Identify from schematics and block diagrams the various servo circuits; give short explanations of the components and their characteristics; and of each circuit and its characteristics.
3. Trace the flow of data through the components of typical servo systems from input(s) to outputs(s) (cause to effect).

SERVOS

Servo mechanisms, also called SERVO SYSTEMS or SERVOS for short, have countless applications in the operation of electrical and electronic equipment. In working with radar and antennas, directors, computing devices, ship's communications, aircraft control, and many other equipments, it is often necessary to operate a mechanical load that is remote from its source of control. To obtain smooth, continuous, and accurate operation, these loads are normally best controlled by synchros. As you already know, the big problem here is that synchros are not powerful enough to do any great amount of work. This is where servos come into use.

A servo system uses a weak control signal to move large loads to a desired position with great accuracy. The key words in this definition are <u>move</u> and <u>great</u> <u>accuracy</u>. Servos may be found in such varied applications as moving the rudder and elevators of a model airplane in radio-controlled flight, to controlling the diving planes and rudders of nuclear submarines.

Servos are powerful. They can move heavy loads and be remotely controlled with great precision by synchro devices.

They take many forms. Servo systems are either electromechanical, electrohydraulic, hydraulic, or pneumatic.

Whatever the form, a relatively weak signal that represents a desired movement of the load is generated, controlled, amplified, and fed to a servo motor that does the work of moving the heavy load.

Q-1. What is a servo?

CATEGORIES OF CONTROL SYSTEMS

A control system is a group of components that are linked together to perform a specific purpose. Generally, a control system has a large power gain between input and output. The components used in the system and the complexity of the system are directly related to the requirements of the system's application.

Control systems are broadly classified as either CLOSED-LOOP or OPEN-LOOP.

Closed-loop control systems are the type most commonly used in the Navy because they respond and move the loads they are controlling quicker and with greater accuracy than open-loop systems.

The reason for quicker response and greater accuracy is that an automatic feedback system informs the input that the desired movement has taken place. Upon receipt of this feedback information, the system stops the motor, and motion of the load ceases until another movement is ordered by the input. This is similar to the system that controls heat in many homes. The thermostat (input) calls for heat. The furnace (output) produces heat and distributes it. Some of the heat is "fed back" to the thermostat. When this "feedback" raises the temperature of the room to that of the thermostat setting, the thermostat responds by shutting the system down until heat is again required. In such a system, the feedback path, input to output and back to input, forms what is called a "closed loop." This is a term you will hear and use often in discussions of control systems. Because closed-loop control systems are automatic in nature, they are further classified by the function they serve (e.g., controlling the position, the velocity, or the acceleration of the load being driven).

An open-loop control system is controlled directly, and only, by an input signal, without the benefit of feedback. The basic units of this system are an amplifier and a motor. The amplifier receives a low-level input signal and amplifies it enough to drive the motor to perform the desired job. Open-loop control systems are not as commonly used as closed-loop control systems because they are less accurate.

OPEN-LOOP CONTROL SYSTEM

As we stated previously, an open-loop control system is controlled directly, and only, by an input signal. The basic units of this type consist only of an amplifier and a motor. The amplifier receives a low-level input signal and amplifies it enough to drive the motor to perform the desired job.

The open-loop control system is shown in basic block diagram form in figure 2-1. With this system, the input is a signal that is fed to the amplifier. The output of the amplifier is proportional to the amplitude of the input signal. The phase (ac system) and polarity (dc system) of the input signal determines the direction that the motor shaft will turn. After amplification, the input signal is fed to the motor, which moves the output shaft (load) in the direction that corresponds with the input signal. The motor will not stop driving the output shaft until the input signal is reduced to zero or removed. This system usually requires an operator who controls speed and direction of movement of the output by varying the input. The operator could be controlling the input by either a mechanical or an electrical linkage.

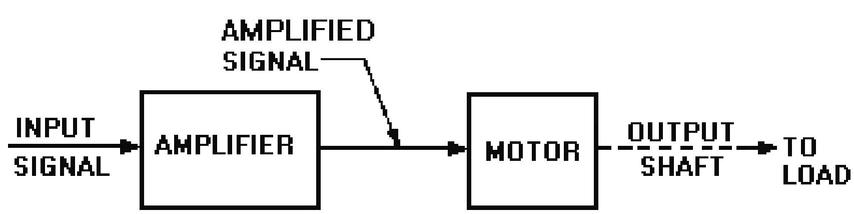


Figure 2-1.—Open-loop control system basic block diagram.

THE CLOSED-LOOP CONTROL SYSTEM

A closed-loop control system is another name for a servo system. To be classified as a servo, a control system must be capable of the following:

1. Accepting an order that defines the desired result
2. Determining the present conditions by some method of feedback
3. Comparing the desired result with the present conditions and obtaining a difference or an error signal
4. Issuing a correcting order (the error signal) that will properly change the existing conditions to the desired result
5. Obeying the correcting order

We have discussed the open- and closed-loop control systems and defined a servo system as a closed-loop control system. Although not technically accurate by definition, open-loop control systems are also often referred to in the Navy and many publications as servo systems even though they lack one of the five basic requirements, that of feedback.

Q-2. In an open-loop control system, what action reduces the input to zero so the load is stopped at the desired position?

Q-3. What basic requirement of a closed-loop system (not present in open-loops) enables present load position to be sensed?

OPERATION OF A BASIC SERVO SYSTEM

For the following discussion of a servo system, refer to figure 2-2, view (A), view (B), view (C) and view (D).This closed-loop servo system is the most common type in the Navy today. It is normally made up of electromechanical parts and consists basically of a synchro-control system, servo amplifier, servo motor, and some form of feedback (response).

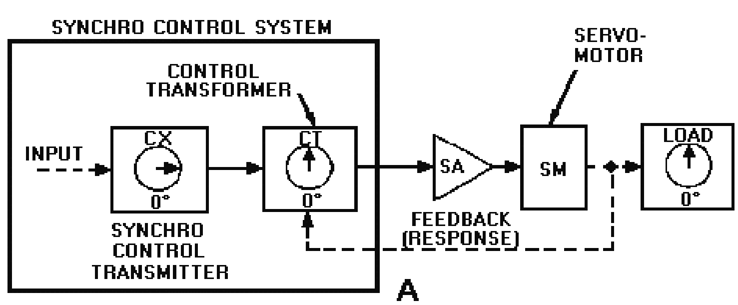

Figure 2-2A.—A basic servo system (closed-loop).

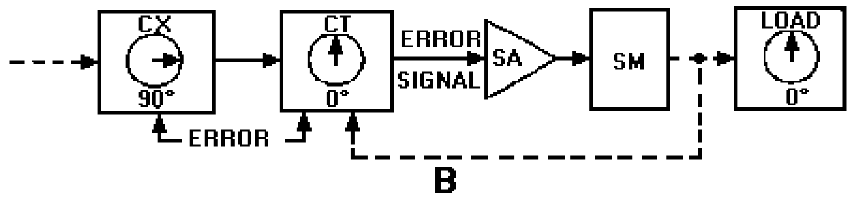

Figure 2-2B.—A basic servo system (closed-loop).

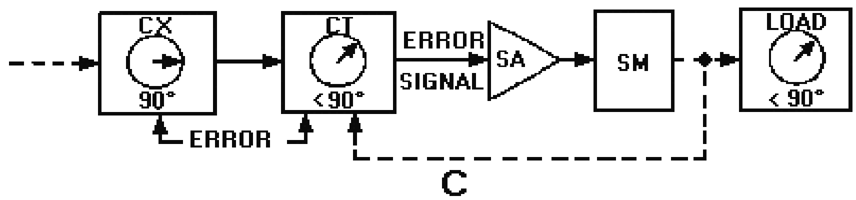

Figure 2-2C.—A basic servo system (closed-loop).

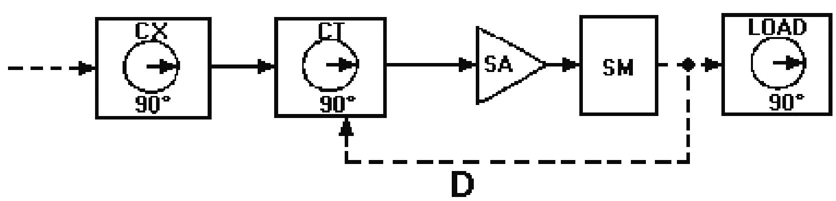

Figure 2-2D.—A basic servo system (closed-loop).

The synchro-control system provides a means of controlling the movement of the load, which may be located in a remote space. The servo amplifier and servo motor are the parts of the system in which power is actually developed (to move the load).

As you remember, the controlling signal from a CT is relatively weak, too weak to drive an electric motor directly. In views A through D of figure 2-2, assume that the control signal will be initiated by a handcrank input connected to the synchro transmitter (CX). The dials located on the CX and the CT indicate the positions of the synchro's rotors, while the dial on the load indicates the position of the load.

In view A, the dials of both the CX and the load indicate that the load is in the desired position. Because the load is where it should be, there will be no error signal present at the servo amplifier and no power to the servo motor.

In view B, the rotor of the CX has been moved by the handcrank to 90º. (This indicates that it is ordered to move the load by 90º.) Notice that the rotor of the CT is still at 0º. The CT now develops a signal, called the ERROR SIGNAL, which is proportional in amplitude to the amount the CT rotor is out of correspondence with the CX rotor. The phase of the error signal indicates the direction the CT rotor must move to reduce the error signal to zero or to "null out." The error signal is sent to the servo amplifier. In view C, the error signal has been amplified by the servo amplifier and sent on to the servo motor. The motor starts to drive in the direction that will reduce the error signal and bring the CT rotor back to the point of correspondence. In this case the motor is turning clockwise.

The mechanical linkage attached to the servo motor also moves the rotor of the CT. This feedback causes the amplitude of the error signal to decrease, slowing the speed at which the load is moving.

In view D, the servo motor has driven both the load and the rotor of the CT, so that the CT is now in correspondence with the CX rotor. As a result, the error signal is reduced to zero (nulled). The load stops at its new position. Note that in this servo system, we moved a heavy load to a predetermined position through the simple turning of a handcrank. In responding to the handcrank, the servo system performed a basic positioning function.

Two key points for you to remember, thus far, about the operation of the closed-loop servo system are:

1. The original error (movement of the CX rotor) was "detected" by the CT. For this reason the CT is called an ERROR DETECTOR.

2. The servo motor, in addition to moving the load, also provides mechanical feedback to the CT to reduce the error signal. For this reason the servo motor is also called an ERROR REDUCER.

Q-4. An error signal is the difference between what two quantities fed to the CT (error detector)?

Q-5. What are the two functions of the servo motor in the system shown in figure 2-2?

FUNCTIONAL SERVO LOOPS

Servo systems are also classified according to their functions: POSITION, VELOCITY, and ACCELERATION. We will cover the most common, POSITION and VELOCITY, in detail.

The Position Servo Loop

The primary purpose of the POSITION SERVO is to control the position of the load it is driving. It can be used to position a great number of devices (for example, valves, control surfaces, weapons, etc.). The basic servo loop we just explained using the block diagram in figure 2-2 is that of an ac position servo system. In the ac position servo system, the amplitude and phase of the ac error signal determine the amount and direction the load will be driven.

In a dc position servo system, the amplitude and polarity of a dc error signal respectively are used to determine the amount and direction the load will be driven.

Figure 2-3, view A, is a block diagram of a closed-loop de position servo. Note the Greek letter Sigma (Σ), meaning summation, surrounded by a circle.

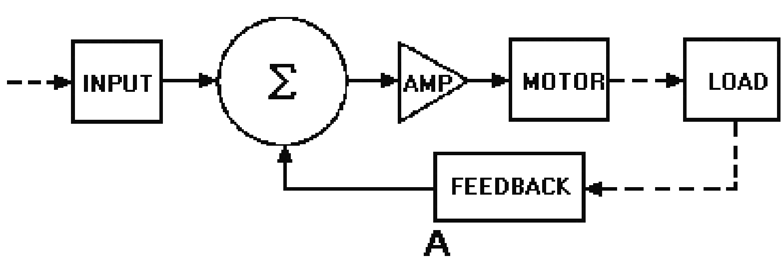

Figure 2-3A.—Block diagram of a position servo.

This is the summation, or "sum point" where the input signal, and the response signal (feedback) are summed to produce the error signal.

View B shows a more in-depth illustration of view A. With the wiper arms of R_1 and R_4 at the midpoint of travel, the voltage from the wiper arm to ground is zero volts. Therefore, zero volts would also be measured at the connection point between R_2 and R_3 (the summation point). This means that the error signal is zero. With no input signal, the amplifier output is zero; therefore, the motor shaft remains stationary.

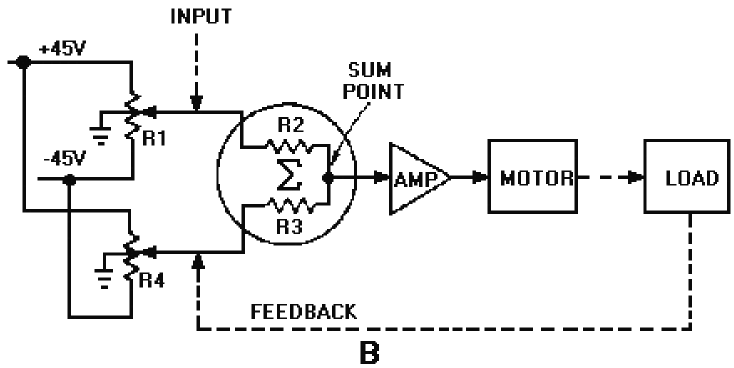

Figure 2-3B.—Block diagram of a position servo.

For the purpose of explanation, imagine that the R_1 wiper arm is mechanically moved upward to a new position where a voltage between the wiper arm and ground measures +10 volts. Further measurement shows zero volts between the wiper arm of $R_4$and ground. Since R_2 and R_3 are of equal values, +5 volts is measured between the sum point and ground because 5 volts is dropped across each resistor. The +5 volts at the sum point is the "error" signal.

As shown in figure 2-4, (view A, view B, and view C),when no error is present, the voltage at the sum point is zero. This is because the network composed of R_1, R_2, R_3, and R_4 is balanced. When the wiper of R_1 is moved toward +45 volts, the network becomes unbalanced as shown in view B. The left-hand side of R_2 becomes positive. This causes current to flow from +45 volts through R_3 and R_2 to the +10 volts at the left side of R_2. Because R_2 and R_3 are of equal value, the voltage drops then will be equal; therefore, the voltage at the sum point will equal +5 volts.

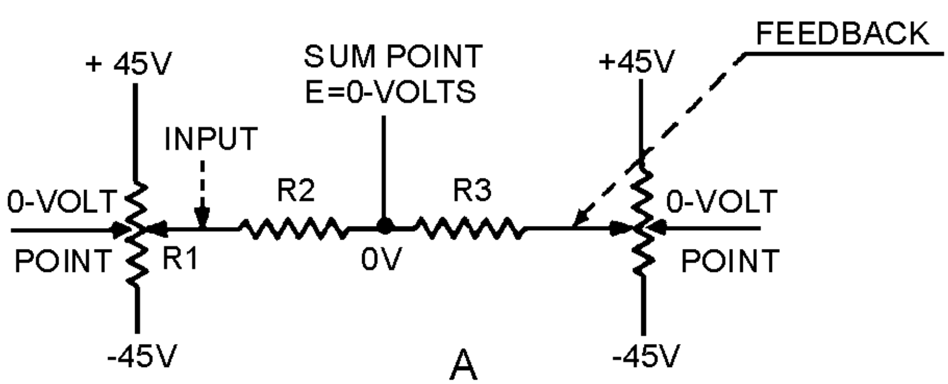

Figure 2-4A.—Development of the error signal.

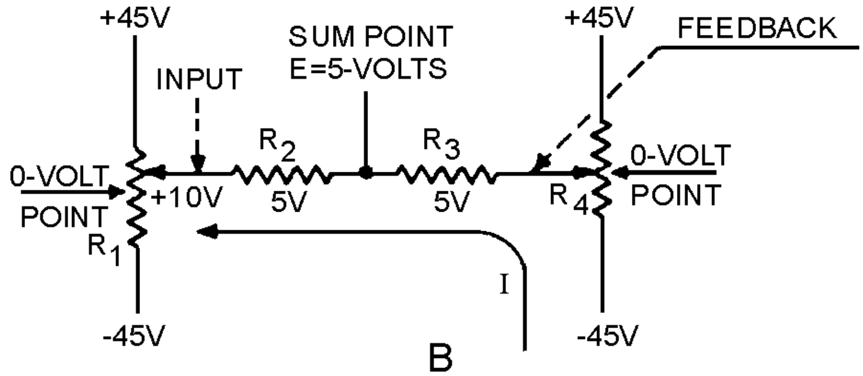

Figure 2-4B.—Development of the error signal.

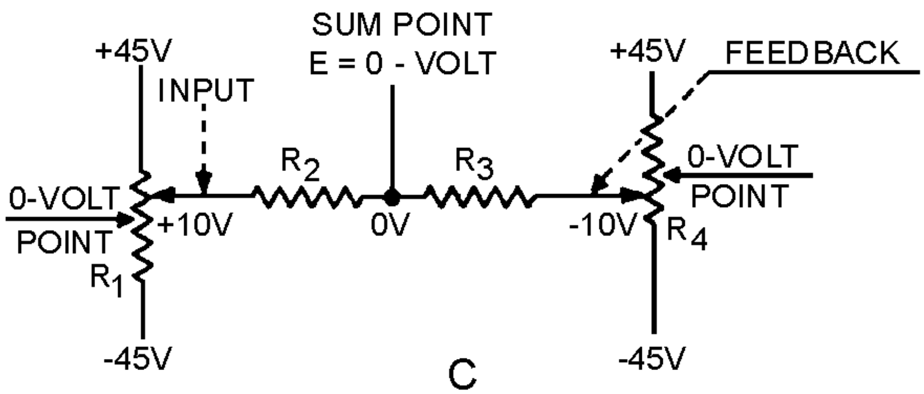

Figure 2-4C.—Development of the error signal.

The +5 volt error signal is fed into the amplifier. The amplified output starts driving the motor. The mechanical feedback from the motor drives the R_4 wiper arm down when the R_1 wiper is moved up, as shown in view C. This causes the right-hand side of R_3 to go negative. When the R_4 wiper travels far enough toward negative, it causes the right-hand side of R_3 to equal the voltage, but of opposite polarity, of the left-hand side of R_2. Simply stated, the voltage at the sum point will be zero again, and the motor will stop. This is true because R_2 and R_3 are of equal ohmic value, and when the left-hand side equals +10 volts, the right-hand side equals -10 volts. The point between the two resistors becomes zero volts at this time. At the instant that this occurs, the output shaft will have positioned the load to the new position.

Figure 2-5 shows the basic operation of a typical position servo having wide application in Navy equipment. Remember that in a position servo, an input order indicates a position in which a load is to be placed. The load in figure 2-5 is a gun turret. The purpose of the system is to position the gun by means of an order from a remote handcrank. The load is mechanically coupled through a gear train to the rotor of a CT so that the turret's position is always accurately represented by the position of the CT's rotor. An order signaling the desired position of the gun turret is fed into the servo by positioning the rotor of the CX with the handcrank. A corresponding signal immediately appears across the CT stator. This signal differs from the actual position of the gun turret, causing an error voltage to be developed across the CT rotor. The error voltage is fed from the CT rotor to the servo amplifier. At this point it is converted into power with a polarity or phase relationship that drives the motor in the direction necessary to bring the load into the desired position. As the turret moves, mechanical feedback turns the CT rotor toward agreement with the CX rotor. As the load approaches the proper position, less and less power is supplied to the motor because of the decreasing error voltage developed in the CT. When the electrical position of the CT rotor agrees with the position of the CX rotor, the error voltage reaches zero and power is removed from the motor. The turret is now in the desired position.

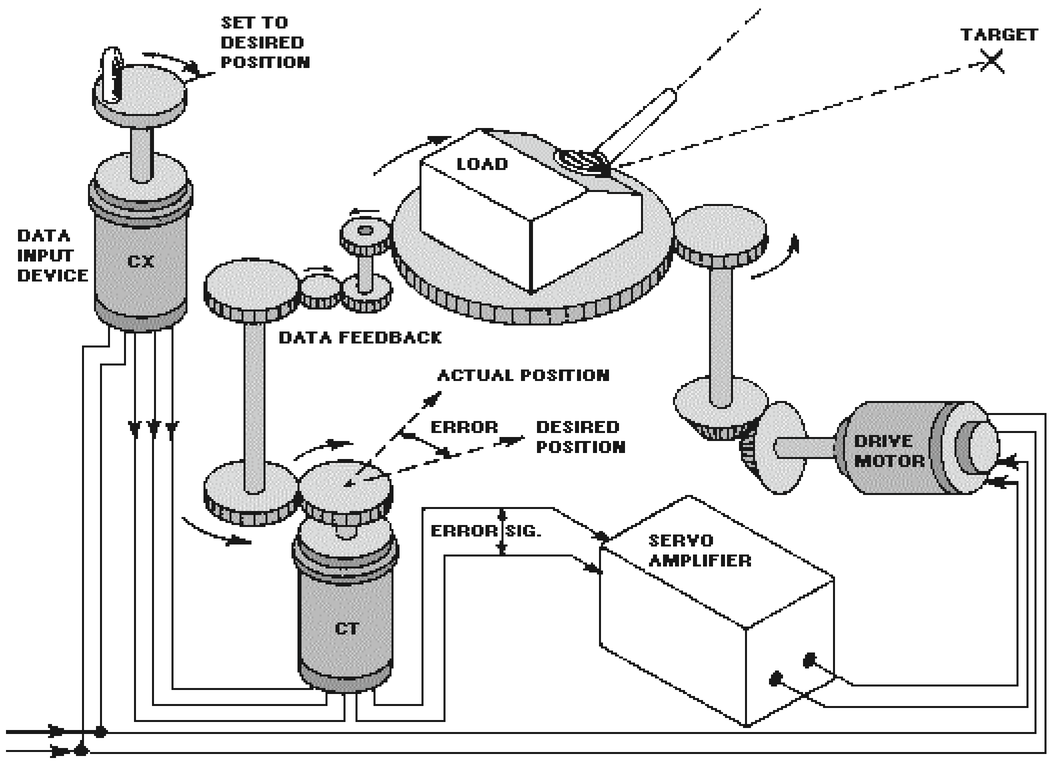

Figure 2-5.—Typical position servo.

In the actual system, the heavy gun turret's momentum tends to carry it past the desired position. This overshoot causes the rotor of the CT to move out of correspondence with the CX rotor. This, in turn, develops a new error signal that is opposite in polarity to the original input signal. The new error signal causes the turret to drive back toward the desired position — but the turret's momentum once again causes an overshoot, making the system drive in the opposite direction again. If this oscillation of the load around the desired position is allowed to go unchecked, a condition known as HUNTING results. Figure 2-6 shows graphically the result of a series of overtravels of the correspondence point (hunting). In most servos an electronic network known as an ANTIHUNT or DAMPING system is used to minimize this undesirable effect. We will cover antihunt and damping systems in depth later in this chapter.

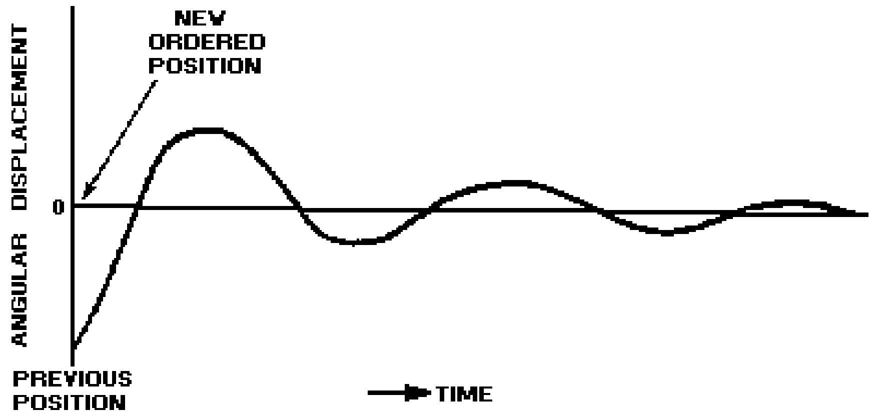

Figure 2-6.—Overtravels of the correspondence point (hunting).

Q-6. What are the three relatively common classifications of servo systems by function?

Q-7. The output of the sum point must contain information that controls what two factors of load movement in a position servo?

Q-8. What term is used for a series of overshoots in a servo system?

Velocity Servo Loop

The VELOCITY SERVO is based on the same principle of error-signal generation as the position servo, but there are some operational differences. Two major differences are as follows:

1. In this loop the VELOCITY of the output is sensed rather than the position of the load.
2. When the velocity loop is at correspondence or null position, an error signal is still present and the load is moving.

This type of servo is used in applications where the load is required to be driven at a constant speed. This speed is governed by the level of the error signal present. Radar antennas, star-tracking telescopes, machine cutting tools, and other devices requiring variable speed regulation are all examples of the types of load this servo may be used to drive.

Figure 2-7 is a block diagram of a velocity servo. It is similar to the block diagram of the position servo loop except that the velocity servo loop contains a TACHOMETER in the feedback line. The tachometer (tach) is a small generator that generates a voltage proportional to its shaft speed.

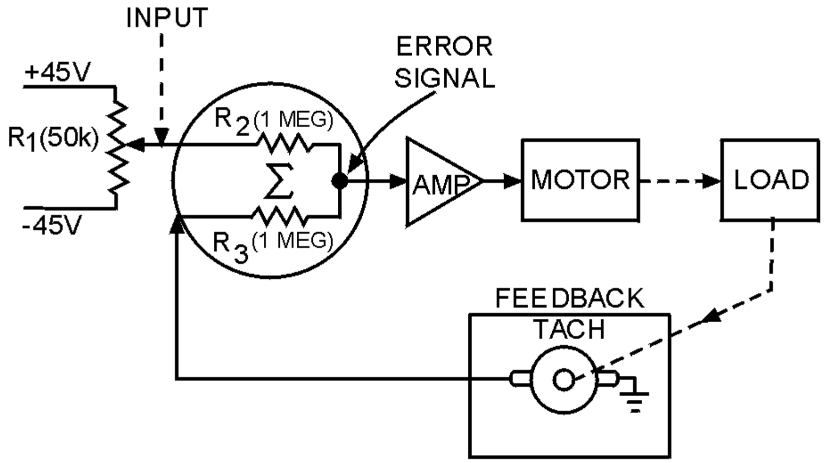

Figure 2-7.—Block diagram of a velocity servo.

In this application, the tach is used as a feedback device and is designed to produce 1 volt of feedback for each 10 rpm.

Let's assume that the motor is designed to turn 10 rpm for each volt of error signal. Figure 2-7 shows the tach mechanically connected to the load. With this arrangement, the shaft of the tach rotates as the load rotates, and the tach can be said to "sense" the speed of rotation of the load. For purposes of explanation, we win assume that the load is an antenna that we want to rotate at 30 rpm.

Initially, the wiper arm of R_1 is set at the 0-volt point (mid-position). This applies 0 volts to the left side of R_2. Since the motor is not turning, the load is not being driven, and the tach output is 0 volts. This applies 0 volts to the left side of R_3. Under these conditions, 0 volts is felt at the sum point and the motor is not driven. The voltage at the sum point is the error signal. When the wiper arm of R_1 is moved to the −9 volt point, an error signal appears at the sum point. At the first instant, the error signal (at the sum point) is −4.5 volts. This is because, at the first instant, the load and tach have not started to move. With the tach output at 0 volts, and the wiper of R_1 at −9 volts, −4.5 volts is present at the sum point. This voltage will cause the motor to start to rotate the load.

After a period of time, the load (and tach) are rotating at 10 rpm. This causes the tach to have an output of +1 volt. With +1 volt from the tach applied to the bottom of R_3, and −9 volts (from R_1 wiper) applied to the top of R_2, the voltage at the sum point (error signal) is –4 volts. Since the motor will turn 10 rpm for each volt of error signal, the motor continues to speed up. When the load reaches 30 rpm, the tach output is +3 volts. With this +3 volts at the bottom of R_3 and the −9 volts at the top of R_2, the error signal at the sum point is −3 volts. This −3 volts is the voltage required to drive the motor at 30 rpm, and places the system in balance. This satisfies the two conditions of the velocity servo. (1) The velocity of the output is sensed (by the tach), and (2) an error signal (−3 volts) is still present and the load continues to move when the velocity loop is at correspondence (30 rpm).

You may ask why the velocity loop and feedback are necessary. If this motor turns 10 rpm for each 1 volt error signal, why not simply feed −3 volts into this amplifier from the wiper of R_1 and not have a tach or summing network?

The answer is that the velocity loop will regulate the speed of the load for changing conditions. If the load in figure 2-7 were a rotating antenna on a ship, the antenna would tend to slow down as the wind opposed its movement and speed up as the wind aided its movement. Whenever the antenna slowed down, the output of the tach would decrease (since the tach is connected to the load). If the tach output decreased, the error signal would increase in amplitude and cause the motor to speed up. In the same way, if the antenna were to speed up, the tach output would increase, decreasing the error signal and the motor would slow down. Without the velocity loop to compensate for changing conditions, the load could not respond in the desired manner.

The system shown in figure 2-7 is a simplified version of a velocity loop. In practice, the reaction of the motor to error voltage and the output of the tach would not be equal (10 rpm per volt and 1 volt per 10 rpm). This would be compensated for by gearing between the motor and load and between the load and tach, or by using a summation network in which the resistors (R_2 and R_3) are riot equal. This use of unequal resistors is called a SCALING FACTOR and compensates for tach outputs and required motor inputs. This is just another way of saying that the individual components of the velocity loop must be made to work together so that each can respond in a manner that produces the desired system result.

Q-9. What are two major differences between velocity servos and position servos?

Q-10. In a typical velocity servo block diagram what device is placed in the feedback loop that is not present in the position servo?

Q-11. What is the advantage of using a closed-servo loop to control load velocity?

The Acceleration Servo

The acceleration servo is similar to the two loops we just discussed except that the acceleration of the load is sensed, rather than the position or velocity. In this loop, the tachometer of the velocity loop is replaced by an accelerometer (a device that generates a signal in response to an acceleration) as the feedback device.

We have not provided an illustration of the acceleration servo because of the complexity of its applications as well as its components. This type of servo is widely used in the rocket and missile fields, and is used whenever acceleration control is required.

SERVO CHARACTERISTICS

Servo characteristics vary primarily with the job the servo is designed to do. There are almost as many types of servos as there are jobs for servos. All servos usually have the common purpose of controlling output in a way ordered by the input. Ideally, motion and output shaft position should duplicate the track of the input shaft. However, this ideal performance is never achieved. We will discuss the major reasons for this, and show some methods used in the attempt to approach the ideal.

Because a servo compares an input signal with a feedback response, there will always be a TIME LAG between the input signal and the actual movement of the load. Also, the weight of the load may introduce an additional time lag. The time lag of the servo can be decreased by increasing the gain of the servo amplifier. If the gain is set too high, however, the servo output will tend to oscillate and be unstable. From this you can see that the gain of a servo is limited by stability considerations. Servo sensitivity must be considered along with stability to reach a "happy medium."

TIME LAG

To reduce time lag, the gain of the servo amplifier could be increased. Increasing the gain of the servo amplifier will decrease the lag time and cause the load to move faster. However, there is a serious drawback because the load is moving faster, its inertia will likely cause it to go past the desired position (overshoot). When the load attempts to drive back to the desired position, the high gain of the amplifier may cause it to overshoot in the opposite direction. Therefore, the system must be stabilized to minimize or eliminate the problem of overshoot. This is done through DAMPING. Damping can be done by either introducing a voltage in opposition to the signal voltage or placing a physical restraint on the servo output. The actual function of this antihunting is to reduce the amplitude and duration of the oscillations that may exist in the system. Every system has one or more natural oscillating frequencies that depend on the weight of the load, designed speed, and other characteristics.

The degree of damping is determined by the purpose and the use of the system. If the system is OVERDAMPED, it will not be bothered by oscillations. However, the large amount of restraint placed on the servo presents an additional problem. This is an excessive time requirement for the system to reach synchronization. Figure 2-8 is a graphic representation showing the time relationship with regard to degree of damping.

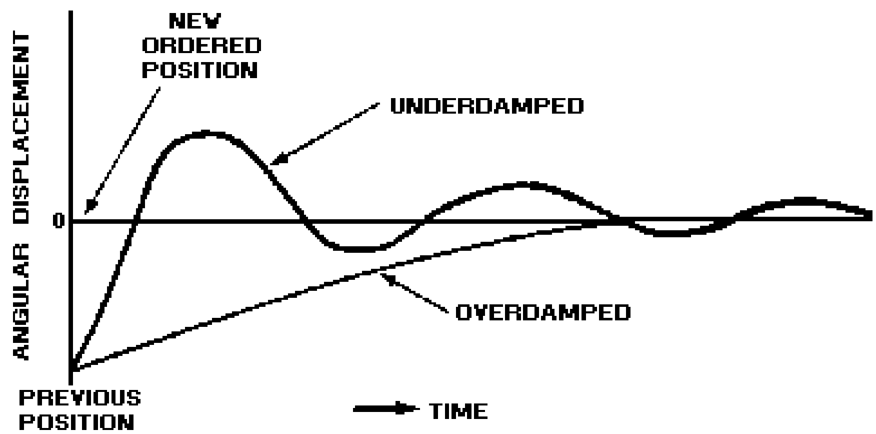

Figure 2-8.—Degree of damping.

An UNDERDAMPED servo system has other traits. The favorable one is its instantaneous response to an error signal. The unfavorable trait is an erratic operation around the point of synchronization because of the low amount of restraining force placed on the servo. Somewhere between overdamped and underdamped, there is a combination of desirable accuracy, smoothness, and moderately short synchronizing time.

The simplest form of damping is FRICTION damping. Friction damping is the application of friction to the output shaft or load that is proportional to the output velocity. The amount of friction applied to the system is critical, and will materially affect the results of the system. Friction absorbs power from the motor and converts that power to heat.

A pure friction damper would absorb an excessive amount of power from the system. However, two available systems have some of the characteristics of a friction damper, but with somewhat less power loss. These are the *friction clutch* and the *magnetic clutch*.

Q-12. If a position servo system tends to oscillate whenever a new position is selected, is the system overdamped or underdamped?

Q-13. If a position servo system does not respond to small changes of the input, is the system overdamped or underdamped?

Friction Clutch Damping

The friction clutch damper uses a friction clutch to couple a weighted flywheel to the output drive shaft of the servo motor. As the servo motor rotates, the clutch couples some of this motion to the flywheel. As the flywheel overcomes inertia and gains speed, it approaches the motor speed. The flywheel, in turning, absorbs energy (power) from the servo motor. The amount of energy stored in the flywheel is determined by its speed (velocity). Because of inertia, the flywheel resists any attempt to change its velocity.

As the correspondence point of the system is approached, the error signal is reduced and the motor begins to slow down. In an attempt to keep the output shaft turning at the same speed, the flywheel releases some of its energy into the shaft. This causes the first overshoot to be large. When the servo system drives past the point of correspondence, a new error signal is developed. The new error signal is of opposite polarity and causes the servo system motor to drive in the opposite direction. Once again the flywheel resists the motor movement and absorbs energy from the system. This causes a large reduction in the second overshoot and all subsequent overshoots of the system. The overall effect is to dampen the oscillations about the point of correspondence and reduce the synchronizing time.

The motor rotation is transmitted to the flywheel through the friction clutch. The inertia of the flywheel acts as an additional load on the motor. The friction clutch is designed to slip with a rapid change of direction or speed. This slipping effectively disconnects the flywheel instantaneously, and thus governs the amount of power the flywheel draws from the motor.

Magnetic Clutch

Another type of damper is the MAGNETIC CLUTCH. This type is similar in function to the friction-clutch damper. The main difference between the two is the method used to couple the flywheel to the shaft of the servo motor. There are two distinct types of magnetic clutch dampers. The first uses a magnetic field to draw two friction clutch plates together to produce damping. The action is similar to the friction clutch we just described.

The second version of the magnetic clutch uses the action of a magnetic field generated by two sets of coils, or one set of coils and the induced eddy currents, which result from rotation of the single set of coils near a conducting surface (the flywheel).

Coupling in this type of clutch is made by the interaction of two magnetic fields without a physical contact between the two. The two-coil or eddy-current type of magnetic clutch offers smoother operation than a pure friction clutch and has no problem of wear because of friction.

In summary, a smooth, efficient operating servo system can only be achieved by a system of compromises. As you recall, earlier we increased the gain of the amplifier to reduce time lag. This had the drawback of increasing hunting or oscillations about the point of correspondence. We overcame this difficulty through friction damping. This solved the problem of hunting and smoothed out servo operation but acted as part of the servo load. It caused a large first overshoot and increased the time lag. Some form of damping that can be used with high amplification to obtain smooth servo operation and minimum time lag is needed. The answer lies with the use of ERROR-RATE damping.

Q-14. Why is damping needed in a practical servo system?

Error-Rate Damping

Error-rate damping is a method of damping that "anticipates" the amount of overshoot. This form of damping corrects the overshoot by introducing a voltage in the error detector that is proportional to the rate of change of the error signal.

This "correction" voltage is combined with the error signal in the proper ratio to obtain the desired servo operation with reduced overshooting and minimum time lag.

The advantages of error-rate damping are as follows:

1. Maximum damping occurs when a maximum rate of change of error signal is present. This normally would occur as the servo load reverses direction.

2. Since a CHANGE in the signal causes damping, there is a minimum amount of damping when no signal, or a signal of constant strength, is present.

Error-rate voltages are generated by either electromechanical devices or electrical networks in the equipment. One electromechanical device widely used to generate an error-rate voltage is the tachometer generator. As you learned previously, its output voltage is proportional to the output velocity of the servo. Hence, the output voltage of the tachometer can be used to anticipate sudden movement changes of the load.

The compensating electrical network used for error-rate damping consists of a combination of resistors and capacitors forming an RC, differentiating or integrating network. You should recall that a differentiating circuit produces an output voltage that is proportional to the rate of change of the input voltage and that an integrating circuit produces an output proportional to the integral of the input signal.

Figure 2-9 shows a basic RC INTEGRATOR. It can be recognized by the output voltage being taken across the capacitor. R_1 is added in this circuit to develop the transient error signal (small variation in the signal from the error detector). The RC integrator is sometimes referred to as an INTEGRAL CONTROL CIRCUIT and will be used to explain electrical error-rate damping.

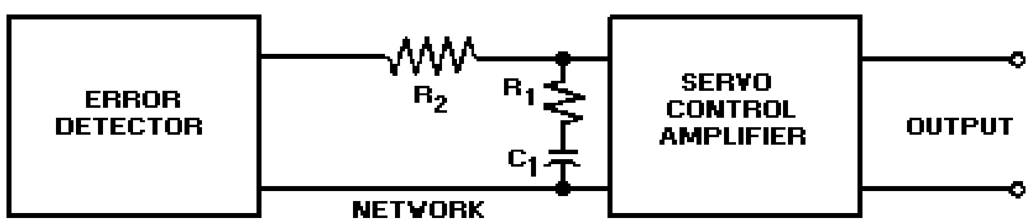

Figure 2-9.—Error rate stabilization network using an RC integrator.

The network consists of a capacitor and two resistors connected in series with the servo amplifier. The components of this circuit are designed to work with a constant or very slowly changing error signal.

Initially, all of the error voltage is divided between R_1 and R_2. But the longer the error voltage is applied, the more C_1 charges, and the greater the voltage at the input of the amplifier. Because of the RC time of the circuit, it takes time for the capacitor to charge to the value of the error input signal. Because of the long charge time of C_1, the circuit can not respond instantaneously to a rapid change in error signal.

What this means is that all error signals will be integrated (or smoothed out). The load will not respond as quickly. The inertia of the load will be reduced, and the system will be damped.

The capacitor, by not responding instantaneously to the error signal, causes the damping action. This action is used to stabilize the servo system at the new velocity. By tailoring the stabilization network (through the proper selection of the RC components) to the system's performance requirements and the type of load to be driven, undesirable load or performance characteristics can be minimized.

The various compensating networks that you will encounter will depend on the design of the individual servo system and will be covered in the associated system's technical manual.

In summary, the key to understanding compensating networks is to realize that components are chosen so the capacitor does not have time to charge and discharge in response to large, rapid fluctuations.

Q-15. Error-rate damping is effective because the circuitry has the capability of ______________the amount of overshoot before it happens.

FREQUENCY RESPONSE

The frequency response of a servo is the range of frequencies to which the system is able to respond in moving the load. It is a characteristic of the system, chosen by the designers so the system will be able to respond to whatever frequencies are expected to be present in the input signal for the particular application.

Oscillating Input Signal

At first, we considered the input order to a servo as being suddenly put at a fixed desired value. Later, we studied the case where the order slowly increased to the desired value. Actually, the input order to a servo in a given application may accelerate, start, stop, or oscillate about a fixed point. We will now consider the actions of a servo while the order oscillates. When the order is constant, oscillations of the load are undesirable. When the order oscillates, the load must oscillate in a similar manner.

Let's assume that an oscillating input signal (order) is applied to a servo. The load may behave in several ways. Ideally, it would respond in perfect sync with the order. Actually, the amplitude and phase of the load are different from those of the order, figure 2-10. As we noted above, the frequency response of the system is normally designed so the load is able to respond to the order.

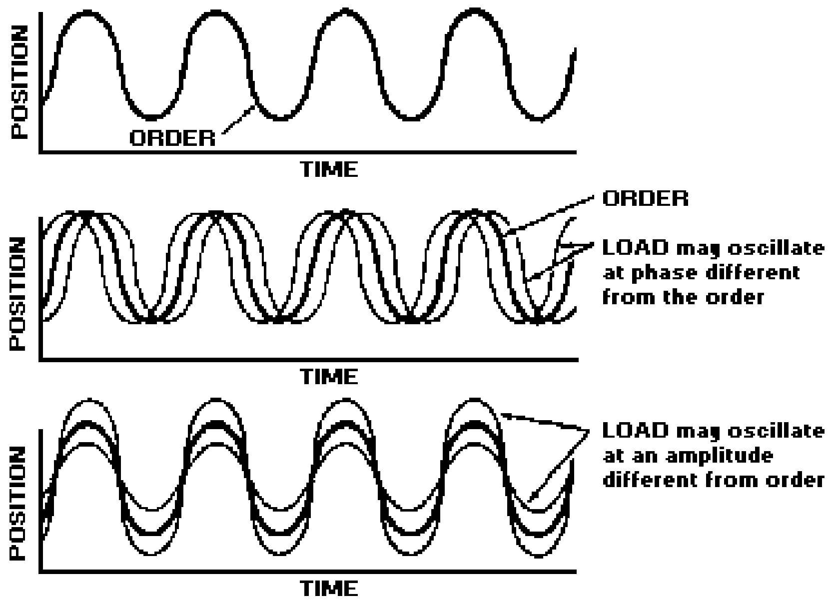

Figure 2-10.—Frequency response.

A servo may follow the order in amplitude and differ in phase; it may follow the order in phase, and differ in amplitude; or it may differ in both phase and amplitude.

Bandpass Frequencies in a Servo system

Servos are plagued by noise signals that ride through the system on desired electrical signals. These noise signals cause roughness in the servo system and must be eliminated to obtain smooth servo operation.

By examining the different signals in a servo system, we can determine which frequencies are related to the movement of the load and which ones are from noise sources, such as static, motors, harmonics, and mechanical resonances.

Filters in the signal circuit can be used to shunt some of the unwanted frequencies away from the amplifier, and allow only those frequencies that represent load movement to enter the amplifier. This can also be accomplished by designing the BANDWIDTH of the servo amplifier to accept only the range of frequencies that represents valid servo signals and to reject all others. This smooths servo response, but has the drawback of reducing amplifier gain. Reduced amplifier bandwidth is another compromise in achieving optimum servo operation.

Q-16. In a properly designed servo system that has an oscillating input (order), what should be the response of the load?

Q-17. What is the advantage of designing a limited bandwidth into a servo amplifier?

SERVO COMPONENTS AND CIRCUITS

In this section we will discuss the circuits and components that make up a typical servo system. We cannot cover all possible servo applications here because of the vast number of servo system configurations. The circuits and components discussed in the following pages are the most commonly used and represent a broad view of the systems used in the Navy today. We have not attempted to put the units into any rigid classification system. We will mention some of the more common terms used by manufacturers and the Navy to classify the devices to familiarize you with the wide variety of nomenclatures.

We will be covering much of the electronic application without discussing the theory of the units. You may want to review some of the applicable NEETS modules or other sources before or during this discussion. You will find that much of the material necessary to understand these subjects is contained in the basic theory of electricity and electronics.

POSITION SENSORS

A position sensor is a device that changes a mechanical position into a voltage that represents that position. The output of a position sensor can be either ac or dc voltage. There are many different kinds of position sensors. In the last chapter you learned about the CX, a synchro device that represents the position of its rotor by a voltage on its stators. You saw a CX used as a position sensor in a servo system earlier in this chapter. Other devices can be used as position sensors. The potentiometer is one of these devices.

Potentiometers

Potentiometer position sensors are generally used only where the input and output of the servo mechanism have limited motion They are characterized by high accuracy and small size, and may have either a dc or an ac output voltage. Their disadvantages include limited motion and a life problem resulting from the wear of the brush on the potentiometer wire. Also the voltage output of the potentiometer changes in discrete steps as the brush moves from wire to wire. A further disadvantage of some potentiometers is the high drive torque required to rotate the wiper contact.

A potentiometer is one of the simplest means of converting mechanical positional information to a proportional voltage. A schematic representation of a potentiometer is shown in figure 2-11.

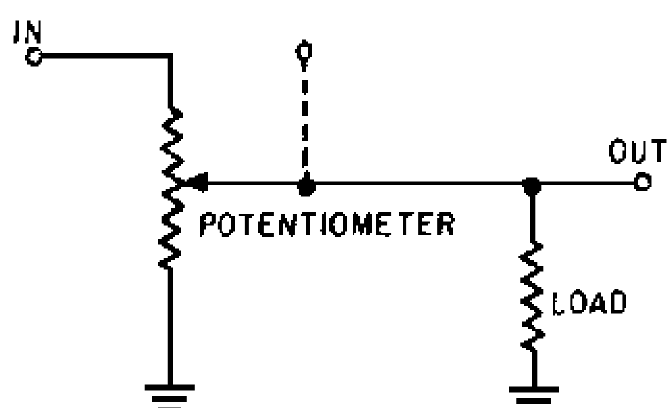

Figure 2-11.—A potentiometer.

A potentiometer is a variable voltage divider, with an output voltage that is a percentage of the input voltage. The amount of output voltage is proportional to the position of the wiper relative to the grounded end. For example, if the resistance from ground to the wiper is 50% of the total, the output voltage sensed by the load will be 50% of the total voltage across the potentiometer.

A basic, closed-loop servo system using a balanced potentiometer as a position sensor is shown in figure 2-12.

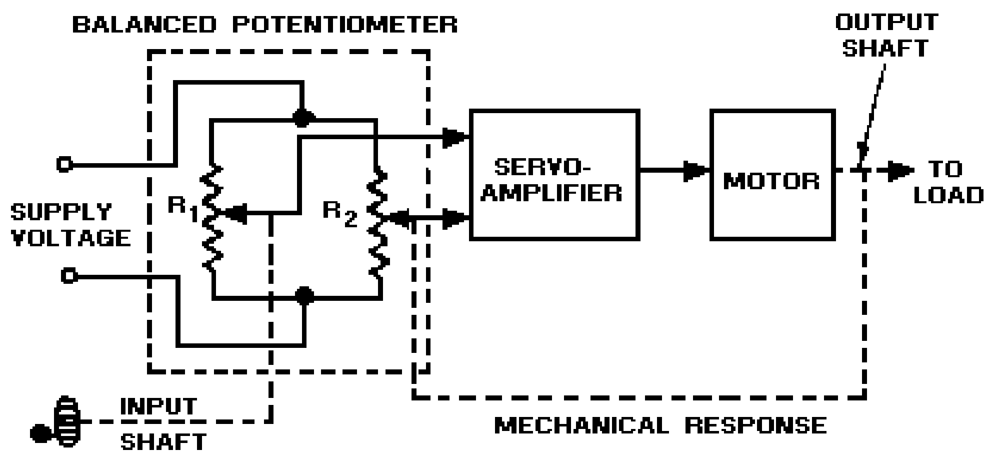

Figure 2-12.—Balanced potentiometer used In position sensing.

The command input shaft is mechanically linked to R_1, and the load is mechanically linked to R_2. A supply voltage is applied across both potentiometers.

The system is designed so that when the input and output shafts are in the same angular position, the voltages from the two potentiometers are equal and no error voltage is felt at the amplifier input. If the input shaft is rotated, moving the wiper contact of R_1, an error voltage is applied to the servo amplifier. This error voltage is the difference between the voltages at the wiper contents of R_1 and R_2. The output of the amplifier causes the motor to rotate the load and the wiper contact of R_2. This continues until both voltages are again equal. When the voltages are equal, the motor stops. In effect, the position of the output shaft has been sensed by the balanced potentiometer.

Q-18. When the input and output wipers of a balanced potentiometer are in the same angular position, what is the value of the error voltage?

ERROR DETECTORS

Electrical error detectors may be either ac or dc devices, depending upon the requirements of the servo system. An ac device used as an error detector must compare the two signals and produce an error signal in which the phase and amplitude will indicate the direction and amount of control, respectively, that are necessary for correspondence. A dc device differs in that the polarity of the output error signal determines the direction of the necessary correction. We will discuss in the following paragraphs various devices that are commonly used in servo systems.

Summing Networks

Summing networks, as we mentioned earlier, are used as error detectors in servo applications where the servo output must be proportional to the algebraic sum of two or more inputs. A typical circuit is shown in figure 2-13.

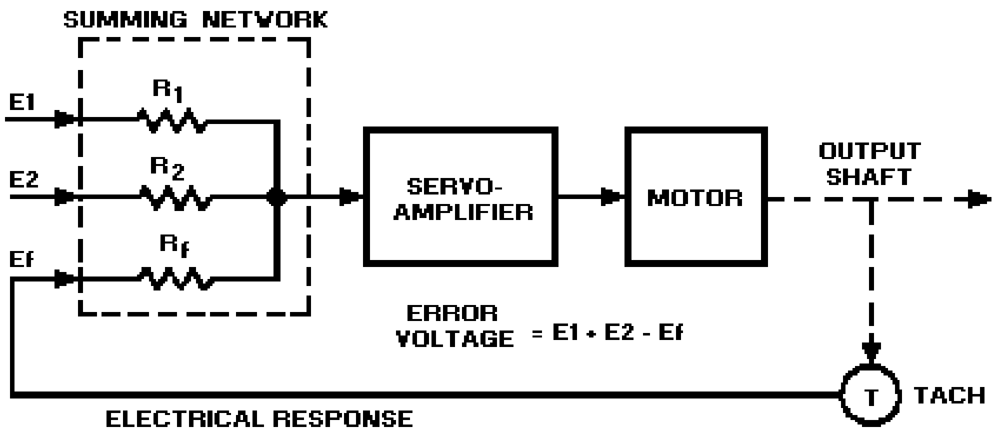

Figure 2-13.—Summing network as an error detector.

As in the case of potentiometers, the networks may use either ac or dc voltage, with the phase or polarity of the input voltage determining whether the signals are additive or subtractive. Refer to figure 2-13. If two input signals E_1 and E_2 are applied to the network, the network will provide an error voltage output that is proportional to the algebraic sum of the two signals. The servo motor drives the load and also a tachometer that supplies feedback voltage to resistor R_f. Resistor Rf nulls the error signal.

In some installations, the servo motor may position the wiper arm of a potentiometer instead of driving a tachometer to supply the feedback voltage.

E-Transformers

The E-transformer is a type of magnetic unit that is used as an error detector in systems in which the load is not required to move through large angles.

In the basic E-transformer shown in figure 2-14, an ac voltage is applied to the primary coil (2) located on the center leg of the laminated, E-shaped core. Two secondary coils (1 and 3) are wound series-opposing on the outer poles of the core. The magnetic coupling between the primary (coil 2) and the two secondaries varies with the position of the armature. The armature can be physically moved left or right in the magnetic circuit by mechanical linkage to the load. This changes the reluctance between either pole and the armature.

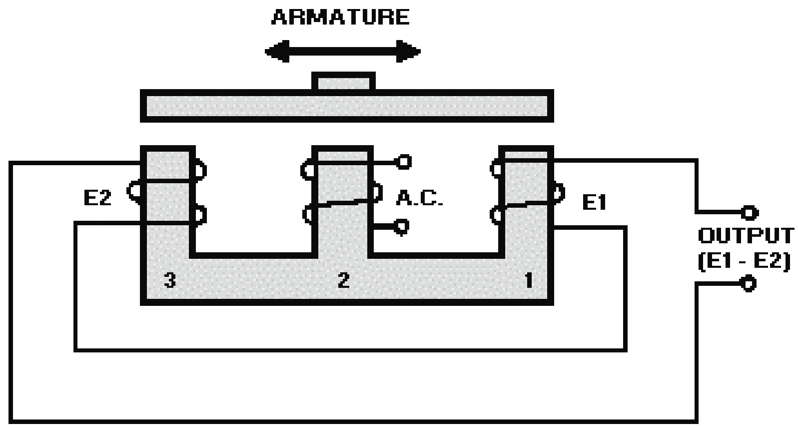

Figure 2-14.—Basic-E transformer.

When the armature is located in the center of the E-shaped core, as shown in the figure, equal and opposite voltages are induced in the secondary coils. The difference between them is zero. Thus, the voltage at the output terminals is also zero.

But, if the armature is moved, say to the tight, the voltage induced in coil 1 increases, while the voltage induced in coil 3 decreases. The two voltages are then unequal, so that the difference is no longer zero. A net voltage results at the output terminals. The amplitude of this voltage is directly proportional to the distance the armature has been moved from its center position. The phase of this output voltage, relative to the ac on the primary, controls the direction the load moves in correcting the error.

The basic E-transformer will detect movement of the armature in one axis only (either the horizontal or vertical depending upon the way the unit is mounted). To detect movement in both the horizontal and vertical axes, a CROSSED-E-TRANSFORMER is used.

If you place two E-transformers at right angles to each other and replace the bar armature with a dome-shaped one (fig. 2-15), you have the basic configuration of what is known as the crossed-E transformer, or pickoff. In most applications the dome-shaped armature is attached to a gyro, and the core assembly is fixed to a gimbal, which is the servo load.

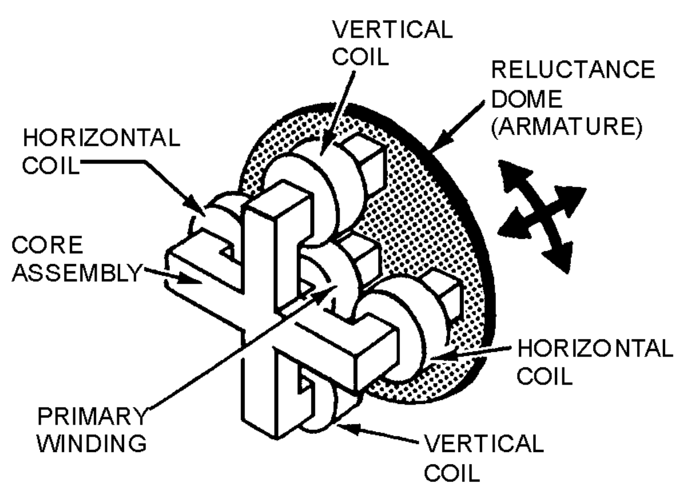

Figure 2-15.—Crossed-E transformer.

The crossed-E transformer assembly consists of five legs (poles). Each leg is encased by a coil. The coil around the center leg is the primary, which is excited by an alternating voltage. The remaining four coils are the secondaries. From this view, you can see how it gets the name, crossed-E.

When the reluctance dome (armature) is moved to the left of center, more flux links the left leg with the primary coil, and the voltage induced in the left secondary increases. The right leg has fewer flux linkages with the center coil; therefore, the voltage induced in the right coil will be less than that in the left coil. Thus there will now be a net voltage out of the pickoff. The phase of the output will be that of the larger voltage. If the dome were moved to the right, the opposite condition would exist. From this brief description, you can see that the crossed-E transformer works on the same fundamental principle as the basic type described earlier. The major difference between the two is in shape and the number of secondaries, and in the fact that the armature has universal movement.

Control Transformers

A commonly used magnetic error detector is the synchro-control transformer, which is used as a control device in servo systems. Recall that we covered the CTs operation in depth in chapter 1 of this module, and discussed its application to the servo system earlier in this chapter.

As an error detector, the CT compares the input signal impressed upon its stator with the angular position of its rotor, which is the actual position of the load. The output is an electrical (error) signal taken from the rotor, which is the difference between the ordered position and the actual position of the load.

A primary advantage of the CT over other types of error detectors is its unlimited rotation angle; that is, both the input and the output to the synchro control transformer may rotate through unlimited angles. A disadvantage is that the output supplied to the servo amplifier is always an ac error signal, and must be demodulated if it is to be used in a dc servo system.

Q-19. In the output of an ac error detector, what indicates the (a) direction and (b) amount of control necessary for correspondence?

Q-20. What two basic types of magnetic devices are used as error detectors?

RATE GENERATOR (TACHOMETER)

As we mentioned earlier, the tachometer in the velocity servo system is the heart of the feedback loop. It is used to sense the speed (velocity) of the load. The tachometer is sometimes referred to as a RATE GENERATOR. Whatever the name, it is a small ac or dc generator that develops an output voltage (proportional to its rpm) whose phase or polarity depends on the rotor's direction of rotation. The dc rate generator usually has permanent magnetic field excitation. The ac rate generator field is excited by a constant ac supply. In either case, the rotor of the tachometer is mechanically connected, directly or indirectly, to the load.

The AC Rate Generator

One type of ac rate generator used widely in the past is the drag-cup type.

The tachometer generator shown in figure 2-16 has two stator windings 90º apart, and an aluminum or copper cup rotor. The rotor rotates around a stationary, soft-iron, magnetic core. One stator winding is energized by a reference ac source. The other stator winding is the generator output, or secondary winding the voltage applied to the primary winding produces a magnetic field at right angles to the secondary winding when the rotor is stationary, as shown in view A. When the rotor is turned by mechanical linkage from the load, it distorts the magnetic field so that it is no longer 90 electrical degrees from the secondary winding. Flux lines cut the secondary winding, and a voltage is induced in the output winding as shown in views B and C. The amount of magnetic field that will be distorted is determined by the speed of the rotor. Therefore, the magnitude of the voltage induced in the secondary winding is proportional to the rotor's velocity (speed).

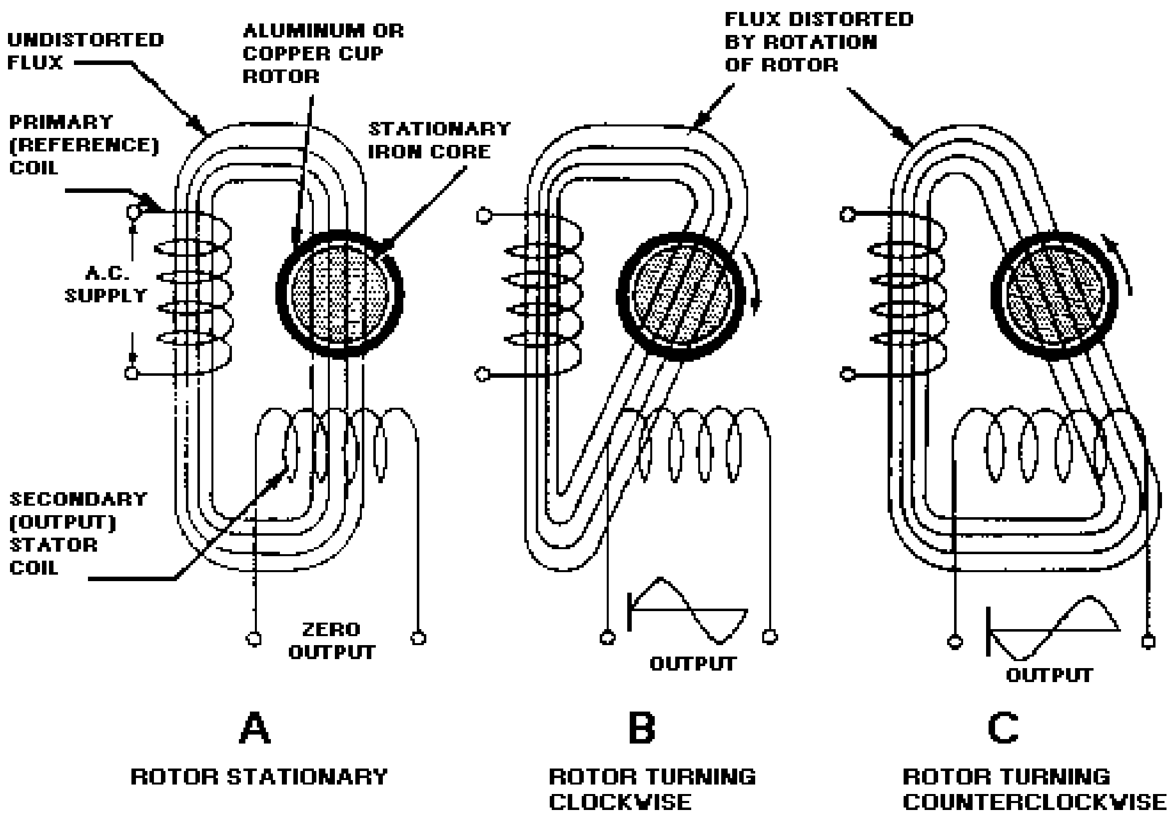

Figure 2-16.—Ac drag-cup rate generator.

The direction of the magnetic field's distortion is determined by the direction of the rotor's motion. If the rotor is turned in one direction, the lines of flux will cut the secondary winding in one direction. If the motion of the rotor is reversed, the lines of flux will cut the secondary winding in the opposite direction. Therefore, the phase of the voltage induced in the secondary winding, measured with respect to the phase of the supply voltage, is determined by the direction of the rotor's motion. The phase relationship is shown in views B and C at the output winding.

The frequency of the tachometer generator output voltage is the same as the frequency of the reference voltage. The output voltage is generated by the primary alternating flux field cutting the secondary winding; therefore, the output voltage must have the same frequency as the supply voltage.

Other types of ac tachometer generators have a squirrel-cage rotor. Otherwise their construction and principles of operation are identical to the drag-cup type.

The DC Rate Generator

The dc rate generator uses the same principles of magnetic coupling as the ac rate generator. The dc rate generator, however, has a steady (nonfluctuating) primary magnetic field. This magnetic field is usually supplied by permanent magnets. The amount of voltage induced in the rotor winding is proportional to the number of magnetic flux lines cut. The polarity of the output voltage is determined by the direction in which the rotor cuts the lines of magnetic flux.

The physical makeup and theory of operation of the dc rate generator (tach) is very similar to the dc generator (NEETS, Module 5, *Introduction to Generators and Motors*). The only major differences are size and the prime mover. The tach is much smaller and is linked mechanically to the servo motor or load instead of to a prime mover.

Tachometer generators are used in servo systems to supply velocity or damping signals and are sometimes mounted on or in the same housing as the servo motor.

Q-21. What is the basic difference between the primaries of ac and dc rate generators?

MODULATORS IN THE SERVO SYSTEM

Because of problems associated with dc amplifiers, such as drift (where the output varies with no variation of the input signal), the ac amplifier is more widely used in servo applications. This creates a need for a device to convert a dc error signal into an ac input for the servo amplifier. Such a device is referred to as a MODULATOR.

Modulator and modulating techniques vary with different types of electronic equipment. The modulator in the servo system performs a completely different function than its counterparts in radar or communications systems.

The servo modulator converts a dc error signal into an ac error signal. The modulator uses two inputs to produce the ac error signal. One input is the dc error signal (for example from an input potentiometer); the other input is an ac reference voltage from some other source, such as the swp's ac supply system. The ac output error signal must contain the same control information that is contained in the original dc error signal. This is done in the following manner:

1. The phase between the ac output and the ac reference signal is determined by the polarity of the dc input signal. The phase of the ac output indicates the direction of error (direction of the load movement).
2. The amplitude of the ac output is proportional to the amplitude of the dc input signal and indicates the amount of error signal (speed or angular displacement of the load).

These relationships of phase and amplitude must be maintained to ensure that the load will move the desired amount, or the proper speed, and in the right direction.

A typical modulator that you will see in a servo system is the CRYSTAL DIODE MODULATOR. The following paragraphs provide a brief explanation of how this modulator works.

Crystal Diode Modulators

The crystal diode modulator (fig. 2-17) consists of a diode bridge and a transformer network. When the ac reference voltage is applied to transformer T_1, diodes CR_2 and CR_3 conduct during the negative half-cycle. Conversely, diodes CR_1 and CR_4 conduct on the positive half-cycle. The diodes will conduct under these conditions because of the 180º phase reversal across T_1. Current flow during the positive and negative half-cycles is represented by dotted arrows and solid arrows, respectively. Suppose a positive, dc error signal is applied during the negative-going ac input half-cycle at the primary of T_1. Current will flow from ground, through the upper half of the primary winding of transformer T_2, through diode CR_2, and through the upper half of the secondary winding of transformer T_1 to the dc source. This produces a positive-going voltage (error signal) across the secondary of T_2 (the first half-cycle of the output signal).

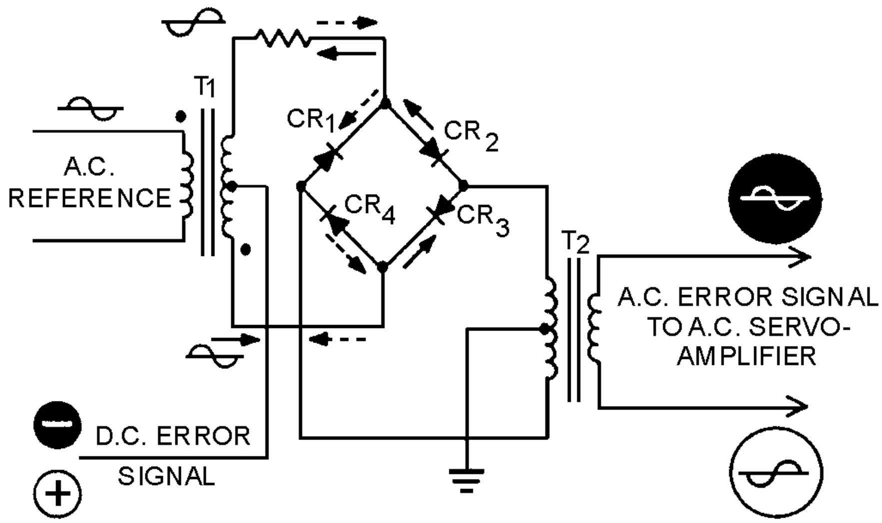

Figure 2-17.—Crystal diode modulator.

On the positive-going ac input reference voltage half-cycle, current will flow from ground, through the lower half of the primary of transformer T_2, through diode CR_4, and through transformer T_1 to the dc error signal source. This produces a negative-going voltage (error signal) across the secondary of T_2 (completing the cycle of the ac input reference). Notice that the error signal is 180º out of phase with the reference signal.

If a negative dc error signal is applied to the modulator, under the same conditions of ac reference signal, current flow through the circuit will be reversed. Keep in mind that this occurs, for example, when the load approaches the desired position from an opposite direction. This circuit will work with either a positive or a negative dc input signal, but only one condition will exist at any given time.

With a negative dc error applied, current will flow from the dc error signal source through diodes CR_3 and CR_1 (on different half-cycles of the ac reference) to ground. This causes an ac voltage to be produced across the secondary of T_2 in the same manner as previously described with the positive dc error signal input.

The only difference is that current will flow through the upper and lower halves of T_2 in a different direction (toward ground) and cause the output to be in phase with the ac reference signal.

In summary, the modulator produced an ac output, either in phase or 180º out of phase with the ac reference signal, depending upon the polarity of the dc input signal. The amplitude of the output will be proportional to the dc input signal amplitude and at the frequency of the ac reference voltage.

Q-22. What is the purpose of a modulator in a servo system?

DEMODULATORS IN THE SERVO SYSTEM

As you know, servo systems use both ac and dc servo motors depending upon the requirements of the system. Systems that are required to move light loads at constant speed use ac motors. Systems that are required to move heavy loads with a wide speed range use dc motors. When the requirements of the system call for a dc motor or other dc devices, the ac error signal within the servo system must be converted to a dc error signal before being fed to the dc servo amplifier. The conversion is made by the circuit known as a DEMODULATOR.

As with the modulator, the demodulator maintains the same relationships between its input and output signals. Just like the modulator, the demodulator's output amplitude is proportional to its input signal and its output polarity is determined by the phase of the input signal. These relationships, as in the modulator you just studied, are necessary so the "new" error signal will control the servo motor in the desired manner.

Diode Demodulator

One example of a servo demodulator is the DIODE DEMODULATOR, sometimes called a phase detector, shown in figure 2-18. This circuit is used in servo systems because it not only converts ac to dc, but it is also able to distinguish the phase of the ac signal by comparing it to a reference voltage. Do not confuse this circuit with other phase detector circuits, such as those used in radar or communications systems. This demodulator (phase detector) distinguishes signals that are either in phase or 180º out of phase. For this reason this circuit is useful in servo systems where the ac output from the error detector (CT) is either in phase with the reference signal or 180º out of phase. Whatever type of error detector is used in the servo system, the reference voltage to the error detector and to the demodulator must be IN PHASE with each other for the demodulator to do its job.

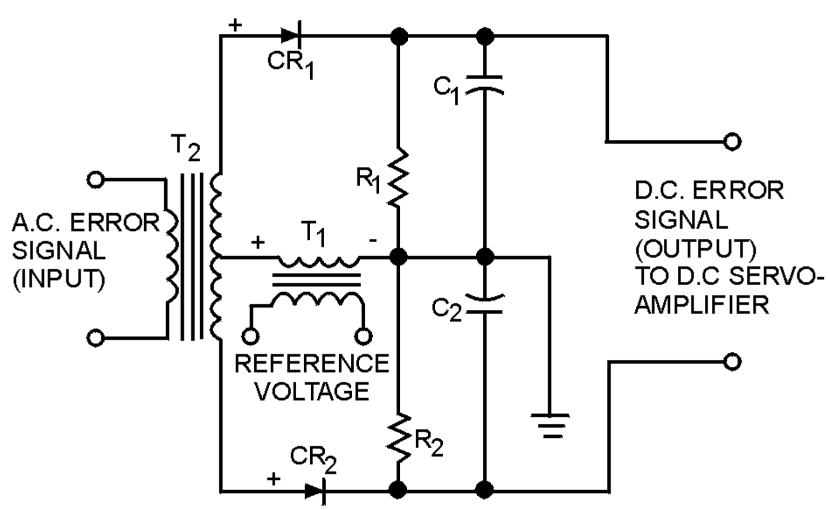

Figure 2-18.—Diode demodulator.

As shown in figure 2-18, the anodes of the two diodes are supplied with the same reference voltage.

With no ac error input signal applied to T_2 (quiescent state), both diodes will conduct equally on the positive half-cycle of the reference voltage. The voltage drops across $R_1$1 and R_2 are equal. This results in the two output terminals being at the same potential; therefore, the output voltage is zero for the positive half-cycle. During the negative half-cycle, a negative voltage is felt on the anodes of both diodes, both diodes are cut off, and zero potential is felt across the output terminals. The circuit will remain in this condition until an ac error signal is applied. As we make this circuit work, you will notice that CR_1 will conduct when the input signal is in phase with the reference voltage and then only on the positive half-cycle. CR_2 will remain in cutoff unless the phase relationship between the ac error signal and the reference voltage changes by 180º. At this time CR_1 will cut off. This change could be brought about by the error detector in the servo system sensing a change in the direction of the load. Effectively, we have a one-diode circuit for one direction of rotation.

Assume that an ac error signal is applied to T_2, making the anode of CR_1 positive and the anode of CR_2 negative. At the same time, the reference voltage on the anodes of CR_1 and CR_2 is on its positive half-cycle. Under these conditions, CR_1 will conduct and CR_2 will be cut off. A positive voltage will be developed across Ri and felt on the output terminals. During the negative half-cycle, a negative voltage will be felt on the anodes of CR_1, and CR_2 and will cut them off. The output of the circuit for one complete cycle of the reference signal will be a filtered, pulsating, dc voltage. As long as the input and reference signals are in phase, the circuit acts as a half-wave rectifier and a filter network.

As we mentioned earlier, this circuit will also respond to a 180º phase reversal between the input and reference signals. For instance, when the error signal applied to T_2 is 180º out of phase with the reference signal, CR_2 conducts and CR_1 cuts off, causing the output voltage to change polarity. You may encounter variations of the diode phase detector; however, they all depend on the same basic principle of operation.

To quickly summarize, the demodulator converted the ac input signal to a dc error signal. The polarity of the dc error signal was determined by the phase relationship between the ac error input signal and the reference signal. The amplitude of the dc error signal was directly proportional to the magnitude of the ac input signal.

Q-23. What is the purpose of a demodulator in a servo system?

SERVO AMPLIFIERS

The servo amplifiers previously discussed were used in servo systems to amplify either the ac or dc error signal to a sufficient amplitude to drive the servo motor. These amplifiers are the same amplifiers in principle as covered in NEETS Module 8, *Introduction to Amplifiers*. The basic amplifier chosen for use in the servo system must have the following characteristics:

1. Flat gain versus frequency response over the broad band of frequencies of interest.
2. Minimum phase shift with a change in input signal (zero phase shift is desired, but a small amount of phase-shift is acceptable, if constant).
3. A low output impedance.
4. A low noise level.

Up to this point in our discussion of servos, the amplifiers have been directly connected to the motor that drove the load. Servo amplifiers are also used within the system itself to amplify the error signal. For example, the signal from the demodulator or filter network may require additional amplification to maintain signal strength. In cases where the amplifier is used to feed large drive motors, to move large loads, the basic electronic amplifier that was presented earlier in this training series is not adequate to do the job. This type of work is done by large power amplifying devices such as the amplidyne generator (NEETS, Module 5, *Introduction to Generators and Motors*) and the MAGNETIC AMPLIFIER, which we will discuss later in this chapter.

AC SERVO MOTORS

Large ac motors are too inefficient for servo use. To move large loads, the ac motor draws excessive amounts of power, and is difficult to cool. Hence, ac servo motors are used primarily to move light loads. Most of the ac servo motors are of the two-phase or split-phase induction type. Fundamentally, these motors are constant-speed devices, although their speeds can be varied within limits by varying the amplitude of the voltage to one of the motors stator windings. When the load becomes heavy, the workhorse dc servo motor is used.

DC SERVO MOTORS

The control characteristics of dc servo motors are superior to those of ac servo motors. The dc servo motor can control heavy loads at variable speeds. Most dc servo motors are either the permanent magnet type, which are used for light loads, or the shunt field type, which are used for heavy loads. The direction and speed of the dc motor's rotation is determined by the armature current. An increase in armature current will increase the motor's speed. A reversal of the motor's armature current will change the motor's direction of rotation More thorough explanations of ac and dc motors are given in NEETS Module 5, *Introduction to Generators and Motors.*

SYNCHRONIZING CIRCUITS

As we explained in chapter 1, the use of a multi-speed synchro transmission system increases the accuracy of data transmission. The accuracy of the servo system depends in part upon the accuracy of the input fed from the synchro system. For example, a dual-speed synchro system operating in conjunction with a servo system uses two CTs (one coarse and one fine) to define a quantity accurately. This is done by feeding the output of the COARSE CT to the servo amplifier when the system is far out of correspondence and then shifting to the output of the FINE CT when the system is within 2 or 3 degrees of synchronization. A circuit that will perform this job is known as a SYNCHRONIZING NETWORK.

A synchronizing network (also called a crossover or switching network) senses how far the servo load is from the ordered position and then switches either the coarse signal or the fine signal into control. The signal selected by the circuit is the input to the amplifier. The selection is based on the size of the error signals the circuit receives. The coarse signal is the predominant factor in the selection, since it is a measure of the servo's output position throughout its limit of motion. The coarse signal drives the system into approximate synchronization, and then the fine signal is shifted into control.

Semiconductor-Diode Synchronizing Network

The SEMICONDUCTOR-DIODE SYNCHRONIZING NETWORK is fairly common and typical of the type used in servo systems. Let's take a look at a circuit that uses this technique. Figure 2-19 is an illustration of the circuit. In the following explanation, we will assume that the system is far out of correspondence (more than 3º). At this time, the coarse signal is large in amplitute. With this condition, CR_3 and CR_4, or CR_5 and CR_6, will be forward-biased, depending upon the polarity of the input signal. This will cause current to flow through R_1. The voltage developed across R_1 is felt on one leg of the summing newtork. A large amplitude fine signal CANNOT be present in the summing network, because CR_1 and CR_2 are designed to limit the fine amplitude to a small value. With this condition present at the summing network, the coarse signal maintains control and drives the load toward correspondence.

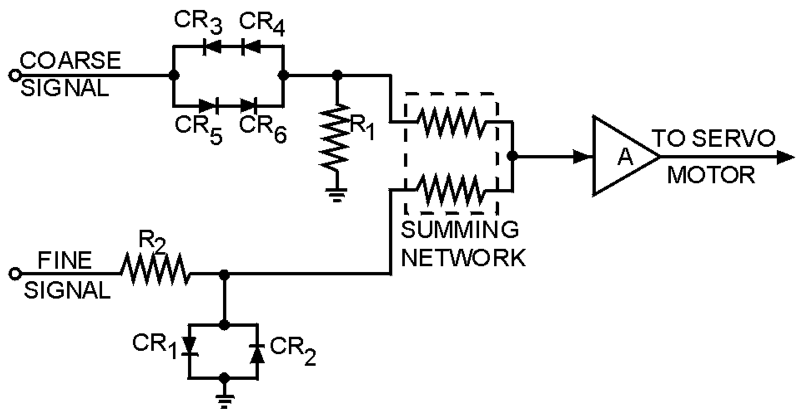

Figure 2-19.—Semiconductor diode synchronizing network.

When the load is within 3º of correspondence, the coarse signal is no longer large enough to forward bias the coarse diode network. The effect of this is to cause a large impedance across the diode network, which then drops most of the coarse signal. Practically no coarse signal voltage is felt across R_1 and one leg of the summing network. On the other hand, the fine signal is also small at this time, since the load is close to correspondence. Small fine signals are unaffected by CR_1 and CR_2. Therefore, the small fine signal is impressed across the summing network. With the fine signal being the only signal felt at the summing network, it takes control and drives the load to the exact point of correspondence. There are various types of synchronizing circuits used in servo systems. Some applications call for electron tubes, relays, and different types of semiconductor diodes. The theory of the specific type you will encounter in servo equipments will be explained in detail in the equipment's technical manual.

Q-24. What is the purpose of a synchronizing network in a servo system?

MAGNETIC AMPLIFIERS

As we stated earlier in this chapter, various types of servo amplifiers are used to drive servo motors. When the amplifier is required to produce a large amount of power, the conventional electronic amplifier becomes less efficient than some other types. The following is a brief discussion of a typical magnetic amplifier used in a servo system where large amounts of power are required to move a heavy load. If you need to refresh your memory on the theory of the magnetic amplifier, refer to Module 8 of this training series, *Introduction to Amplifiers*.

Magnetic Amplifiers in a Servo

Figure 2-20 illustrates a magnetic amplifier being used as the output stage of a servo amplifier.

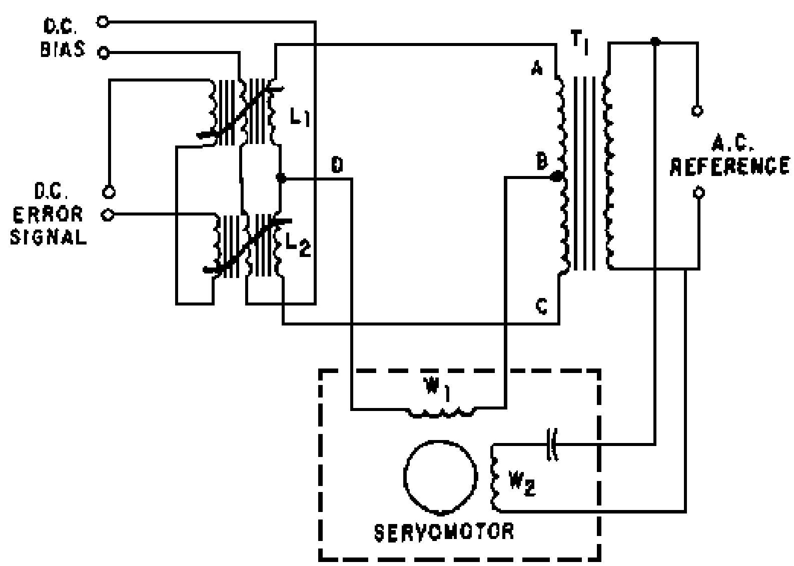

Figure 2-20.—Magnetic amplifier used to drive a servo motor.

The output of the servo amplifier is connected to one of the motor windings (controlled winding W_1). The other winding (uncontrolled winding W_2) is connected across the ac source, in series with a capacitor. The capacitor provides the required 90º phase shift necessary to cause motor rotation. The phase relationship of the current through the two windings determines the direction of rotation of the servo motor.

The magnetic amplifier consists of a transformer (T_1), and two saturable reactors (L_1 and L_2), each having three windings. The key point to the operation of this circuit lies in the fact that the error signal windings are connected in series-opposing while the bias windings are series-aiding.

With the circuit in the quiescent state (no input), the dc bias voltage causes the dc bias current to equally and partially saturate both reactors (L_1 and L_2). The reactances of L_1 and L_2 now being equal result in canceling currents through the W_1 windings of the servo motor. With only one input to the motor, it remains at rest.

Now, let's apply an error signal to the error signal windings. L_2 saturates and L_1 is driven further out of partial saturation, because the error windings are in series-opposition. This results in the error signal aiding the bias current in reactor L_2 and tending to cancel the bias current in reactor L_1. The reactance of L_2 is reduced, causing an increased current through the L_2 circuitry. In the other circuit (L_1), the reverse is true; its current decreases. This imbalance in the L_1 and L_2 circuitry results in current flow through W_1, say from left to right, and causes the motor to turn

Reversing the polarity of the error signal causes the direction of motor rotation to change. This is done by saturating reactor L_1 instead of reactor L_2 and causing current to reverse directions through W_1.

In the previous discussion, an ac motor was driven by the output of the magnetic amplifier. If a dc motor is required in the servo to move a heavy load, the ac output from the magnetic amplifier must be rectified.

NOTE: All of the components that have been described as units within a servo system are, in general, the same components used in many other electronic and electrical applications. The theory of these components has been discussed here and in other modules of the Navy Electricity and Electronics Training Series. If you have the desire or a need for an in-depth study of these components, the following are excellent references:

- Electronics Installation and Maintenance Books, NAVSEA 0967-LP-000-0130, for synchro and servo subjects.

- Electronics Installation and Maintenance Books, NAVSEA 0967-LP-000-0120, for the basic components of the servo system.

These references should be available in the technical library of your ship or station.

Q-25. What the three basic components make up the typical magnetic amplifier?

MULTI-LOOP SERVO SYSTEMS

Now that we have gone through the various servo loops and their components, let's continue our discussion with a realistic application of a servo system.

Very seldom will we find applications where one type of servo loop is used by itself. Usually several loops are combined through the use of various types of relays and switches. The many components of a complex system are caused to work together by switching them in and out as necessary.

Figure 2-21 illustrates a practical application of a multi-loop servo system. You should be able to recognize by now the different loops and components that make up this system. Nothing is really new in the system; we discussed all the loops and components earlier in this chapter.

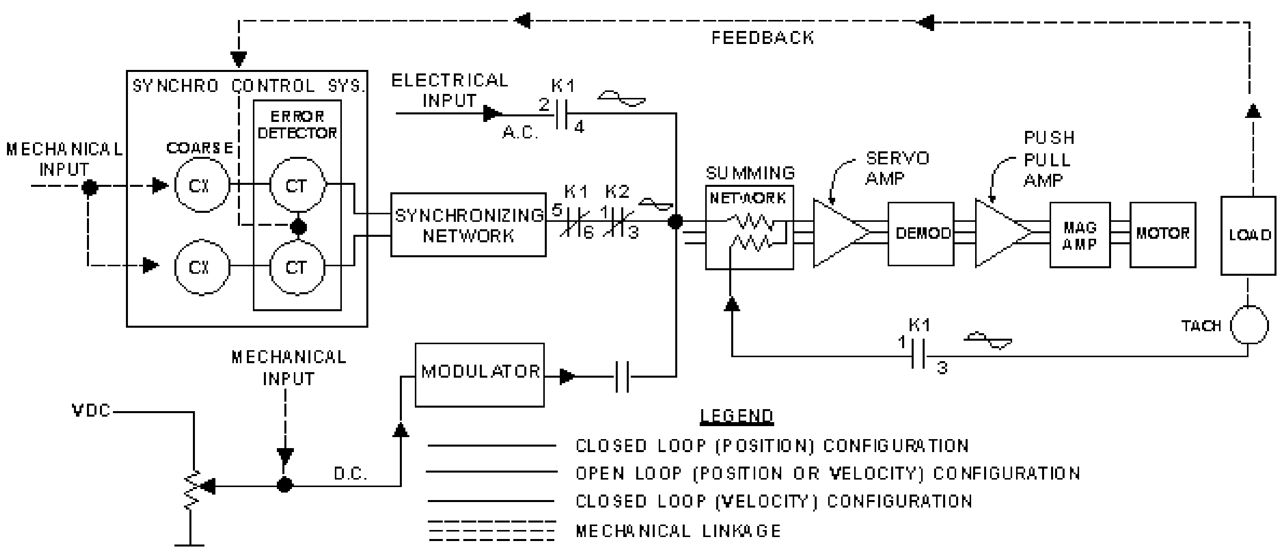

Figure 2-21.—Multi-loop servo system.

As shown by the relay conditions, the system is configured, in its normal state, as a closed-loop position servo. This is indicated by the heavy dark lines in the figure. An alternate configuration positions the load in this system by using the potentiometer. This is done by energizing relay K_2, and switching the system to an open-loop configuration. At the same time, the deenergized contacts of K_2 (1-3) open, thereby breaking the closed loop. The open loop is shown by the medium density lines in the figure. This loop is not as accurate as the closed loop, because the operator must intervene by turning the shaft of the potentiometer back to the zero voltage position to stop the load at the desired position. This type of circuit could be used by maintenance personnel to position the load for easy access to equipments, such as on an antenna or gun mount. The open loop can also function as a basic velocity loop by simply not returning the potentiometer to the zero position. This results in a constant error signal being present at the wiper arm of the potentiometer. With this condition, the load will continue to drive at some speed (rate) determined by the components in the loop.

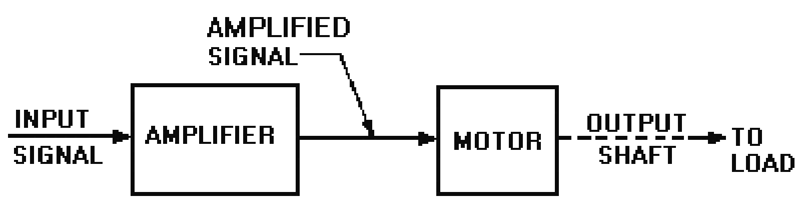
The last loop we will consider is the closed-loop velocity servo, indicated by the fine density lines.

This loop is switched into operation by energizing K_1. Notice that there are two inputs to the summing network with K_1 energized, the electrical input through contacts 2-4 and the feedback from the tach through contacts 1-3. The two signals are compared in the summing network, and their difference is used as the error signal to drive the load. When a state of equilibrium is reached in the circuit, the load will be moving at the desired velocity.

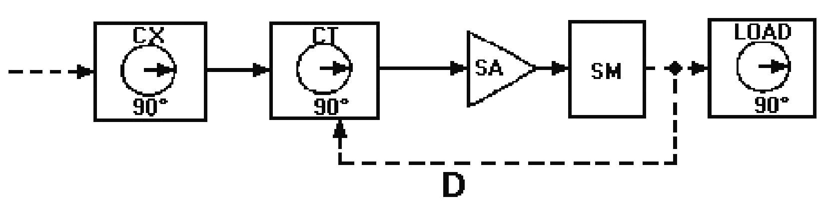
SUMMARY

This chapter has provided information basic to understanding servo systems and their components. The following is a summary of specific points in the chapter.

The **OPEN-LOOP CONTROL SYSTEM** is controlled directly, and only by an input signal. It has no feedback and is therefore less accurate than the closed-loop control system. The open-loop system usually requires an operator to control the speed and direction of movement of the output.



The **CLOSED-LOOP CONTROL SYSTEM** is the most common type used in the Navy. It can respond and move loads quickly and with greater accuracy than the open-loop system. The closed-loop system has an automatic feedback system that informs the input that the desired movement has taken place.



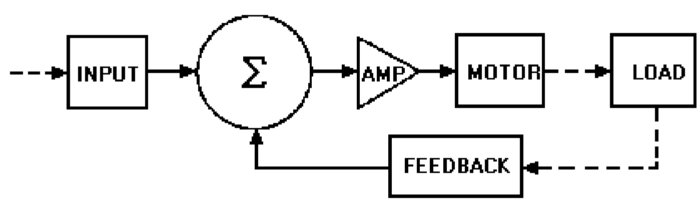
The **SERVO SYSTEM** is classified as a closed- loop system when it is capable of:

1. Accepting an order and defining the desired result,
2. Evaluating present conditions,
3. Comparing the desired result with present conditions and obtaining a difference or an error signal,
4. Issuing a correcting order, and changing the existing conditions to the desired result, and
5. Obeying the correcting order.

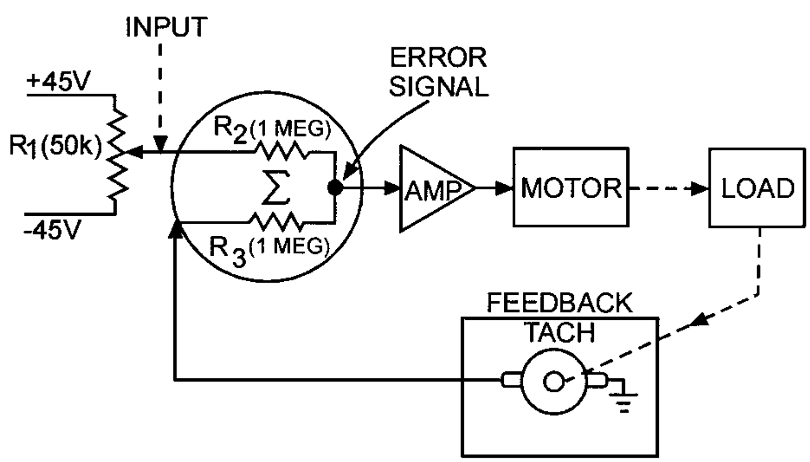
The **BASIC SERVO SYSTEM** is normally made up of electromechanical parts, and consists of a synchro-control system, servo amplifier, servo motor, and some form of feedback.

The **POSITION SERVO** has the goal of controlling the position of the load. In the ac position servo system, the amplitude and phase of the ac error signal determine the amount and direction the load will be driven.

In the dc position servo system, the amplitude and polarity of the dc error signal are used to determine the amount and direction the load will be driven.



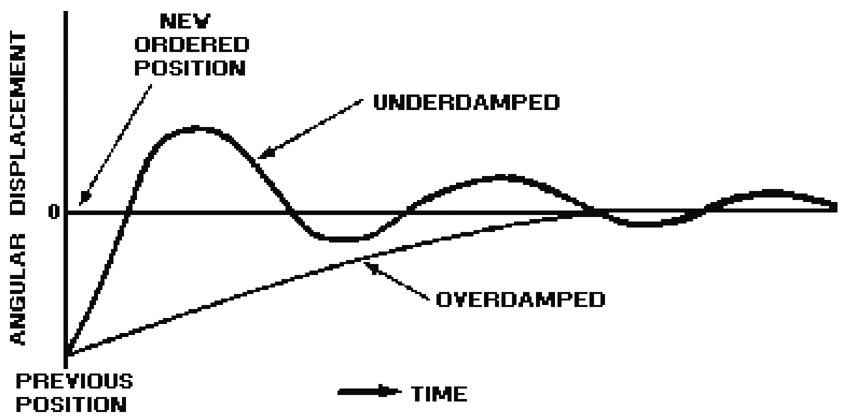
The **VELOCITY SERVO** is based on the same principle of error-signal generation as the position servo, except that the VELOCITY of the output is sensed rather than position of the load. When the velocity loop is at correspondence, an error signal is still present, and the load is moving at the desired velocity.



The **ACCELERATION SERVO** is similar to the velocity and position servos except that the acceleration of the load is being sensed rather than the position or velocity. In this loop, the tachometer of the velocity loop is replaced with an accelerometer.

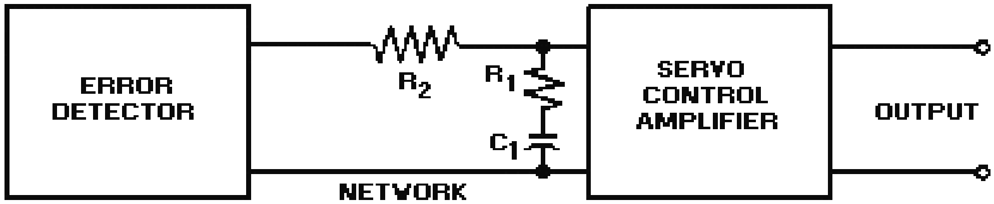
TIME LAG is a servo characteristic defined as the time between the input of the signal and the actual movement of the load. Time lag is undesirable and is reduced through the use of high-gain amplifiers. Damping systems are then added to attain smooth, efficient operation.

An **OVERDAMPED** system will not be subject to oscillations but takes an excessive amount of time to reach synchronization. An UNDERDAMPED system provides instant response to an error signal but results in the load oscillating about the point of synchronism. Somewhere between overdamped and underdamped, designers achieve adequate accuracy, smoothness, and a moderately short synchronizing time.

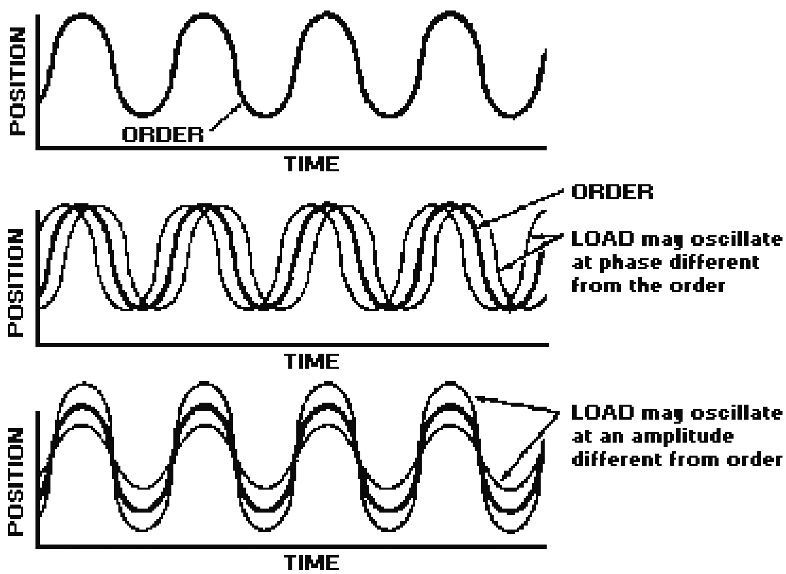


DAMPING is used to stabilize a system-to minimize or eliminate the problem of overshoot. The simplest form of damping is FRICTION CLUTCH damping. MAGNETIC CLUTCH damping is similar to friction clutch damping. The difference is in how the flywheel is coupled to the shaft of the servo motor. Magnetic coupling uses a magnetic field to draw two friction plates together to produce damping. Another method uses the magnetic field set up by a pair of coils or one coil in conjunction with a conducting surface (flywheel) to produce damping.

ERROR-RATE DAMPING is defined as a method of damping that "anticipates" the amount of overshoot. This form of damping corrects the overshoot by introducing a voltage in the error detector that is proportional to the rate of change of the error signal. The stabilization network used for error-rate damping consists of either an RC differentiating network or an integrating network. The components of the RC network are chosen to tailor the stabilization network to the requirements of the servo system.



FREQUENCY RESPONSE of a servo is the range of frequencies to which the system is able to respond in moving the load. The ideal system can respond to whatever frequencies are present in the input signal. Frequency response is a good way of judging servo performance. In a given servo system, good frequency response provides maximum stability and minimum time lag.

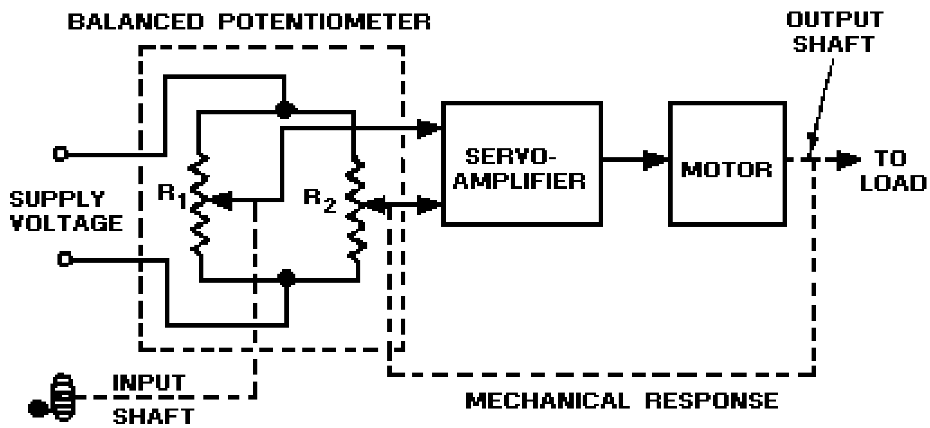


The **BANDWIDTH** of a servo amplifier, ideally, must be able to accept only the range of frequencies that represent valid servo signals.

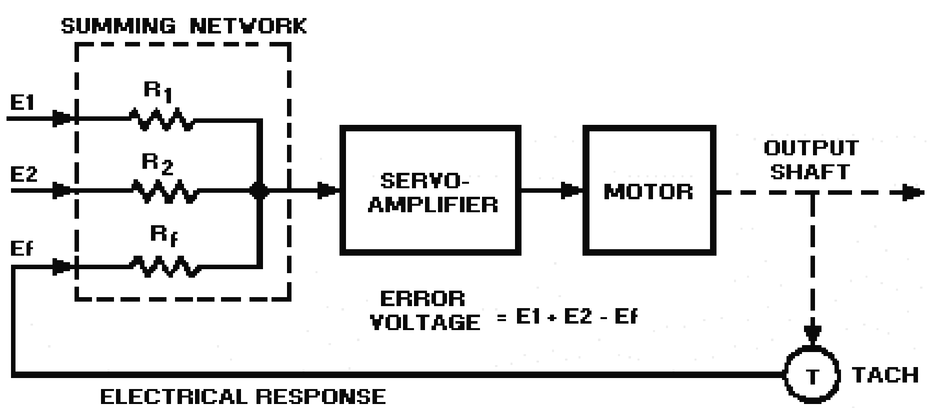
Amplifier bandwidth is another compromise in achieving optimum servo operation.

A **POTENTIOMETER** is one of the simplest position sensor devices and is generally used because of its small size, high accuracy, and output, which can be either ac or dc. Its primary disadvantages are limited motion, limited life due to wear, and high torque required to rotate the wiper contact.

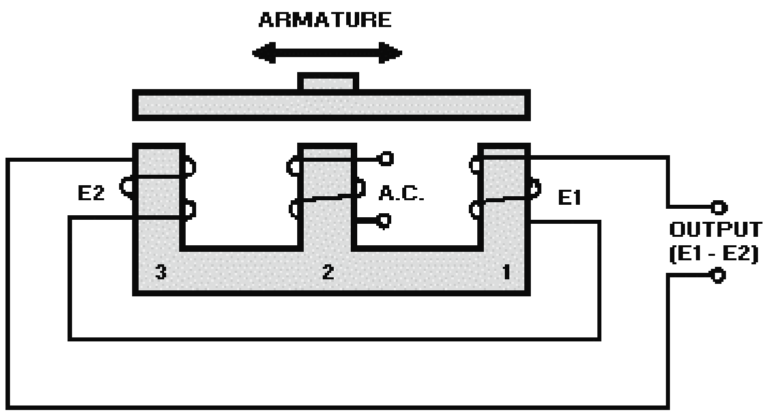
A **BALANCED POTENTIOMETER** in a closed-loop servo system is a voltage divider that functions as a position sensor and produces the error voltage that is fed to the servo amplifier.



SUMMING NETWORKS can be used as error detectors in servo systems to add algebraically two or more inputs and a feedback error voltage.



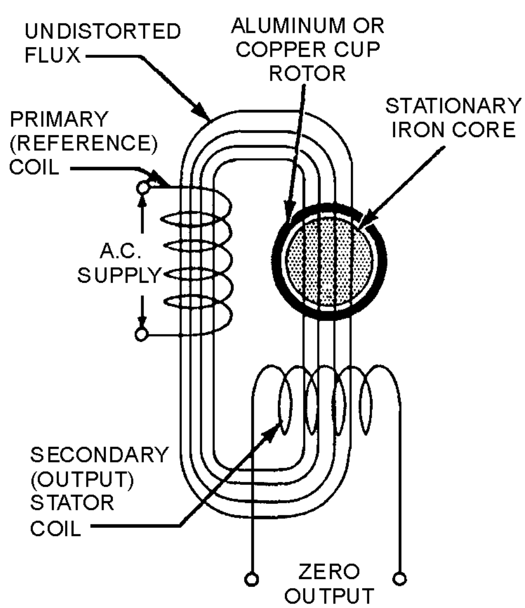
The **E-TRANSFORMER** is a magnetic error detector that can be used in systems limited by large angular movements. Output signals are either in phase, 180º out of phase, or zero, depending on the direction of the E-transformer's armature motion. The amplitude of the signal is determined by the amount of armature motion. The basic E-transformer can only detect motion in one axis.



A **CROSSED-E TRANSFORMER** (or pickoff) is two E-transformers placed at right angles to each other. This type of error detector is capable of detecting error in both horizontal and vertical directions.

A **CONTROL TRANSFORMER (CT)**, when used as a magnetic error detector, can rotate through unlimited angles. The output of this type of CT is always an ac servo error signal that must be demodulated if it is used with a dc servo motor.

A **RATE GENERATOR** (tachometer), when used in the velocity servo loop, is the heart of the feedback loop. The tach senses velocity (speed) of the load. A tachometer can be either an ac or dc rate generator. The output frequency of the ac tach is the same as the reference frequency, varying only in phase depending on the direction of rotation.



MODULATORS are used to change a dc error signal into an ac input error signal for servo amplifiers. This device is required when ac servo amplifiers are used instead of dc amplifiers.

DEMODULATORS convert ac error signals to dc error signals. The dc signal is required to drive a dc servo amplifier.

A **SERVO AMPLIFIER** used in an ac or dc servo system must have a flat gain, minimum phase shift, low output impedance, and low noise level.

AC SERVO MOTORS are used in servo systems that move light loads. Large ac motors are too inefficient for servo use when large loads are to be moved.

DC SERVO MOTORS can control heavy loads, and are widely used in servo systems. The speed and direction of the dc servo motor can be varied easily by varying the armature current.

MAGNETIC AMPLIFIERS are used when power from a conventional servo amplifier is too small to drive large servo motors (either ac or dc).

The **MULTI-LOOP SERVO SYSTEM** combines several closed and/or open servo loops together to control a common load.

ANSWERS TO QUESTIONS Q1. THROUGH Q25.

A-1. A system in which the precise movement of a large load is controlled by a relatively weak control signal.

A-2. Usually the operator senses the desired load movement and reduces the input to stop the motor.

A-3. Feedback.

A-4. Input signal and feedback.

A-5. To move the load and provide feedback data to the error detector.

A-6. Classifications in accordance with position, velocity, and acceleration functions.

A-7. Amount and direction of rotation.

A-8. Hunting.

A-9. Velocity loop senses velocity rather than position. When velocity loop is nulled, an error signal is still present and the load continues to move.

A-10. Tachometer.

A-11. The closed-servo loop can regulate load speed under changing conditions.

A-12. Underdamped.

A-13. Overdamped.

A-14. To minimize overshoot and/or oscillations.

A-15. Anticipating.

A-16. It should oscillate.

A-17. Unwanted noise-generated frequencies are rejected.

A-18. Zero.

A-19. (a) Phase. (b) Amplitude.

A-20. E-transformer and control transformers.

A-21. The method of primary excitation (ac and permanent magnet).

A-22. To convert a dc error signal into an ac error signal.

A-23. To convert an ac error signal into a dc error signal.

A-24. To switch control of the amplifier between either the coarse signal and the fine error signal.

A-25. Two saturable reactors and a transformer.

CHAPTER 3

GYROS

LEARNING OBJECTIVES

Upon completion of this chapter you should be able to:

1. Describe the characteristics of a gyroscopes.
2. List the two basic properties of gyroscopes and explain them.
3. Describe the components of a universally mounted gyro.
4. Describe the factors that determine rigidity in a gyro.
5. List the factors that determine the direction of precession in a gyro.
6. Explain the right-hand rule for gyro precession.
7. Describe the term "Degree of Freedom" as it applies to gyros.
8. Explain the effect of apparent precession (apparent rotation).
9. Explain the purposes of erection systems.
10. Describe the use of gyros with only one degree of freedom.
11. Explain the purpose of an accelerometer.
12. Explain the principle on which accelerometers operate.
13. Explain the need for a pulse-counting accelerometer.

GYROS

The word *gyroscope* was first coined by a French scientist, Leon Foucault, in 1852. It is derived from the Greek words "gyro," meaning *revolution*, and "skopien," meaning to *view*.

The gyroscope, commonly called a GYRO, has existed since the first electron was sent spinning on its axis. Electrons spin and show all the characteristics of a gyro; so does the Earth, which spins about its polar axis at over 1000 miles per hour at the Equator. The Earth's rotation about its axis provides the stabilizing effect that keeps the North Pole pointed within one degree of Polaris (the North Star).

Any rapidly spinning object—a top, a wheel, an airplane propeller, or a spinning projectile—is fundamentally a gyroscope. Strictly speaking, however, a gyroscope is a mechanical device containing a spinning mass that is universally mounted; that is, mounted so it can assume any position in space. Figure 3-1 shows a model of a gyro. As you can see, a heavy wheel (rotor) is mounted so that its spin axis is free to turn in any direction. The wheel spins about axis X; it can turn about axis Y, and it can turn about axis Z. With this mechanical arrangement, the spinning wheel can assume any position in space.

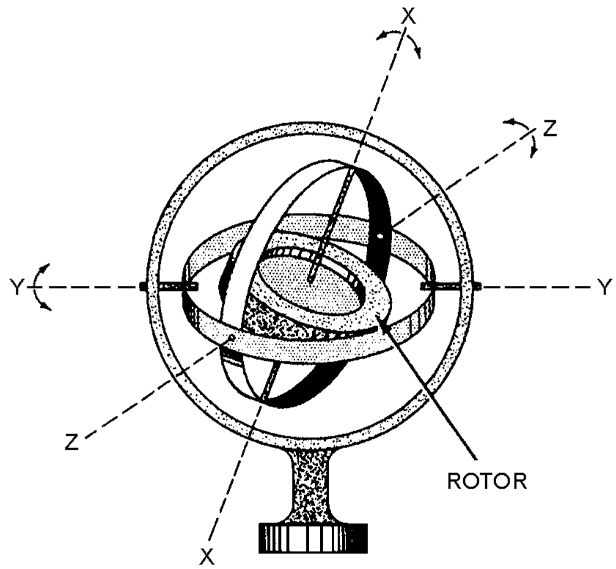


Figure 3-1.—Gyro model, universally mounted.

BASIC PROPERTIES OF GYROSCOPES

Gyroscopes have two basic properties: rigidity and precession. Those properties are defined as follows:

1. RIGIDITY — The axis of rotation (spin axis) of the gyro wheel tends to remain in a fixed direction in space if no force is applied to it.

2. PRECESSION — The axis of rotation has a tendency to turn at a right angle to the direction of an applied force.

The idea of maintaining a fixed direction in space is simple to illustrate. When any object is spinning rapidly, it tends to keep its axis pointed always in the same direction. A toy top is a good example. As long as the top is spinning fast, it stays balanced on its point. Because of this gyro action, the spinning top resists the tendency of gravity to change the direction of its axis. You can think of many more examples. A bicycle is easier to balance at high speed than when it is barely moving. At high speed, the bicycle wheels act as gyros, and tend to keep their axes (axles) parallel to the ground.

Note that it is easy to move the gyro as long as you keep the axis POINTING in the SAME DIRECTION. The gyro resists only those forces that tend to change the direction of its axis. In a bicycle, since the axis of rotation (the wheel's axles) is horizontal, the wheels win resist any force that tends to tilt or turn them to the right or left.

If you can obtain a gyroscope top, you can do some instructive experiments with it. Hold the gyro top with its axis vertical as shown in figure 3-2 and start it spinning. As long as it is spinning fast, it will stay balanced. You can balance it on a string or on the point of your finger; the axis will stay vertical as long as the top is spinning fast. As we mentioned before, this ability of a gyro to keep its axis fixed in space is called RIGIDITY.

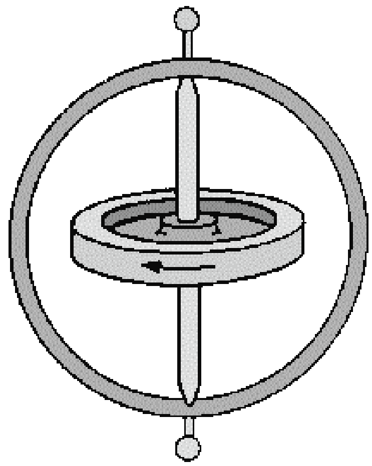

Figure 3-2.—A gyroscope top.

PRECESSION

Now, if you stop the gyro top and turn its axis horizontal, and then start it spinning again, balancing one end on a pivot, (fig. 3-3), it won't fall. The top's axis will stay horizontal, resisting the tendency of gravity to change its direction Although the gyro will RESIST the force that gravity applies to it, the gyro will still RESPOND to that force. The gyro responds by moving its axis at a RIGHT ANGLE to the APPLIED FORCE.

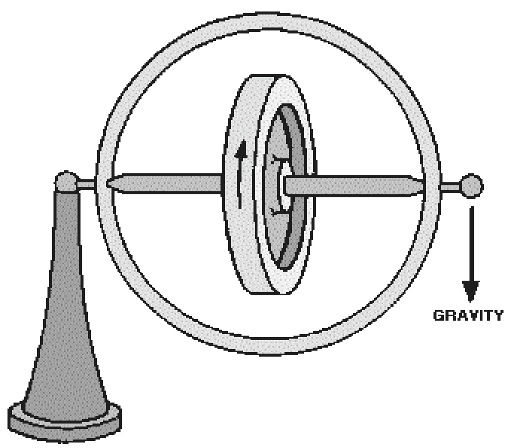

Figure 3-3.—Gyro top with axis horizontal.

The axis will tilt in a direction 90º away from the applied force. This is called PRECESSION.

Figure 3-4 is another view of the same gyroscope. Its far end is still balanced on the pivot. Gravity is pulling down on the gyro. If the gyro rotor is turning in the direction shown by the arrow, the near end of the frame (axis) will move to the left. If the rotor were turning in the opposite direction, the frame would move to the right. Note that in each of these examples the direction of movement was displaced from the applied force (gravity) by 90º. The axis stays horizontal, but the gyroscope responds to the force of gravity by rotating around the pivot.

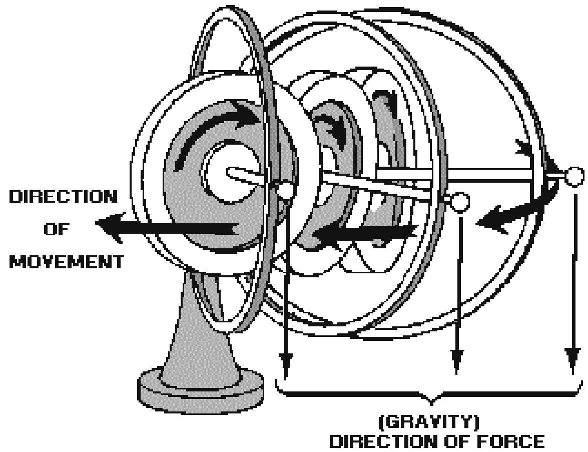

Figure 3-4.—Gyro precession.

Gyro action may be summarized as follows: A spinning gyro tends to keep its axis pointing in the same direction. This is called RIGIDITY. If you apply a force that tends to change the direction of the spin axis, the axis will move at a right angle to the direction of the applied force. The direction of precession will be 90º clockwise from the applied force if the rotor is spinning clockwise (when viewed from the "free" end of the rotor's axis); if the rotor is spinning counterclockwise, the precession will be 90º counterclockwise. If the axis is horizontal, and you try to tilt it, the axis will turn. If the axis is horizontal, and you try to turn it, the axis will tilt. This second characteristic of a gyro is called PRECESSION.

Because of precession, we can control the direction that the spin axis points. This enables us to aim the spin axis where we want it to point. Without precession, the rigidity of the gyro would be useless.

Q-1. Can any rapidly spinning object be considered a gyroscope?

Q-2. In the drawing in figure 3-1, which axis is the gyro spin axis?

Q-3. What gyro property causes the gyro to remain in a fixed position?

Q-4. What type(s) of force does a gyro resist?

Q-5. In what direction will a gyro precess in response to an outside force?

BASIC GYRO ELEMENTS

The gyro shown in figure 3-5 is a basic, universally mounted gyro, sometimes called a free gyro. Its components are rotor, inner gimbal, outer gimbal, and base or support. Gimbals are devices that permit the rotor to assume any position and retain that position when the support is tipped or repositioned. Note that in figure 3-5, the support may be moved about all axes without the rotor position being disturbed.

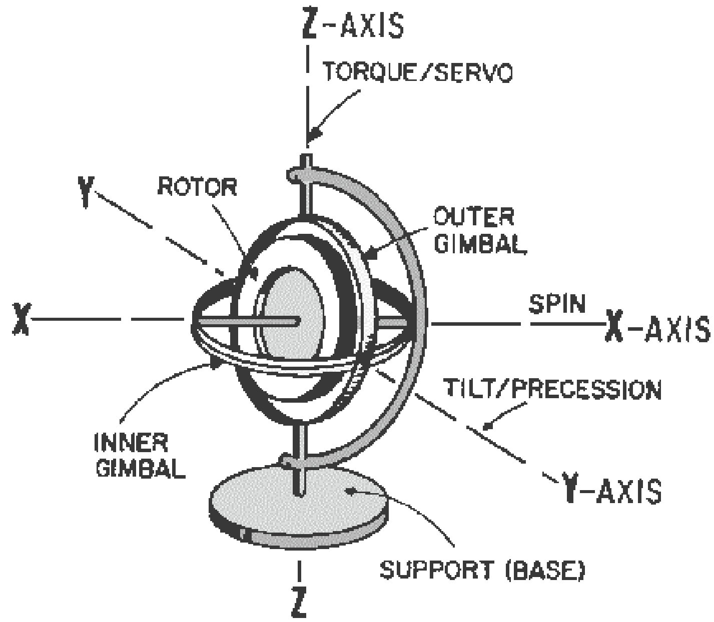

Figure 3-5.—Basic universally mounted gyro.

As you know, gravity is a force that acts along parallel lines upon each particle of matter. A plot of the resultant gravitational force on a body such as a gyro would be equivalent to the sum of these separate forces. The point at which the resultant force is applied is called the CENTER OF GRAVITY. To have a balanced gyro, the center of gravity must be located at the intersection of the three axes of the gyro.

RIGIDITY

A gyroscope is a spinning body that tends to keep its spin axis rigidly pointed in a fixed direction in space. What do we mean by "fixed direction in space"? A fixed direction on Earth is by no means fixed in space, because the Earth turns once on its axis every 24 hours, and makes a complete revolution around the sun every year. The sun itself is moving through space, taking the Earth and the other planets with it. Because of these motions, the expression "fixed direction in space" as used in this explanation is theoretical. For all practical purposes, we can say a line from the Earth to a distant star is a fixed direction in space. If the spin axis of a spinning gyro is pointed at a distant star, it will remain pointed at the star as the Earth turns.

Gyro rigidity is the strength with which a gyro resists any external force that would tilt its rotor spin axis. There are three factors that determine gyro rigidity: weight of the rotor, distribution of this weight, and rotor speed.

The gyro can be considered as an enclosed mechanical system. The energy in the system is equal to the input energy. Hence the energy necessary to spin the gyro rotor is contained in the rotor as angular momentum, which is a function of rotor weight and the speed of rotor rotation. The <u>heavier</u> the gyro rotor, the larger the torque necessary to spin it, and the <u>greater</u> the angular momentum of the rotor. If we have two rotors with identical shapes but different weights spinning at the same velocity, the heavier of the two will be more rigid in its spin axis since it has the greater angular momentum.

Now let's look at the effect of weight distribution in the rotor of a gyro. Consider three rotors of the same weight, as shown in figure 3-6, view (A), view (B), and view (C), with the diameter of one rotor half the diameter of the other two. Now, when we spin these rotors at the same speed, we find that the rotors with the greater diameter are much more rigid than the one with the smaller diameter. Next, we find that we can make the rotors equally rigid by causing the rotor with the smaller diameter to spin faster than the larger rotors. Thus rigidity depends both on speed and distribution of weight. The weight of the larger rotor being farther away from the axis of spin causes it to be more rigid. This effect is even more pronounced if we shape the rotor as shown in view C of figure 3-6. Shifting as much weight as possible to the outer rim of the rotor increases rigidity even further.

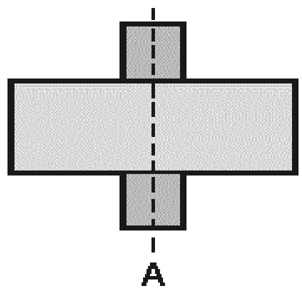

Figure 3-6A.—Gyro rotors with equal weight and unequal diameters.

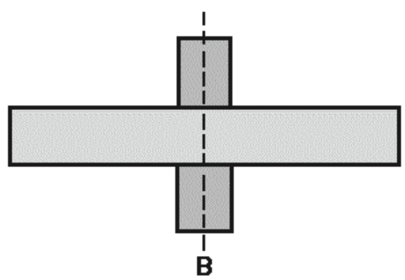

Figure 3-6B.—Gyro rotors with equal weight and unequal diameters.

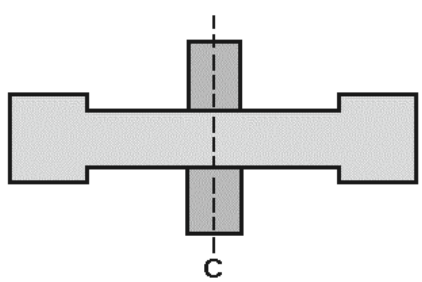

Figure 3-6C.—Gyro rotors with equal weight and unequal diameters.

Q-6. A universally mounted gyro has how many gimbals?

Q-7. What factors determine the rigidity of a gyro?

Q-8. Which gyro rotor in figure 3-6, view (A) view (B) view (C), will have the greatest rigidity if all are rotated at the same speed?

PRECESSION

To provide useful information, a gyro's spin axis must be related to some reference, usually the Earth's surface. This is done by using the second fundamental property of a gyro—PRECESSION. The gyro is precessed until its spin axis is pointed in the desired direction. So far we have covered precession in very general terms. The following paragraphs will cover this "gyro action" in more detail.

We can show precession by using the models in figure 3-7, view (A) and view (B). The gyro wheel is mounted so it is free to have its spin axis pointed in any direction. Here the wheel rotates in a flat loop called the gyro case (inner gimbal). The gyro case is pivoted in the gimbal ring (outer gimbal) and the gyro can swing about the Z axis. The gimbal ring itself turns on pivots that connect it to the fork (support). The fork permits the gyro to tilt from side to side about the Y axis.

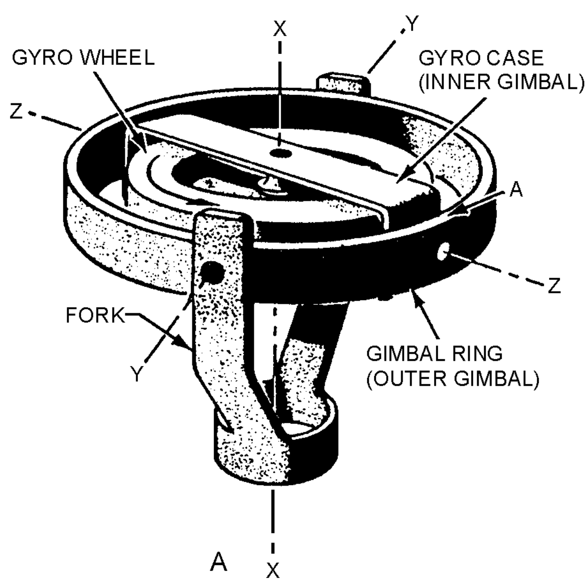

Figure 3-7A.—Gyro action.

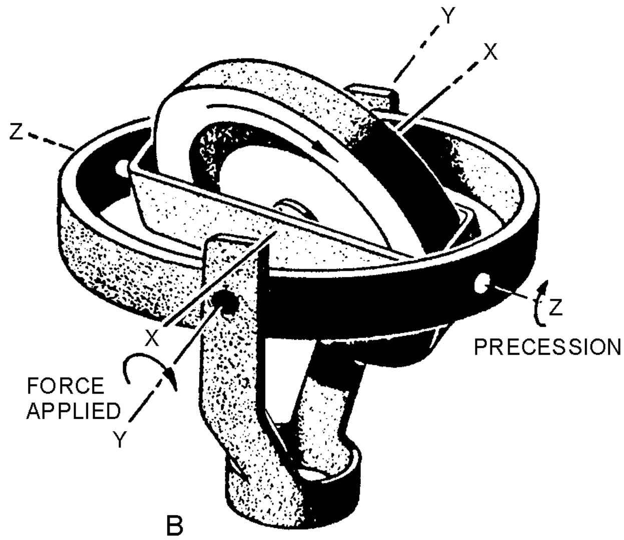

Figure 3-7B.—Gyro action.

Regardless of how the fork is placed, the spinning gyro wheel is free to lie in any given plane. That's why it is called a free gyroscope in this type of mounting.

To show the effect of precession, we can push down on the gimbal ring at point A at the nearer end of the Z-Z axis. (See view A of figure 3-7.) You might expect the ring to tilt around the Y-Y axis. Instead, the gyro case will tilt about the Z-Z axis. You can see the effect of this precession in view B.

Here's a rule that applies to all spinning gyros: THE GYRO WILL ALWAYS PRECESS AT RIGHT ANGLES TO THE DIRECTION OF THE APPLIED FORCE. Look at view A again. If we keep pushing down on the gimbal ring at point (A), the gyro case will keep turning until the spin axis of the gyro wheel is horizontal. Then there will be no further precession. At this point the gyro wheel will be spinning in the same direction in which the applied force is pushing.

Here's another rule: A GYRO ALWAYS PRECESSES IN A DIRECTION TENDING TO LINE ITSELF UP SO THAT ITS ROTOR SPINS IN THE SAME DIRECTION THAT THE APPLIED FORCE IS TRYING TO TURN IT. In other words, the direction of spin chases the applied force. When the direction of spin and the applied force are in the same direction, precession stops.

Now, compare the spin (X) axis in the two parts of figure 3-7. In view A, the spin axis is vertical. In view B, the spin axis has moved from the vertical until it is much closer to being horizontal. By applying the right amount of force in the right place, we have a method of "aiming" the spin axis so that it points to the specific fixed direction in space where we want it. The property of PRECESSION makes the property of RIGIDITY useable.

You should understand that most forces, when applied to the gyro mounting, do not cause precession. For instance, you can swing the fork around in any direction, and the motion will merely be taken up in the Y-Y and Z-Z axes. Similarly, a force applied lengthwise along one of the axes will have no effect.

Any force acting through the center of gravity of the gyroscope does not change the angle of the plane of rotation but moves the gyroscope as a unit. The position of its spin axis in space is not changed. Such forces as those stated above, operating through the center of gravity, are forces of TRANSLATION. In other words, the spinning gyroscope may be moved freely in space by means of its supporting frame, without disturbing the plane of rotation of the rotor. This condition exists because the force that is applied through the supporting frame, acting through the center of gravity produces no torque on the gyro rotor. ONLY THOSE FORCES TENDING TO TILT THE GYRO WHEEL ITSELF WILL CAUSE PRECESSION.

Let's consider further the important characteristic of gyroscopic precession. For a given amount of force, the rate of precession of a gyro is governed by the weight, shape, and speed of the rotor. These factors are the same as those that determine the rigidity of a gyro. Therefore, there is a definite relationship between the rigidity of a gyro and the rate at which a given force will cause it to precess. The greater the rigidity of a gyro, the more difficult it is to cause precession, and the less precession there will be for a given force.

A gyro will resist any force that attempts to change the direction of its spin axis. However, it will move (precess) in response to such force; NOT in the direction of the applied force, but at right angles to it.

The direction a gyro will precess also depends on the direction the gyro is spinning. Precession is actually the result of two forces: angular momentum (spinning force) and the applied force (torque). The direction of precession is always offset from the direction of the applied force. The offset is always in the direction of rotor spin.

For example, when a force is applied upward on the inner gimbal, as shown in figure 3-8, the force may be visualized as applied in an arc about axis Y-Y. This applied force is opposed by the resistance of gyroscopic inertia, preventing the gyro from rotating about axis Y-Y. With the rotor spinning clockwise, the precession will take place 90º clockwise from the point of applied force. The gyro precesses about axis Z-Z in the direction of the arrow "P".

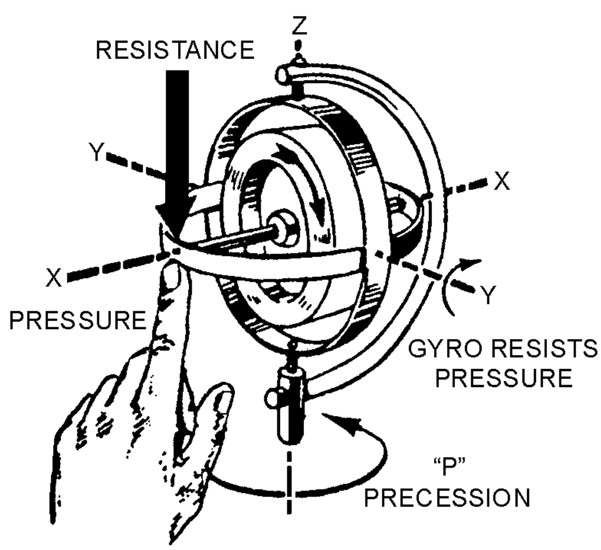

Figure 3-8.—Force applied to a gyro.

The motions of a gyroscope can be analyzed according to three basic quantities:

1. SPIN (the angular velocity of the gyro rotor).

2. TORQUE (the rotary motion applied to change the direction of the rotor axis).

3. PRECESSION (the resulting angular change of the spin axis when torque is applied).

The above quantities are related to vectors so that the relative directions may be easily compared. The SPIN VECTOR lies along the spin axis of the rotor with an arrow indicating the direction of rotation. The TORQUE VECTOR represents the axis about which the applied force is felt. The PRECESSION VECTOR represents the axis about which precession occurs. In all the above cases the direction of the vector is such that the quantity (spin, torque, or precession) is in a clockwise direction if viewed from the tail of the vector.

A simple hand rule will help you determine the direction of the SPIN VECTOR. (See fig. 3-9.) Curve the fingers of your fight hand in the direction in which the rotor is turning as if you intended to grasp the rotor. Your thumb will point in the direction of the spin vector. Similar rules will give you the direction of the TORQUE VECTOR and the PRECESSION VECTOR. With the fingers of your right hand wrapped in the direction of the applied torque (die direction the gyro would rotate if the rotor were not spinning), your thumb points in the direction of the torque vector. Placing your curved fingers in the direction of precession will place your thumb pointing in the direction of the precession vector.

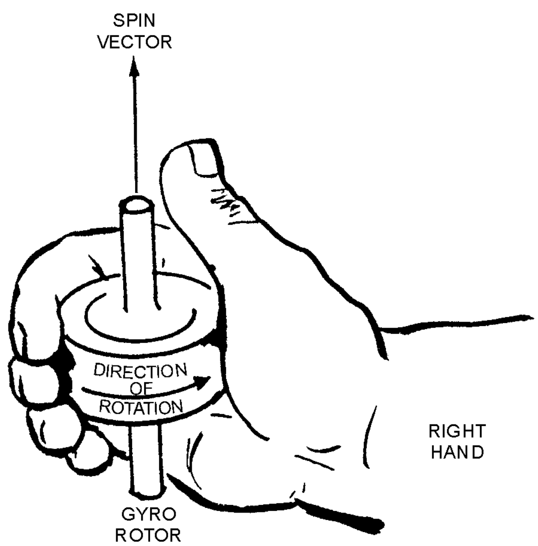

Figure 3-9.—Determining spin vector direction.

All three motions are rotary (angular) and can be represented by vectors that point in such a direction that when you look in the direction of the vector the rotary motion around the vector is clockwise.

Another hand rule convenient for determining the DIRECTION OF PRECESSION uses the fingers of the right hand. This method may not be new to you. A similar method is applied to electric motors (see NEETS, module 5).

You may represent the three vectors listed above by arranging the thumb, forefinger, and middle finger of your right hand mutually perpendicular as shown in figure 3-10. Your thumb points in the direction of the precession vector, your middle finger points in the direction of the torque vector, and your forefinger points in the direction of the spin vector. You can consider these vectors as the axes about which angular motion takes place. If you look in the directions your fingers and thumb point, you can visualize that all the rotary motions are clockwise as indicated in figure 3-10.

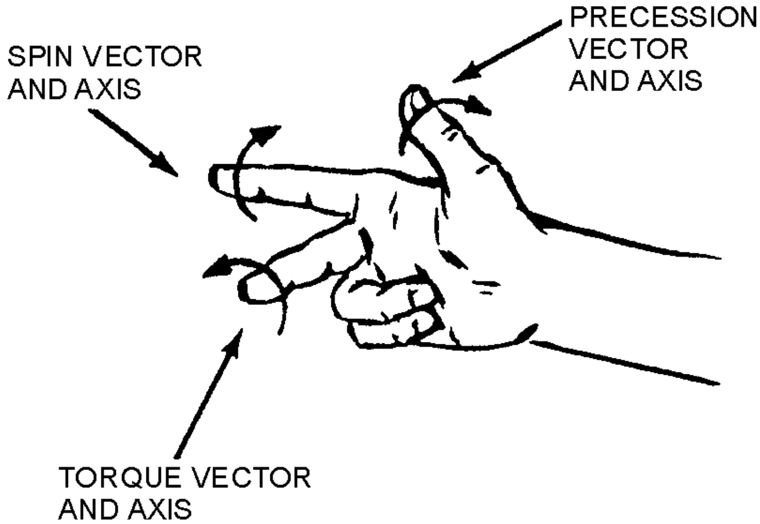

Figure 3-10.—Right-hand rule for determining direction of precession.

This three-finger rule is useful for analyzing any gyroscope motion problem because if the directions of any two of the three vectors are known, the direction of the third vector can be found and the motion around this vector may be determined.

Q-9. What type of force acts ONLY through the center of gravity of a gyro, and does NOT cause precession?

Q-10. The amount of precession that results from a given force is determined by what quantity?

Q-11. What factor determines the direction a gyro will precess in response to a particular force?

Q-12. When using the tight-hand rule to determine precession, which finger indicates the direction of the applied force?

DEGREES OF FREEDOM

A gyro can have different degrees of freedom, depending on the number of gimbals in which it is supported and the way the gimbals are arranged. Do not confuse the term "degrees of freedom" with an angular value such as degrees of a circle. The term, as it applies to gyros, is an indication of the number of axes about which the rotor is free to precess.

A gyro mounted in two gimbals has two degrees of freedom. When two gimbals are used, the gyro is said to be UNIVERSALLY MOUNTED. This arrangement provides two axes about which the gyro can precess. These two axes and the spin axis intersect at the center of gravity of the entire system (excluding the support). Because of this arrangement, the force of gravity does not exert a torque to cause precession. The rotor, inner gimbal, and outer gimbal are balanced about the three principal axes.

TWO DEGREES-OF-FREEDOM GYROS

The two-degrees-of-freedom (free) gyros can be divided into two groups. In the first group, the gyro's spin axis is perpendicular to the surface of the Earth. Thus the gyro's rotor will spin in a horizontal plane. These gyros are used to establish vertical and horizontal planes to be used where stabilized reference planes are needed.

In the second group, the gyro's spin axis is either parallel to the surface of the Earth or at some angle other than perpendicular. The spin axis of the gyro in the gyrocompass, for example, is maintained in a plane parallel to the surface of the Earth It is aligned in a plane of the north-south meridian. Once set, it will continue to point north as long as no disturbing force causes it to precess out of the plane of the meridian.

Effect of Rotation of the Earth

As you have learned, a free gyro maintains its spin axis fixed in space, and not fixed relative to the Earth's surface. To understand this, imagine yourself in a space ship somewhere out in space and looking at the South Pole of the Earth. You see a sphere rotating clockwise, with the South Pole in the center. Maneuver your ship until it is on a direct line with the South Pole and then cut in the automatic controls to keep it in this position. You will now see the Earth make a complete rotation every 24 hours.

You could keep track of that rotation by driving a big post into the Equator as shown in view A of figure 3-11. If this post were upright at 1200, the Earth's rotation would carry it around so it would be pointing to your right at 1800. Likewise, the Earth's rotation would carry the post around so that at 2400 it would be upside down. Then, at 0600 the next day, the post would be pointing to your left. Finally, at 1200 the next day the post would be back in its original position, having been carried, with the Earth, through its complete rotation. Notice that the post has many positions as you observe it—because it is attached to the Earth's surface and does not have rigidity in space.

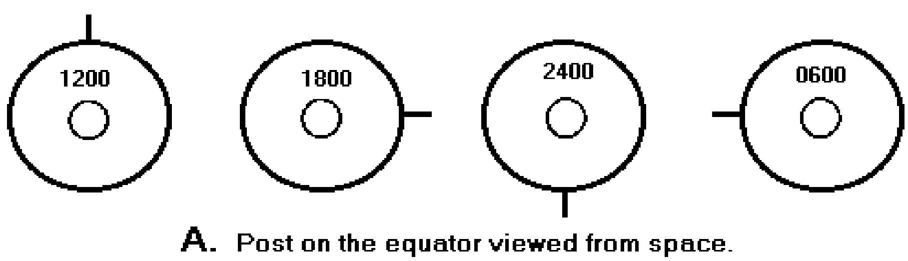

Figure 3-11A.—Fixed direction in space. Post on the equator viewed from space.

If you put a gyroscope in place of the stake, you will see a different action. Imagine a gyroscope mounted at the Equator with its spin axis aligned with the E/W axis of the Earth. The gyro is spinning and has rigidity in space. Now look at view B. At 1200 the spinning axis is horizontal with respect to the Earth's surface. At 1800 the spinning axis is vertical with respect to the Earth's surface; but the gyro is still spinning in the same plane as before, and the black end is pointing away from the Earth's surface. At 2400, the spinning axis is again horizontal. At 0600 the spinning axis is again vertical, and the black end points toward the Earth. Finally, at 1200 the next day, the gyro is in the same position as when it started. The plane of spin of the gyro wheel did not change direction in space while the gyro rotated with the Earth. This is because the gyro is rigid in space.

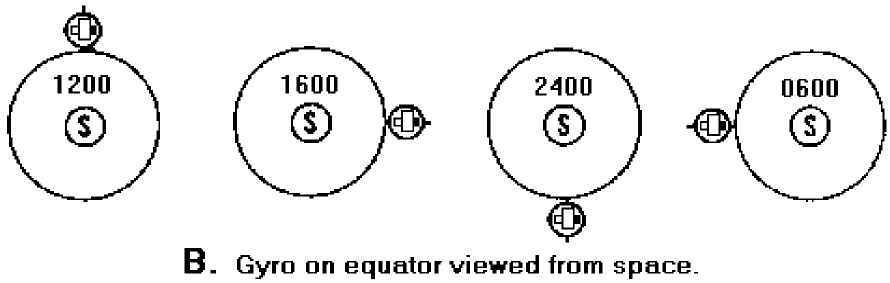

Figure 3-11B.—Fixed direction in space. Gyro on equator viewed from space.

You have just imagined observing the gyro from space. Now, let's come back to Earth and stand right next to the gyro. Look at the gyro in view C. From your viewpoint on Earth, the spinning axis <u>appears</u> to make one complete rotation in one day. As you know, the gyro is rigid, and both you and the Earth are rotating. The effect of the Earth's rotation on a gyro is sometimes called APPARENT DRIFT, APPARENT PRECESSION, or APPARENT ROTATION.

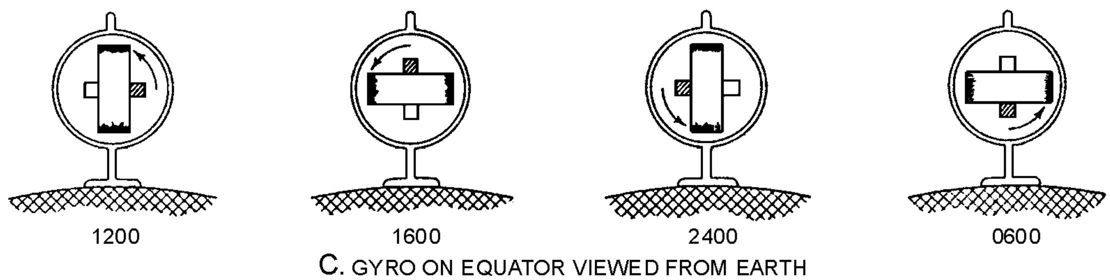

Figure 3-11C.—Fixed direction in space. Gyro on equator viewed from earth.

Effect of Mechanical Drift

A directional error in a gyro is produced by random inaccuracies caused by mechanical drift and the effect of the Earth's rotation (apparent drift).

We shall see later how it is corrected for in the equipment. First, let's consider the causes of mechanical drift.

There are three general sources of mechanical drift:

1. Unbalance. A gyro often becomes dynamically unbalanced when operated at a speed or temperature other than that for which it was designed. The static balance of the gyro is upset when its center of gravity is not at the intersection of the three major axes. Some unbalance of both types will exist in any gyro since manufacturing processes cannot produce a perfectly balanced gyro.

2. Bearing friction. Friction in the gimbal bearings results in loss of energy and incorrect gimbal positions. Friction in the rotor bearings causes mechanical drift only if the friction is not symmetrical. An even amount of friction all around in a rotor bearing results only in a change of the speed of rotation.

3. Inertia of gimbals. Energy is lost whenever a gimbal rotates because of the inertia of the gimbal. The greater the mass of the gimbal, the greater the drift from this source.

The complete elimination of mechanical drift in gyros appears to be an impossibility. However, by proper design it has been kept to a minimum. Any error that still exists can be corrected for.

Q-13. A universally mounted gyro has how many degrees of freedom?

Q-14. If a free gyro is placed at the equator at 1200 in a vertical position; in what position should it be at 1800?

Q-15. What are the three causes of mechanical drift in a gyro?

Establishing and Maintaining a Fixed Position

You now know that a free gyro maintains a fixed position in space. Because of this property, a free gyro can be used to establish a stable, unchanging reference, in any plane (horizontal, vertical, or any specific position in between). The gyro-erecting system has the function of positioning the gyro to the desired position and helping to keep it there.

Any gyro-erecting system must meet the following requirements:

1. The system must provide torques (forces) of sufficient magnitude and direction to precess the gyro so that its spin axis is brought to the desired position after the rotor is spinning at its operating speed.

2. The system must provide torques to precess the gyro back to the required position at the proper rate and direction to cancel the effects of apparent and mechanical drift.

Erection may be done mechanically or electrically, depending on the type of power available. Specific erection systems are many and varied. We will briefly discuss only two of them.

Mercury Erecting System

One of the common erection systems used for vertical gyros uses mercury as the element for sensing gyro position with respect to vertical. Mercury also provides the force to precess the gyro toward vertical when the gyro drifts.

This system consists of two tanks of mercury fastened to opposite sides of the gyro case and connected by a small mercury tube as shown in figure 3-12. A small air tube is also connected between the tanks to prevent a vacuum from forming. If the spin axis tilts away from the vertical, as shown, the mercury will flow from one tank to the other. The added weight in the left tank provides a torque which causes the gyro to precess. At this point, if you were to apply the rule for precession, you would see that the precession would be 90º away from the desired direction.

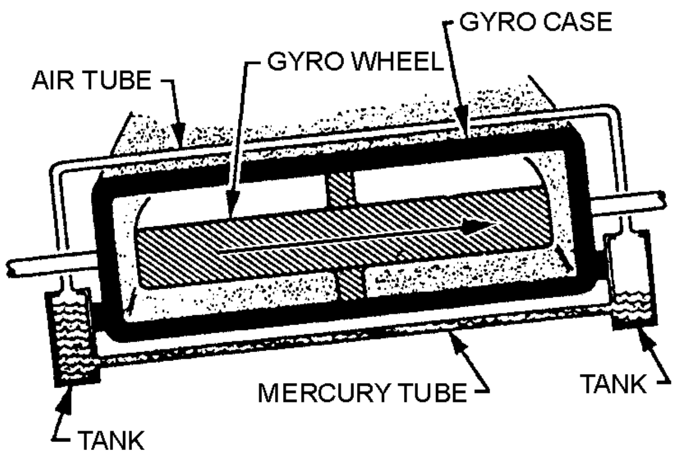

Figure 3-12.—Mercury erecting system.

To overcome this difficulty, the point where the torque is applied must be moved. The torque point is moved by causing the gimbal assembly to slowly and continuously rotate in the proper direction. This is done in the following manner. With a small mercury tube, the mercury will take nearly a second to find its level. At the same time the mercury is flowing, a small motor is rotating the gimbal supporting the gyro about 18 times a minute. Therefore, during the time that it takes the mercury to flow into the low tank, the entire gimbal assembly has rotated 90º. The torque will now be applied at a point which causes the gyro to precess in the proper direction to maintain the gyro spin axis in a vertical position.

Mercury Ballistic Erecting System

The erection system used in many horizontal gyros is very similar to the vertical gyro system just discussed. It is called the *mercury ballistic erection system*. The mercury ballistic system has the added feature of maintaining the spin axis not only in the horizontal plane, but also with the spin axis aligned North-South.

There are many different methods of causing free gyros to precess to either the vertical or the horizontal plane. All such systems use the forces of gravity to sense variation from the desired position: all systems also use the principles of precession to position the gyro property.

Q-16. What is the purpose of an erection system used with a gyro?

Q-17. What is the purpose of rotating the gimbal assembly in a gyro using a mercury erection system?

RATE GYROS

RATE GYROS are used in weapons control equipment, aircraft instrumentation, inertial navigation, and in many other applications to detect and measure angular rates of change.

A rate gyro (sometimes called a rate-of-turn gyro) consists of a spinning rotor mounted in a single gimbal, as shown in figure 3-13. A gyro mounted in this manner has one degree of freedom; that is, it is free to tilt in only one direction. The rotor in a rate gyro is restrained from precessing by some means, usually a spring arrangement. This is done to limit precession and to return the rotor to a neutral position when there is no angular change taking place. Remember, the amount of precession of a gyro is proportional to the force that causes the precession.

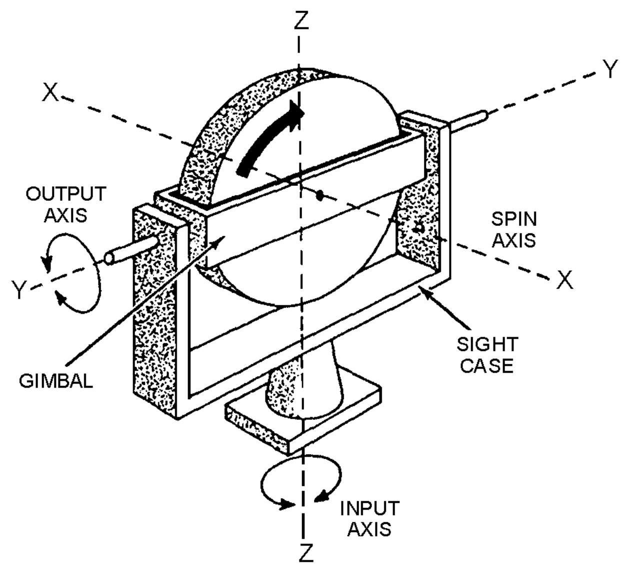

Figure 3-13.—Rate gyro (single degree of freedom).

If you attempt to change the gyro's plane of rotor spin by rotating the case about the input axis, the gyro will precess as shown in figure 3-14. From what you learned earlier in this chapter, the gyro does not appear to be obeying the rules for precession. However, turning the gyro case has the same effect as applying a torque on the spin axis. This is illustrated by arrow F in figure 3-14. You can determine the direction of precession by using the right-hand rule we discussed earlier.

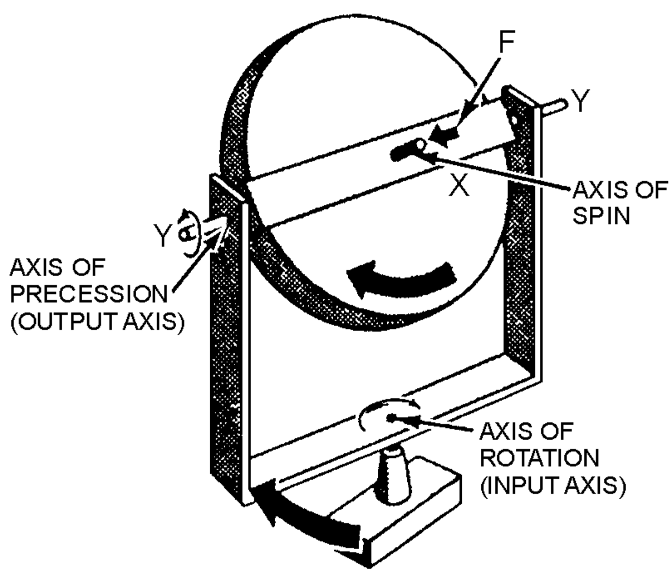

Figure 3-14.—Rate gyro precession.

The force applied at F will cause the gyro to precess at right angles to the force. Likewise, attempting to turn the gyro case will cause the same result. The gyro will precess, as shown by the arrows, around the Y-Y axis (output axis).

Since the rate of precession is proportional to the applied force, you can increase the precession by increasing the speed with which you are moving the gyro case. In other words, you have a rate gyro. The faster you turn the case, the more the gyro will precess, since the amount of precession is proportional to the rate at which you are turning the gyro case.

This characteristic of a gyro, when properly used, fits the requirements needed to sense the rate of motion about any axis.

Figure 3-15 shows a method of restraining the precession of a gyro to permit the calculation of an angle. Springs have been attached to the crossarm of the output shaft. These springs restrain the free precession of the gyro. The gyro may use other types of restraint, but no matter what type of restraint is used, the gyro is harnessed to produce some useful work.

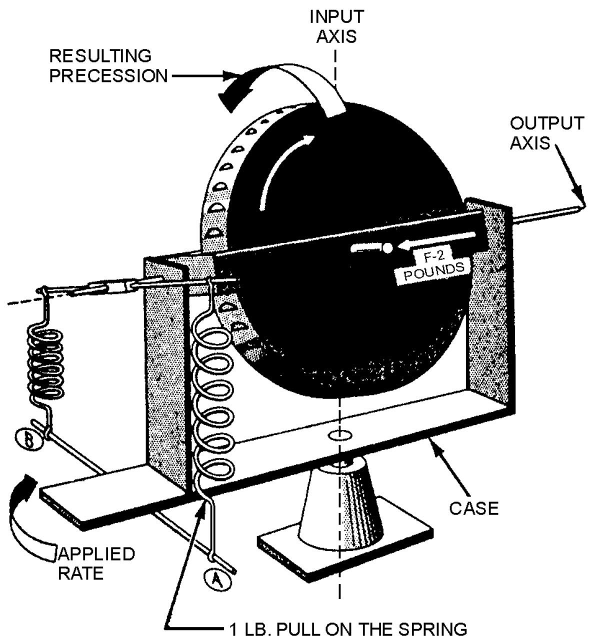

Figure 3-15.—Precession of a spring restrained rate gyro.

As the gyro precesses, it exerts a precessional force against the springs that is proportional to the momentum of the spinning wheel and the applied force. For example, suppose you rotate the gyro case (fig. 3-15) at a speed corresponding to a horizontal force of 2 pounds at F. Obviously, the gyro will precess; and as it does, it will cause the crossarm to pull up on spring A with a certain force, say 1 pound. (This amount of force would vary with the length of the crossarm.)

If you continue to turn the gyro case at this rate, the precession of the gyro will continually exert a pull on the spring. More precisely, the gyro will precess until the 1 pound pull of the crossarm is exactly counterbalanced by the tension of the spring; it will remain in a fixed position, as shown in figure 3-15. That is, it will remain in the precessed position as long as you continue to rotate the gyro case at the same, constant speed. A pointer attached to the output axis could be used with a calibrated scale to measure precise angular rates.

When you stop moving the case, you remove the force at F, and the gyro stops precessing. The spring is still exerting a pull, however, so it pulls the crossarm back to the neutral position and returns the pointer to "zero."

Suppose you now rotate the gyro case at a speed twice as fast as before, and in the same direction. This will be equal to a 4-pound force applied at F and a resulting 2-pound pull by the crossarm on spring

A. In this situation the gyro will precess twice as far before the tension on the restraining spring equals the pull on the crossarm. Precession increases when the rate of rotation increases, as shown in figure 3-16.

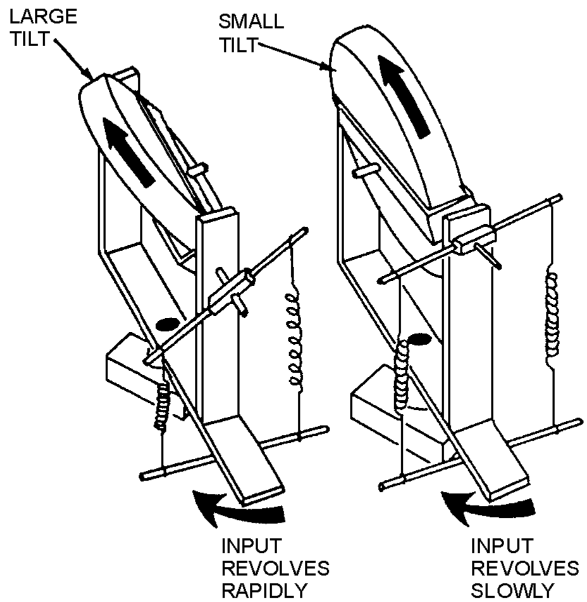

Figure 3-16.—Precession is proportional to the rate of rotation.

Another type of rate gyro (often used in inertial navigation equipment) is the floated gyro unit. This unit generally uses a restraint known as a torsion bar. The advantage of the torsion bar over the spring is that the torsion bar needs no lever arm to exert torque. The torsion bar is mounted along the output axis (fig. 3-17), and produces restraining torque in either direction by twisting instead of pulling. Also, there is no gimbal bearing friction to cause interference with gyro operation.

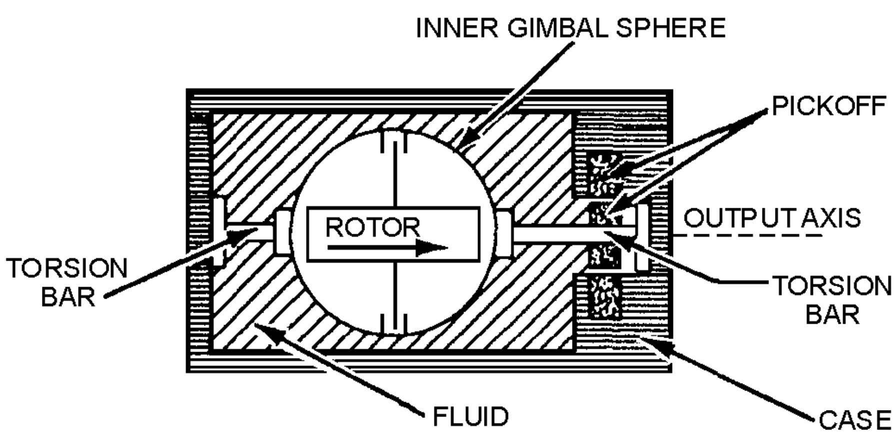

Figure 3-17.—Torsion bar-restrained floated rate gyro.

A fluid surrounds the gyro sphere and provides flotation. It also provides protection from shock, and damps the oscillations resulting from sudden changes in the angular rate input. In this gyro, the inner gimbal displacement must be measured with some type of electrical pickoff. As the gyro case is rotated about the input axis, clockwise or counterclockwise, a precession torque will be developed about the output axis that will cause the inner gimbal to exert torque against the torsion bars. The torsion bars provide a restraining torque proportional to the amount of the inner gimbal's displacement. When the exerted gimbal torque is exactly opposed by the restraining torque provided by the torsion bars, the inner gimbal displacement will be proportional to the rate of rotation of the gyro case about the input axis. The pickoff measures this displacement and provides a signal whose amplitude and polarity (or phase) represent the direction and magnitude of the input angular velocity.

The important point to remember is that every "rate" gyro measures the RATE OF ROTATION ABOUT ITS INPUT AXIS.

Up to this point, we have illustrated only basic gyros. We used these basic, or simple, gyros to explain their principles of operation In actuality, the rate gyros used in typical modern day weapon systems are considerably more complex, and in some cases, very compact. Figure 3-18 shows a cutaway view of a rate gyro used in our Navy's missile systems and aircraft.

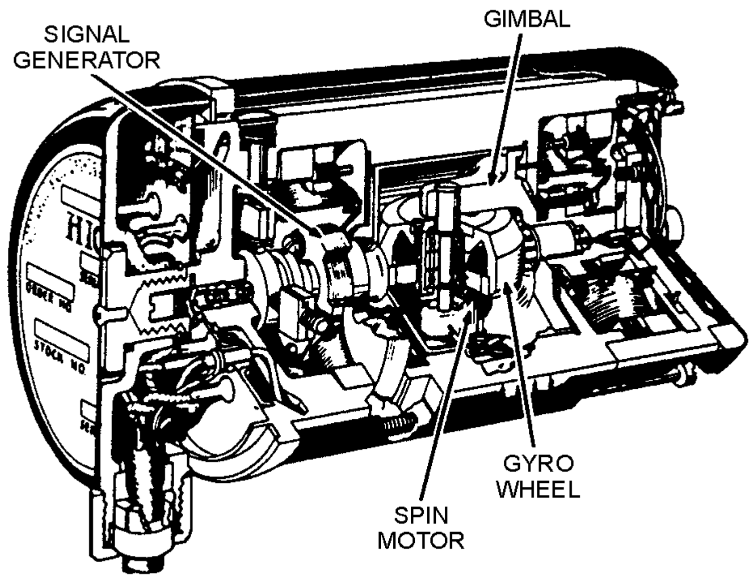

Figure 3-18.—Rate gyro, cutaway view.

Q-18. What are rate gyros primarily used for?

Q-19. How many degrees-of-freedom does a rate gyro usually have?

Q-20. What gyro characteristic provides the basis of the operation of a rate gyro?

ACCELEROMETERS

An accelerometer is a device that gives an indication, usually in the form of a voltage, that is proportional to the acceleration to which it is subjected. The operation of an accelerometer is based on the property of INERTIA (Newton's First Law of Motion). A simple demonstration of inertia happens to us almost every day. You know that if your automobile is subjected to acceleration in a forward direction, you are forced back in the seat. If your auto comes to a sudden stop, you are drawn forward. When your auto goes into a turn, you tend to be forced away from the direction of the turn-that is, if your auto turns left, you are forced to the right, and vice versa.

If we replace the human in an auto with a mass suspended in an elastic mounting system, as shown in figure 3-19, any acceleration of the auto will cause movement of the mass relative to the auto. The amount of displacement is proportional to the force causing the acceleration. The direction the mass moves is always opposite to the direction of the auto's acceleration.

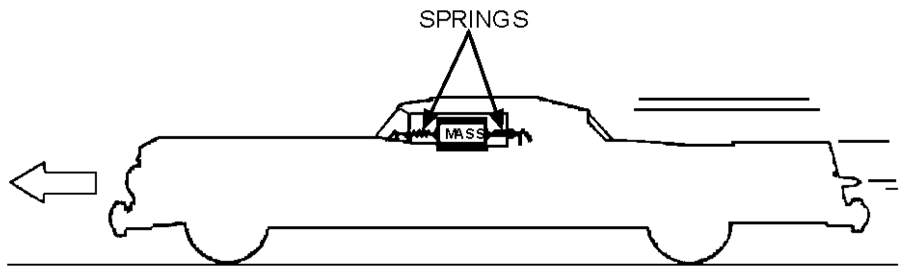

Figure 3-19.—Auto with spring-suspended now.

The mass moves according to Newton's second Law of Motion which states: when a body is acted on by force, its resulting acceleration is directly proportional to the force and inversely proportional to the mass of the body.

When no acceleration is present, the mass will be at rest. When acceleration is present, the mass will lag in proportion to the acceleration force. In other words, the car moves but the mass wants to remain at rest.

Accelerometers are used principally in inertial navigation systems. They are used in aircraft and missile navigation systems as well as aboard ship. Some common types of accelerometers are described briefly in the following paragraphs.

THE BASIC ACCELEROMETER

Figure 3-20 is a simplified drawing of a basic accelerometer. It consists of a mass that is free to slide along the sensitive axis within the case. The movement of the mass is limited by the springs. When the case is accelerated, the mass, because of its inertia, tends to remain stationary. This results in a relative movement of the mass with respect to the case. When the stretch of the springs overcomes the inertia of the mass, the springs cause the mass to stop moving with respect to the case. The displacement of the mass with respect to the case is directly proportional to the acceleration of the case. When the case stops accelerating, the springs return the mass to its zero position (the reference position). To keep the springs from causing the mass to overshoot and oscillate about the reference position, some form of damping is needed. This is usually provided by an oil-filled case with vanes for oil to bypass the mass.

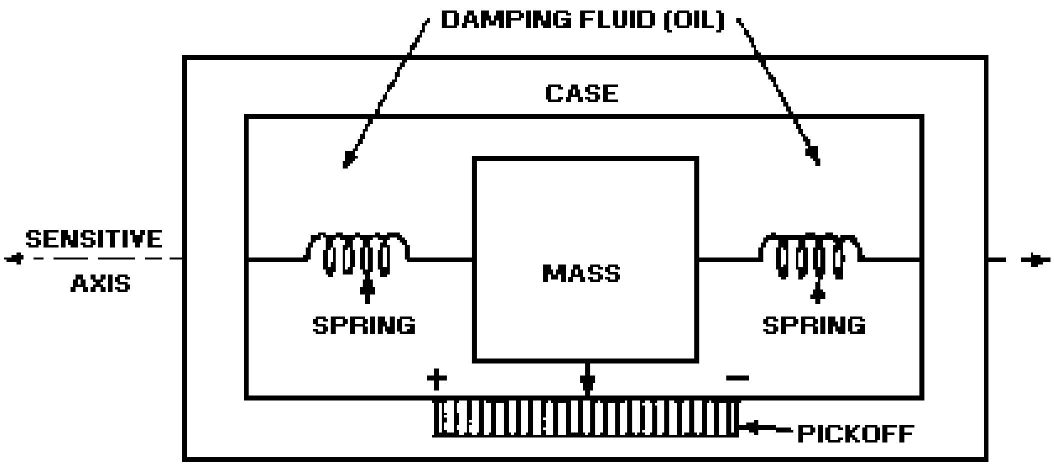

Figure 3-20.—The basic accelerometer.

An accelerometer is sensitive to gravity when its sensing axis is positioned so gravity can move or attempt to move the mass. This is useful in that we can use gravity as a reference for testing purposes, but it can be a serious problem because of the errors it may cause in acceleration measurements. If the unit is placed with the sensing axis vertical, the mass will be displaced such that the output is one "G," or one unit of gravity. This is done during testing. Then when the sensitive axis is turned so it is horizontal to the Earth, the springs center the mass, and the output of the unit is zero.

E-TRANSFORMER ACCELEROMETER

The E-transformer accelerometer (fig. 3-21) consists of a mass suspended from a calibrated leaf spring in a manner similar to a pendulum. The mass is effectively the armature of an E-transformer of the type used as an error detector in a servo system. The mass of the accelerometer is enclosed within a case that is filled with a damping liquid, which helps keep the pendulum from oscillating. The accelerometer is mounted so that acceleration in only the desired geometrical plane is detected.

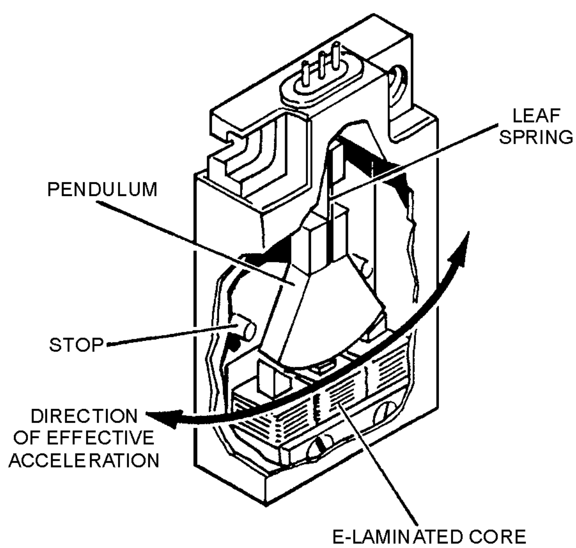

Figure 3-21.—E-transformer accelerometer.

Refer to figure 3-21. Notice that when there is no acceleration, the pendulum remains centered and the accelerometer output is zero. However, when there is acceleration the mass or pendulum swings in the direction opposite to that of the acceleration, causing an output from the E-transformer. Since the amplitude of the pendulum's swing is proportional to the amplitude of the acceleration to which it is subjected, the output of the device indicates both the direction and amplitude of the acceleration. This output is within the limits of the equipment and is limited by physical stops.

PULSE-COUNTING ACCELEROMETER

The outputs of the accelerometers discussed so far are voltages, which are proportional to acceleration. These voltages are assigned scale factors (such as units per volt). The voltage represents the quantity. In many applications there is need for accelerometer output signals to be in digital form, which means that the signal consists of a series of pulses that indicates an actual number. Pulse counting accelerometers satisfy this need. Their pulse output can be supplied directly to computer circuits and other digital logic equipment. A schematic and a pictorial diagram of a pulse counting accelerometer is shown in figure 3-22, view (A) and view (B).

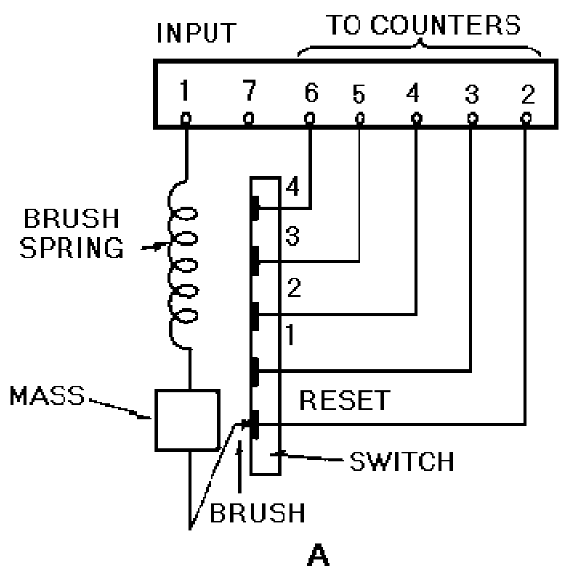

Figure 3-22A.—Pulse counting accelerometer.

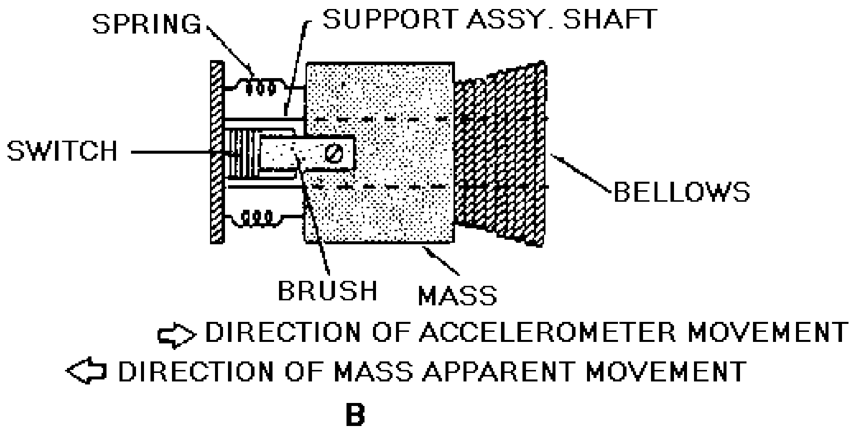

Figure 3-22B.—Pulse counting accelerometer.

When velocity remains constant, the brush spring holds the mass at null, and the brush rests on the reset contact of the switch. As acceleration occurs, the tendency of the mass to remain at a constant velocity causes the spring to compress. As the spring compresses, it allows the brush to move off the reset contact. If the acceleration is great enough, the brush will pass over the switch contacts for acceleration levels 1, 2, 3, and 4. These levels are determined by the stiffness of the spring.

As the brush passes over each contact (in a positive direction), an output pulse from each contact is coupled to one of four counters. This advances the counter one-half count. The accelerometer is designed so that as acceleration decreases, the mass tends to assume the new velocity. The counters will not advance the remaining half count until the brush once again touches the reset contact. With this type of pulse output, it is possible to record each time gravity forces have reached a predetermined level.

Q-21. Operation of an accelerometer is based on what physical property?

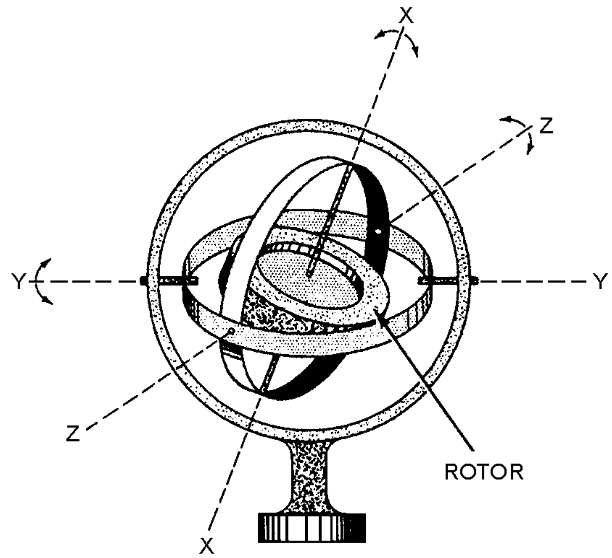
Q-22. What type of systems primarily use accelerometers?

Q-23. What special requirement is the pulse counting accelerometer designed for?

SUMMARY

In this chapter you were introduced to the subject of gyros. You studied the characteristics of gyros and several applications of their use. You were also briefly introduced to the subject of accelerometers. The following information provides a summary of the chapter.

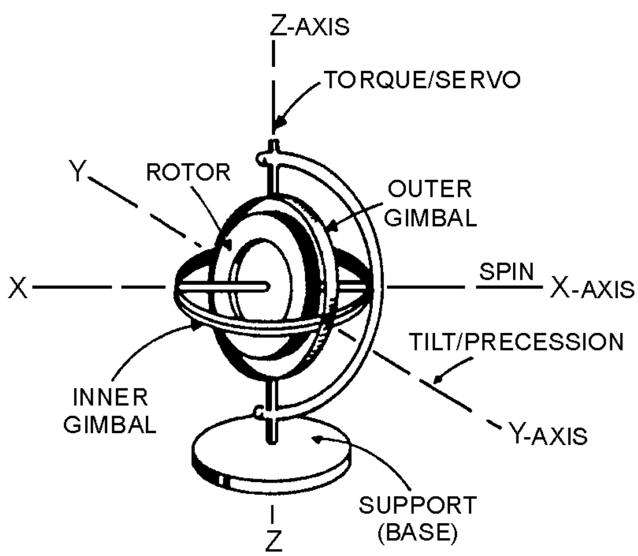
The term **GYROSCOPE** (or GYRO) may be applied to any rapidly spinning object; however, a functional gyroscope is constructed and mounted to take advantage of certain characteristics.



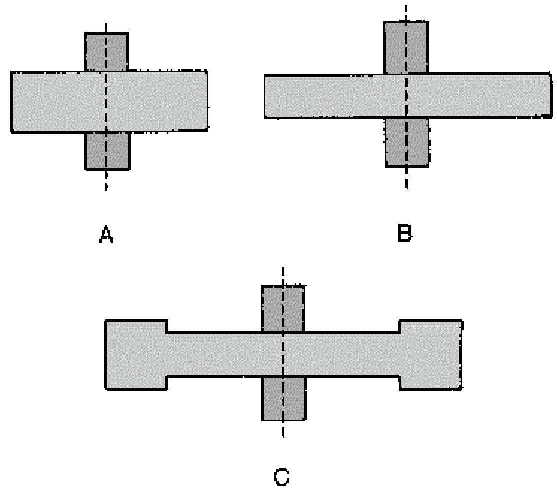
RIGIDITY in a gyro is the tendency of a spinning wheel (rotor) to remain in a fixed position in space.

PRECESSION is the property of a gyro that causes it to tilt in a direction <u>perpendicular</u> to the direction of any outside force.

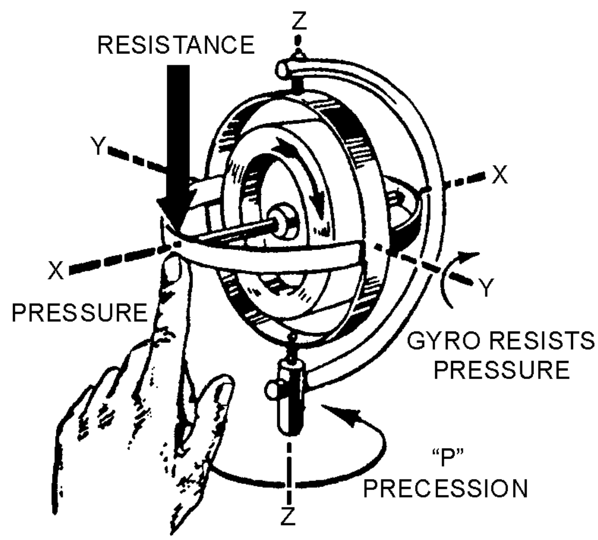
The **COMPONENTS OF A UNIVERSALLY MOUNTED GYRO** are: the Rotor, the Inner Gimbal, the Outer Gimbal, and the Base.



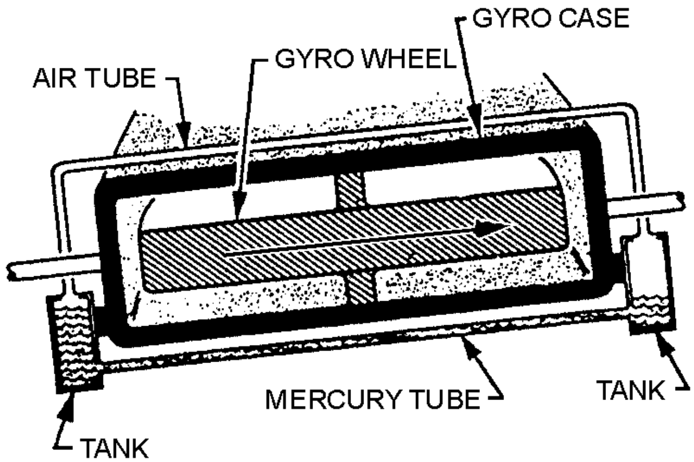
The **FACTORS THAT EFFECT RIGIDITY** are the weight, shape, and speed of rotation of the rotor.



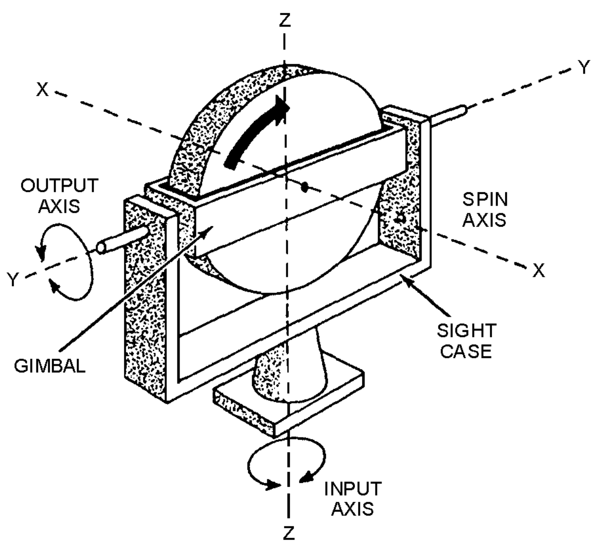
The **DIRECTION OF PRECESSION** in a gyro is always 90º from the direction of the applied force.



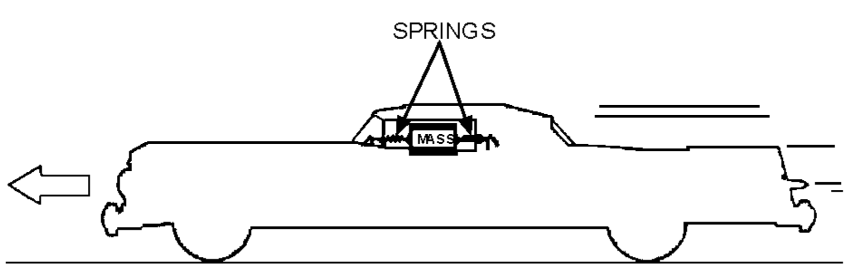
A **GYRO ERECTION SYSTEM** must be capable of sensing the difference between the present rotor position and the <u>desired</u> rotor position, and must apply forces that will cause the gyro to precess toward the desired position. The mercury erection system discussed in this chapter is only one of several possible types of gyro erection systems.



RATE GYROS are specially mounted so they are free to precess in only one direction; they are used to measure angular rates.



An **ACCELEROMETER** is a device used to detect and measure any acceleration along a particular axis.



ANSWERS TO QUESTIONS Q1. THROUGH Q23.

A-1. Yes.

A-2. X-axis.

A-3. Rigidity.

A-4. Any force that attempts to tilt the spin axis.

A-5. Perpendicular (90º) to the force.

A-6. Two.

A-7. Rotor speed, weight, shape.

A-8. C.

A-9. Force of translation.

A-10. Rigidity.

A-11. Direction of spin.

A-12. Middle finger.

A-13. Two.

A-14. Horizontal.

A-15. Unbalanced gyro, inertia of gimbals, bearing friction.

A-16. To achieve and maintain the proper operating position for the gyro (usually vertical or horizontal).

A-17. Applies torque at the proper point for correct precession.

A-18. Measuring angular rates.

A-19. One.

A-20. Precession.

A-21. Inertia.

A-22. Navigation systems.

A-23. When digital data is required from an accelerometer.

CHAPTER 4

RELATED DEVICES

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to:

1. Compare standard synchro system connections with IC synchro connections.

2. Describe the operation of a step transmitter and receiver, and list the advantages and disadvantages of a step-transmission system.

3. Compare the construction and operation of a resolver to those of a transformer, describe the solution of resolution and composition problems by a resolver.

Some other devices that logically should be included in this module are the IC synchros, step motors, and resolvers. These are all electromagnetic devices used in various shipboard and aircraft applications. They can be considered as second cousins of the synchro.

IC SYNCHROS

The engine order telegraph, steering telegraph, rudder-angle indicator, and similar position-indicating systems used on naval ships are usually simple synchro systems. Some ships, however, use IC synchros to transfer such information. These units operate on the same general principle as the synchros we discussed in chapter 1.

The interior communication synchro (IC synchro) is gradually being phased out and replaced by standard synchros when replacement is required. However, you will still find some IC synchros in use today. For that reason, you will find some background information on their purpose and theory to be beneficial. We will present these synchros in very basic form in the following paragraphs.

Because of their construction, IC synchros are sometimes called <u>reversed synchros</u>. The primary winding, consisting of two series-connected coils, is mounted physically on the stator. The secondary, consisting of three Y-connected coils, is mounted physically on the rotor. This is shown schematically in figure 4-1.

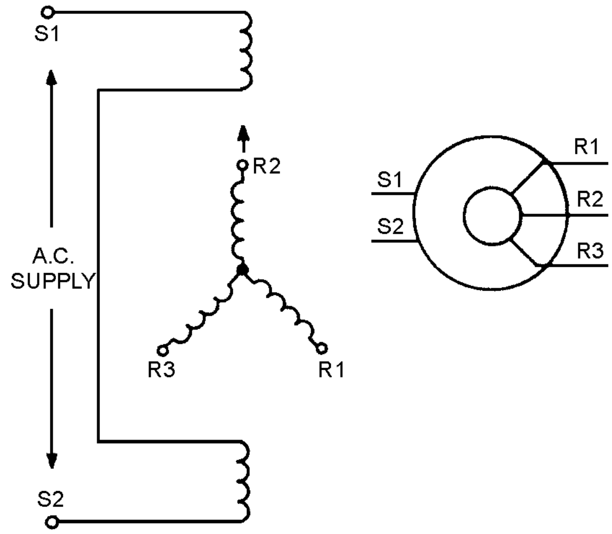


Figure 4-1.—IC synchro schematic diagrams.

IC synchros operate on the same principles of interacting magnetic fields as other synchros, but differ in direction of shaft rotation and amount of torque obtainable. When an IC transmitter and IC receiver are connected in parallel as shown in view A of figure 4-2, the shaft of the IC receiver follows the rotation of the IC transmitter shaft. In view B, the IC transmitter is replaced by a synchro transmitter; the IC receiver shaft now turns in a direction opposite to that of the synchro transmitter. Voltages that cause counterclockwise rotation of a standard synchro shaft cause clockwise rotation of an IC synchro shaft. When it is desirable to have the IC synchro receiver turn in an opposite direction from that of the transmitter, the connections are as shown in view C. For a standard synchro receiver to follow the rotation of an IC transmitter, their connections must be made as shown in view D.

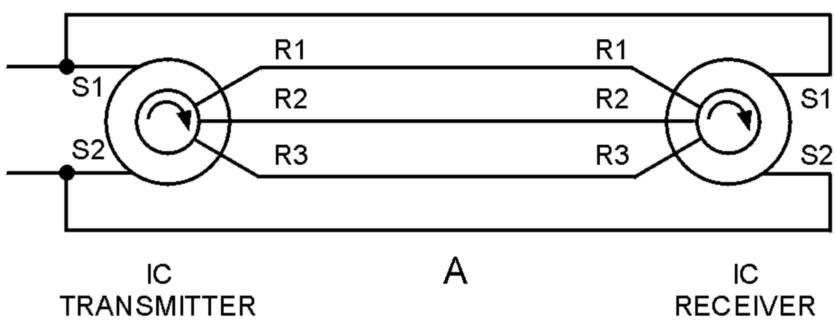

Figure 4-2A.—IC versus standard synchro connections.

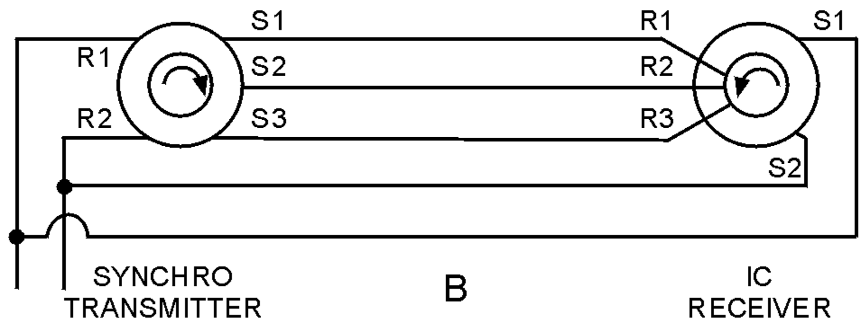

Figure 4-2B.—IC versus standard synchro connections.

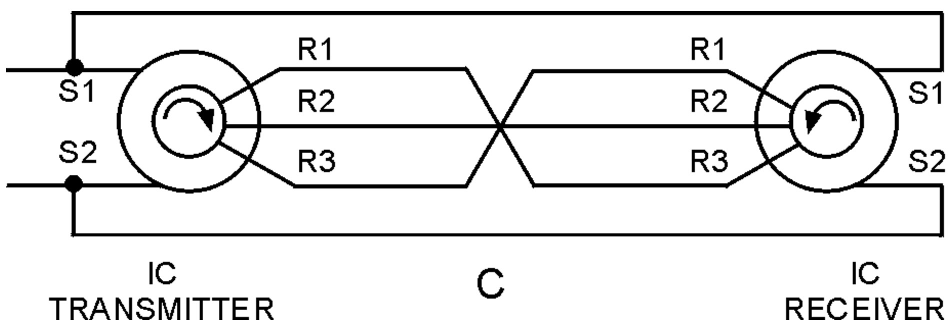

Figure 4-2C.—IC versus standard synchro connections.

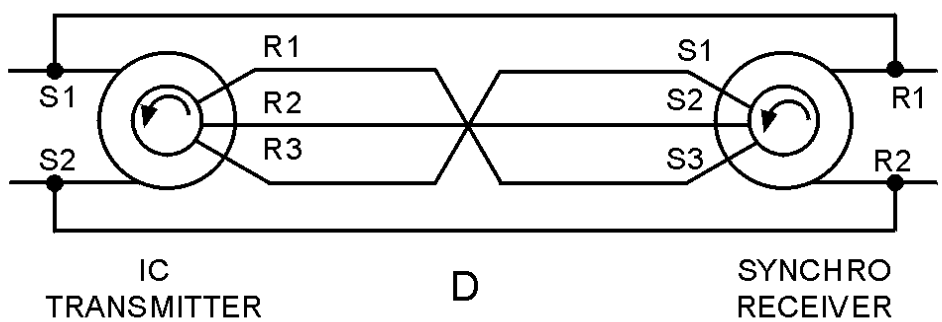

Figure 4-2D.—IC versus standard synchro connections.

The torque obtainable from either an IC synchro or a standard synchro is determined by the magnetizing power, which is limited by the allowable temperature rise. When the stator is energized, as in IC synchros, the magnetizing power can be increased with a resulting larger torque. The reason for this is that the losses are dissipated in the form of heat around the outer shell of the IC transmitter or receiver. In standard synchros, this heat loss is dissipated through the rotor, the air gap, and then the outer shell to the surrounding air.

The electrical zero position for an IC synchro is the position where rotor coil R2 is aligned with the stator as shown in figure 4-1. To zero an IC synchro, apply the same general theory as we described for other synchros.

For further information on IC synchro replacement, alignment, and theory, refer to *Military Handbook, Synchros, Description and Operation*, (MIL-HDBK-225A).

Q-1. What two characteristics of IC synchros cause them to differ from standard synchros?

STEP-TRANSMISSION SYSTEMS

All of the synchro units we have discussed operate on alternating current. In applications where alternating current is not available, there is a need for a system that can use direct current. The STEP-TRANSMISSION SYSTEM (sometimes referred to as the step-by-step system) is such a system.

A geared step-transmission system is often used to drive compass repeaters on naval vessels and merchant ships having dc power.

Although many variations are used, the simplified step-by-step transmission system shown in figure 4-3 is typical. In this system, a step transmitter and a step motor are used together to transmit angular data (information) between remote locations. When rotated, the shaft of the step transmitter periodically switches a dc excitation voltage from one pair of coils to another in the step motor. The step motor, which is the receiver in the system, responds to this varying excitation by rotating an amount that is proportional to the transmitter's shaft position.

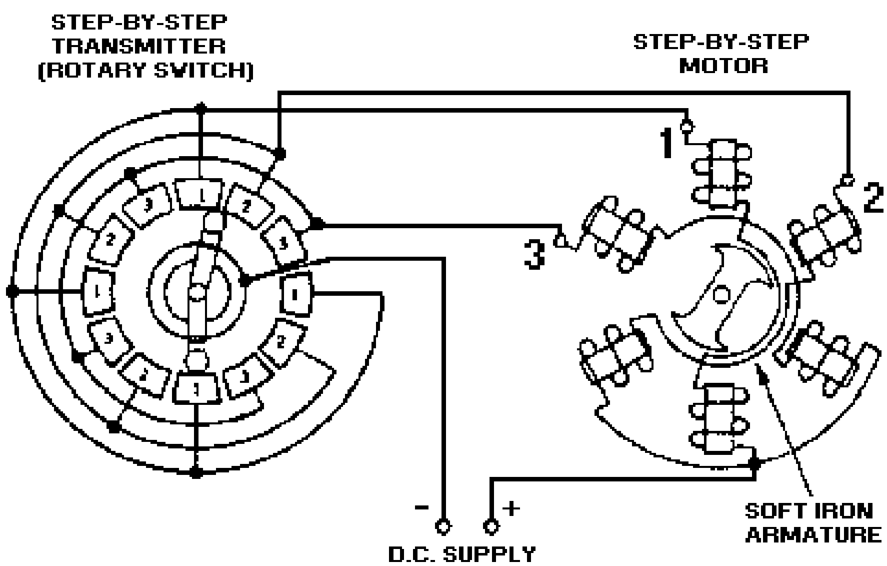

Figure 4-3.—Step-by-step transmission system.

The stator of this step motor has six field coils spaced 60 degrees apart. The coils are connected in three groups of two coils each, with opposite coils connected in series. One end of each pair of coils is connected to one of the brushes in the step transmitter. The other ends of the coils are connected to the other side of the dc supply voltage through a common lead. As the rotor of the step transmitter is turned, the corresponding coils in the step motor are energized in sequence, producing a rotating step-by-step stator field. Thus, the motor rotates in abrupt increments or steps rather than smoothly.

NOTE: The theory of the step-by-step motor is similar to that involved in positioning the bar magnet (chapter 1, fig. 1-10).

For ease of explanation, we will replace the step transmitter with a battery as we discuss the operation of the step motor. If, as shown in view A of figure 4-4, we apply the dc battery voltage across the number 1 coils only, the armature will turn to the position shown. When we apply the voltage also to the number 2 coils, the armature turns to a position midway between the number 1 and number 2 coils, view B. If we now disconnect the number 1 coils, the armature turns until it lines up with the number 2 coils, view C. View D shows the number 2 and 3 coils connected and the armature rotated one step further. As long as this process is continued, the armature can be rotated through 360 degrees.

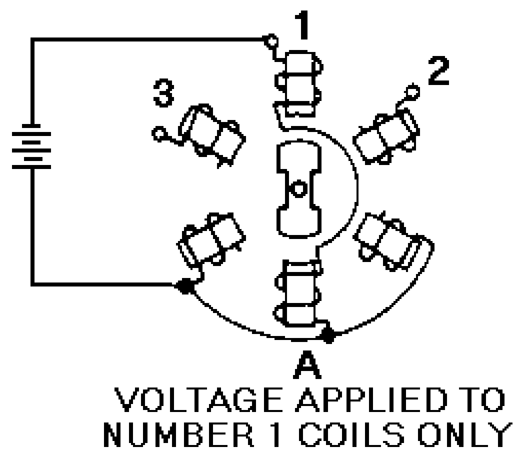

Figure 4-4A.—Step-by-step motor in various positions. VOLTAGE APPLIED TO NUMBER 1 COILS ONLY.

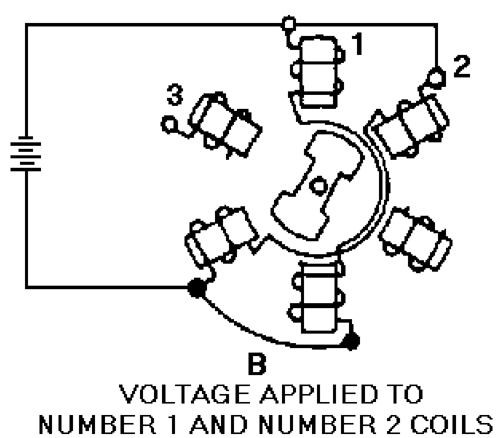

Figure 4-4B.—Step-by-step motor in various positions. VOLTAGE APPLIED TO NUMBER 1 AND NUMBER 2 COILS.

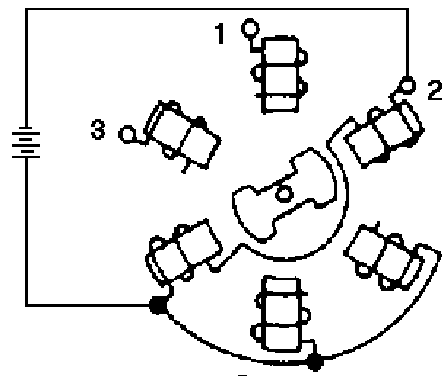

Figure 4-4C.—Step-by-step motor in various positions. VOLTAGE APPLIED TO NUMBER 2 COILS ONLY.

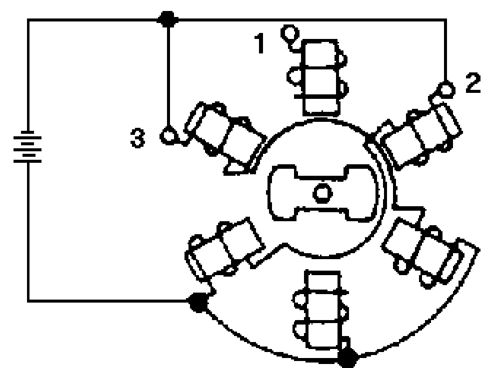

Figure 4-4D.—Step-by-step motor in various positions. VOLTAGE APPLIED TO NUMBER 2 AND NUMBER 3 COILS.

In actual operation, the step-by-step motor is driven by a step transmitter (rotary switch) as shown in figure 4-3. As the switch is rotated, it applies voltage first to coil 1, and then in sequence to 1 and 2 together, coil 2 only, coils 2 and 3 together, coil 3 only, and so on, until the complete revolution is made. As a result, the armature turns in 30-degree steps that follow the rotation of the rotary switch. The rotating arm of the switch can be turned mechanically to angles between zero and 360º in 30-degree steps. The actual angle through which the arm is rotated depends on the specific data to be transmitted by the system. Real systems may transmit data in greater or lesser steps than 30 degrees, depending on system design.

An important point in this type of system is that because the armature is soft iron, either end of the armature may turn and line up with the energized coils. For this reason, a hand reset control is provided on the step-by-step motor. This permits an operator to align the receiver with the transmitter each time the power supply is energized.

A step-transmission system is not self-synchronizing, and its limited number of steps does not permit data to be transmitted smoothly or where relatively small changes in data are required. This type of transmission system is cheap, rugged, and relatively powerful.

Q-2. Compare the power sources of synchros and step-transmission systems.

Q-3. A step transmitter is a modification of what electrical device?

RESOLVERS

The last device we will discuss is the resolver. Physically, resolvers are similar to synchros, and are used to perform mathematical computations electrically. They are rotary electromechanical devices that provide outputs that are trigonometric functions of their inputs. As you may know, the branch of mathematics that deals with the quantities and angles of a right triangle is known as trigonometry. Many "trig" problems that can be solved with paper and pencil can be solved by applying the proper electrical or mechanical quantities to a resolver. The resolver has the advantage of giving instantaneous solutions if the input quantities are changing continuously.

Resolvers are classified according to size (diameter) in the same manner as standard synchros and may be mounted with most standard synchro mounting hardware. A cutaway view of a resolver is shown in figure 4-5.

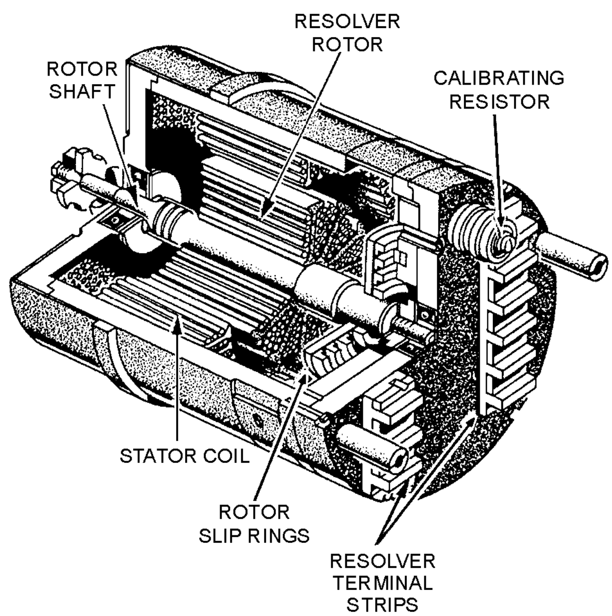

Figure 4-5.—Cutaway view of a resolver.

Notice that the stator of the resolver is a cylindrical structure of slotted laminations on which two coils are wound. The rotor is composed of a shaft, laminations, two windings, and four slip rings. Compensator components, which improve the angular accuracy of resolvers, may consist of resistors or additional windings in the stator and rotor winding circuits. Compensator windings, which increase the accuracy of the resolver, are located inside the stator. Compensating (calibrating) resistors, which compensate for voltage inaccuracies and phase shifts, may be mounted either inside or outside the resolver housing.

A cylindrical frame with a standardized mounting flange houses the assembled resolver. External and internal connections can be made to an insulated terminal board on the rear of the housing. Miniature resolvers often have lead wires brought out through the rear of the resolver, eliminating the need for a terminal block. A reference line is scribed on the face of the housing for alignment with a similar line on the end of the rotor shaft. These are used in determining coarse electrical zero.

Basically, a resolver is a transformer in which the secondary windings can be rotated with respect to the primary windings. Consequently, the amount of magnetic coupling between the primary and the secondary is variable. In the most common form, a resolver consists of a stator and a rotor, each having two separate windings placed precisely at right angles to each other as shown in figure 4-6.

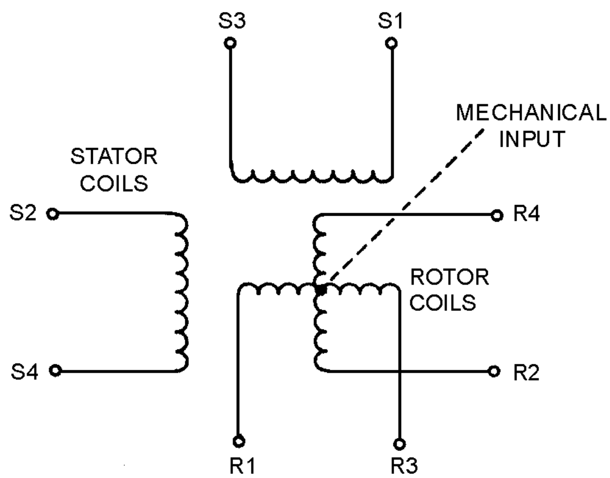

Figure 4-6.—Resolver schematic.

Since the two stator windings are physically and electrically at right angles to each other, there is no magnetic coupling between them. The stator windings are mounted on the resolver housing and are stationary with respect to it.

Similarly, the rotor windings of the resolver are wound at right angles to each other. Hence, there is no magnetic coupling between the two windings. The rotor windings are mounted on the rotor shaft and turn with it. The rotor is capable of unlimited rotation. Thus, the rotor windings can be set at any angle with respect to the stator windings.

Because of the 90º physical and electrical relationships, the resolver has the ability to separate a quantity into its two right-angle components. This is called RESOLUTION.

Figure 4-7 illustrates the use of a resolver in solving a resolution problem. Assume that a voltage, E, and an angle, R, represent the magnitude and direction of a known quantity. To determine the two right-angle components of the quantity, feed the magnitude of the quantity to one stator coil and physically turn the rotor through angle R. The input voltage (E) induces voltage E1 and E2 in the two rotor coils. The values of these rotor voltages represent the vertical and horizontal components of the known quantity and depend on both the value of E and the angle (R) through which the rotor was turned.

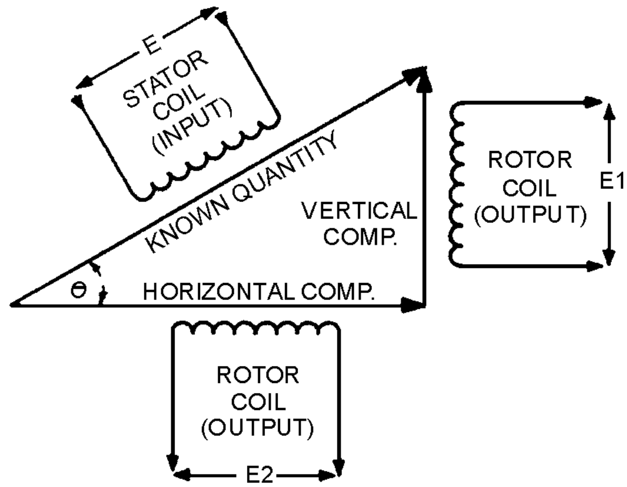

Figure 4-7.—One example of resolution.

Similarly, the resolver has the ability to add two vectors that are at right angles to each other and produce the resultant vector (hypotenuse) at the resultant angle. This is called COMPOSITION.

Figure 4-8 illustrates one use of a resolver in solving a composition problem. Assume that we have two known quantities, vertical and horizontal components, that are represented by E1 and E2, respectively. Each of these is fed to a stator coil. These two voltages induce a voltage, ET, in one of the rotor coils. ET represents a voltage that is proportional to the hypotenuse. The voltage induced in the other rotor coils is fed to a closed-loop servo, which positions the rotor shaft to the angle (direction) of the hypotenuse.

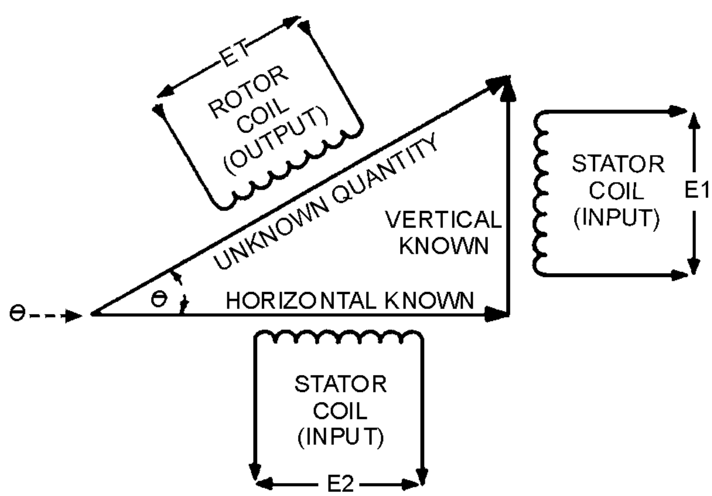

Figure 4-8.—One example of composition.

Other mathematical solutions are possible to designers who apply resolvers in equipment. Typical naval problems solved by resolvers involve distances, speeds, angular quantities, etc.

In most cases, as in figures 4-7 and 4-8, only resolver coils actively used in solving a particular problem are shown in schematics.

Resolvers can also perform a third function COMBINATION. This is the process of resolution and composition taking place simultaneously.

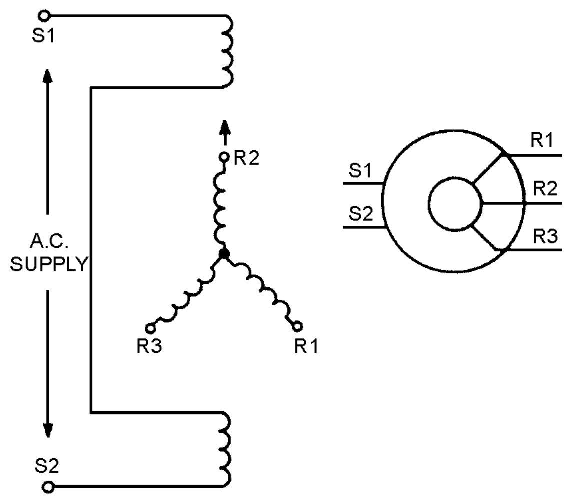
The resolver is a precision component, whose electrical characteristics are critical, and any deviation may result in excessive errors in the system. Before working on or replacing resolvers, you should check the associated equipment technical manual.

Q-4. What type of mathematical problem is solved by resolvers?

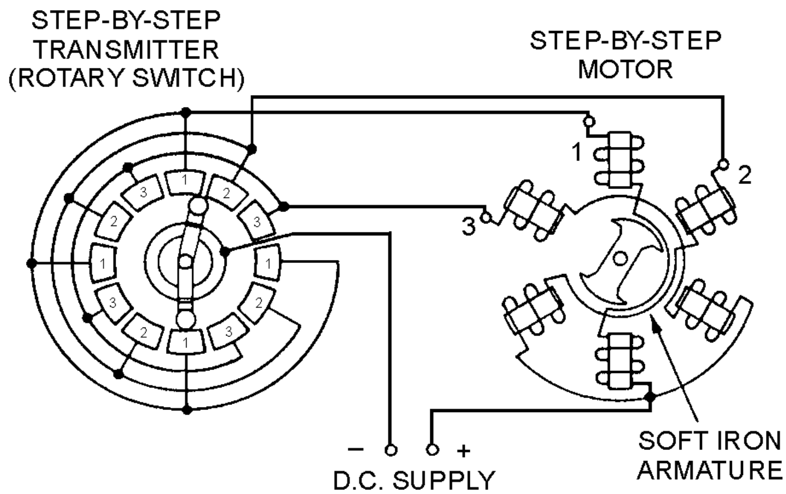
SUMMARY

The following are brief summaries of the **IC SYNCHROS, STEP-TRANSMISSION SYSTEMS**, and RESOLVERS we covered in this chapter.

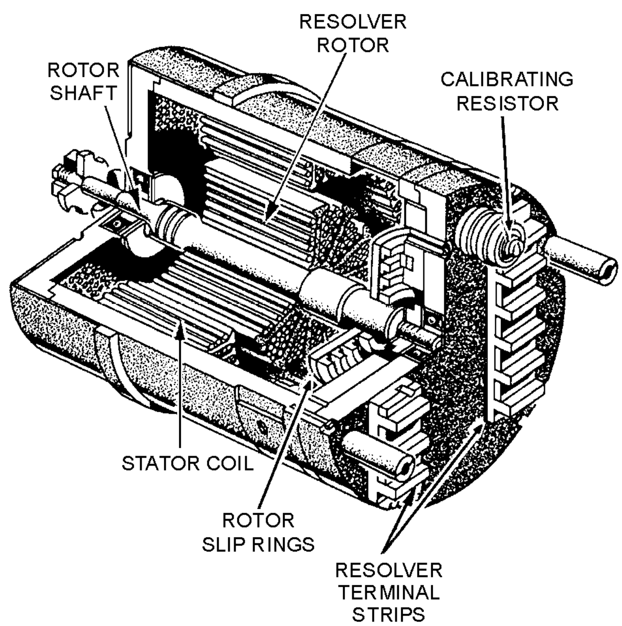
IC SYNCHROS, sometimes referred to as reversed synchros, are used in systems where transfer of information is desired. They operate on the same principles as synchros but differ in the direction of shaft rotation and amount of torque obtained.



A **STEP-TRANSMISSION SYSTEM (STEP-BY-STEP SYSTEM)** is similar to a synchro system, except that it is energized by direct current. This system uses a rotary switch to transfer angular data (information) between remote locations. The system is cheap, rugged, relatively powerful, but is not used where small changes in data are required.



RESOLVERS are physically similar to synchros and are used to perform mathematical computations. They are used extensively in analog computers, radar sets, direction and target designation equipment.



ANSWERS TO QUESTIONS Q1. THROUGH Q4.

A-1. Direction of rotation and amount of torque.

A-2. Synchros use ac; step transmission uses dc.

A-3. Rotary switch.

A-4. Right-triangle, or trigonometric, problems.

APPENDIX I

GLOSSARY

ACCELERATION SERVO SYSTEM—A servo system that controls the acceleration (rate of change in velocity) of a load.

ACCELEROMETER—A device that measures acceleration to which it is subjected and develops a signal proportional to it.

ANGULAR POSITION—The counterclockwise angular displacement of a synchro rotor, measured in degrees from its electrical zero position, as viewed from the shaft extension end of the synchro.

APPARENT DRIFT—The effect of the Earth's rotation on a gyro, which causes the spinning axis to appear to make one complete rotation in one day. Also called APPARENT PRECESSION or APPARENT ROTATION.

APPARENT PRECESSION—See apparent drift.

APPARENT ROTATION—See apparent drift.

AXIS—A straight line, either real or imaginary, passing through a body, around which the body revolves.

BANDWIDTH—The range of frequencies a servo amplifier can amplify without causing unacceptable distortion to the input signal.

CONTROL DIFFERENTIAL TRANSMITTER (CDX)—A type of synchro that transmits angular information equal to the algebraic sum or difference of the electrical input supplied to its stator, and the mechanical input supplied to its rotor. The output is an electrical voltage taken from the rotor windings.

CONTROL SYNCHRO SYSTEMS—Synchro systems that contain control synchros and are used to control large amounts of power with a high degree of accuracy. The electrical outputs of these systems control servo systems, which in turn generate the required power to move heavy loads.

CONTROL SYSTEM—A group of components, systematically organized to perform a specific control purpose. These systems are categorized as either closed- or open-loop systems. The main difference between the two is that the closed-loop system contains some form of feedback.

CONTROL TRANSFORMER (CT)—A type of synchro that compares two signals: the electrical signal applied to its stator and the mechanical signal applied to its rotor. The output is an electrical voltage, which is taken from the rotor winding and is used to control a power amplifying device. The phase and amplitude of the output voltage depend on the angular position of the rotor with respect to the magnetic field of the stator.

CONTROL TRANSMITTER (CX)—A type of synchro that converts a mechanical input, which is the angular position of its rotor, into an electrical output signal. The output is taken from the stator windings and is used to drive either a CDX or CT.

CORRESPONDENCE—The term given to the positions of the rotors of a synchro transmitter and a synchro receiver when both rotors are on 0 or displaced from 0 by the same angle.

DAMPING—A mechanical or electrical technique used in synchro receivers to prevent the rotor from oscillating or spinning. Damping is also used in servo systems to minimize overshoot of the load.

DATA TRANSMISSION—The transfer of information from one place to another or from one part of a system to another.

DEGREE-OF-FREEDOM—The number of axes about which a gyro is free to precess.

DEMODULATOR—A circuit used in servo systems to convert an ac signal to a dc signal. The magnitude of the dc output is determined by the magnitude of the ac input signal, and its polarity is determined by whether the ac input signal is in or out of phase with the ac reference voltage.

DOUBLE RECEIVER—A fine and coarse synchro receiver enclosed in a common housing with a two-shaft output (one shaft inside the other).

E-TRANSFORMER—A special form of differential transformer using an E-shaped core. The secondaries of the transformer are wound on the outer legs of the E, and the primary is on the center leg. An output voltage is developed across the secondary coils when its armature is displaced from its neutral position. This device is used as an error detector in servo systems that have limited load movements.

ELECTRICAL-LOCK—A synchro zeroing method. This method is used only when the rotors of the synchros to be zeroed are free to turn and their leads are accessible.

ELECTRICAL ZERO—A standard synchro position, with a definite set of stator voltages, that is used as the reference point for alignment of all synchro units.

ERECTING (A GYRO)—The positioning of a gyro into a desired position and the maintaining of that position.

ERROR DETECTOR—The component in a servo system that determines when the load has deviated from its ordered position, velocity, etc.

ERROR REDUCER—The name commonly given to the servo motor in a servo system. So named because it reduces the error signal by providing feedback to the error detector.

ERROR SIGNAL—In servo systems, the signal whose amplitude and polarity or phase are used to correct the alignment between the controlling and the controlled element. It is also the name given to the electrical output of a control transformer (CT).

EXCITATION VOLTAGE—The supply voltage required to excite a circuit.

FREQUENCY RESPONSE—The measure of a servo's ability to respond to various input frequencies.

GIMBAL—A mechanical frame, with two perpendicular, intersecting axes of rotation, used to support and furnish a gyro wheel with the necessary freedom to tilt in any direction.

GYRO—Abbreviation for gyroscope.

GYROSCOPE—A mechanical device containing a spinning mass mounted so that it can assume any position in space.

IC SYNCHROS—Electromechanical devices, used to transmit information, that operate on the same principles of interacting magnetic fields as synchros, but differ in their direction of rotation and the amount of torque obtainable. Because of their construction, they are sometimes called reversed synchros.

INERTIA—The physical tendency of a body in motion to remain in motion and a body at rest to remain at rest unless acted upon by an outside force (Newton's First Law of Motion).

MAGNETIC AMPLIFIER—An electromagnetic device that uses one or more saturable reactors to obtain a large power gain. This device is used in servo systems requiring large amounts of power to move heavy loads.

MILITARY STANDARD SYNCHROS—Synchros that conform to specifications that are uniform throughout the Armed Services.

MODULATOR—A circuit used in servo systems to convert a dc signal to an ac signal. The output ac signal is a sine wave at the frequency of the ac reference voltage. The amplitude of the output is directly related to the amplitude of the dc input. The circuit's function is opposite to that of a DEMODULATOR.

MULTI-LOOP SERVO SYSTEM—A servo system that contains more than one servo loop, each loop designed to perform its own function.

MULTISPEED SYNCHRO SYSTEMS—Systems that transmit data at different transmission speeds; for example, dual-speed and tri-speed synchro systems.

NEWTON'S SECOND LAW OF MOTION—If an unbalanced outside force acts on a body, the resulting acceleration is directly proportional to the magnitude of the force, is in the direction of the force, and is inversely proportional to the mass of the body.

POSITION SENSOR—A component in a servo system that measures position and converts the measurement into a form convenient for transmission as a feedback signal.

POSITION SERVO SYSTEM—A servo system whose end function is to control the position of the load it is driving.

POTENTIOMETER—An electromechanical device, used as a position sensor in servo systems, having a terminal connected to each end of a restrictive element, and a third connected to a wiper contact. The output is a voltage that is variable depending upon the position of the wiper contact. The potentiometer is commonly referred to as a variable voltage divider. It, in effect, converts mechanical information into an electrical signal.

PRECESSION—The rotation of the spin axis of a gyro in response to an applied force. The direction of precession is always perpendicular to the direction of applied force.

PRECESSION VECTOR—In a gyro, a vector representing the angular change of the spin axis when torque is applied. The precession vector represents the axis about which precession occurs.

PRESTANDARD NAVY SYNCHROS—Synchros that are designed to meet Navy, rather than servicewide, specifications.

RATE GYRO—A gyro used to detect and measure angular rates of change.

RESOLVER—A rotary, electromechanical device used to perform trigonometric computations by varying the magnetic couplings between its primary and secondary windings. It is generally used in circuits that solve vector problems, such as analog computers and conversion equipment. The resolver solves three different type problems: (1) resolution—separating a vector into two mutually perpendicular components; (2) composition—combining two components of a vector to produce a vector sum; (3) combination—the process of resolution and composition taking place simultaneously.

RESULTANT MAGNETIC FIELD—The magnetic field produced in a synchro by the combined effects of the three stator magnetic fields.

RIGIDITY—The tendency of the spin axis of a gyro wheel to remain in a fixed direction in space if no force is applied to it.

ROTOR—The rotating member of a synchro that consists of one or more coils of wire wound on a laminated core. Depending on the type of synchro, the rotor functions similar to the primary or secondary winding of a transformer. In a gyro, the rotating member is sometimes called a gyro wheel.

SCALING FACTOR—The term used to describe the use of unequal resistors in a servo's summing network to compensate for differences between input and output signal levels.

SERVO AMPLIFIER—An ac or dc amplifier used in servo systems to build up signal strength. These amplifiers usually have relatively flat gain versus frequency response, minimum phase shift, low output impedance, and low noise level. The dc amplifier is subject to excessive drift and is relatively unstable. However, the ac amplifier is considered drift free and has a constant dynamic gain over a variety of operating points.

SERVO MOTOR—An ac or dc motor used in servo systems to move a load to a desired position or at a desired speed. The ac motor is usually used to drive light loads at a constant speed, while the dc motor is used to drive heavy loads at varying speeds.

SERVO SYSTEM—An automatic feedback control system that compares a required condition (desired value, position, etc.) with an actual condition and uses the difference to adjust a control device to achieve the required condition.

SIGNAL—The angle through which a synchro transmitter rotor is mechanically turned.

SPIN VECTOR—In a gyro, a vector representing the angular velocity of the gyro rotor. The spin vector lies along the spin axis of the rotor.

STATOR—The stationary member of a synchro that consists of a cylindrical structure of slotted laminations on which three Y-connected coils are wound with their axes 120 apart. Depending on the type of synchro, the stator's functions are similar to the primary or secondary windings of a transformer.

STEP-TRANSMISSION SYSTEM—A data transmission system that operates on direct current. It consists of a step transmitter (rotary switch) and a step motor interconnected to transmit data (information) between remote locations.

STICKOFF VOLTAGE—A low voltage used in multispeed synchro systems to prevent false synchronizations.

SUMMING NETWORK—A combination of two or more parallel resistors used in servo systems as error detectors. The output of the network is the algebraic sum of the inputs.

SYNCHRO—A small motorlike device that operates like a variable transformer and is used primarily for the rapid and accurate transmission of data among equipments and stations.

SYNCHRO CAPACITOR—A unit containing three delta-connected capacitors. The synchro capacitor is used in synchro systems to increase the system's accuracy by cancelling or reducing phase shift introduced by synchro inductance.

SYNCHRO SYSTEM—Two or more synchros interconnected electrically. The system is used to transmit data among equipments and stations.

SYNCHRO TESTER—A synchro receiver with a calibrated dial. This receiver is used primarily for locating defective synchros. It can also be used for zeroing synchros.

SYNCHRO TROUBLESHOOTING—The locating or diagnosing of synchro malfunctions or breakdowns by means of systematic checking or analysis.

SYNCHRONIZING NETWORK—A circuit used in servo systems, also called a crossover or switching network, to sense how far the load is from the point of correspondence and then functions to switch the appropriate signal into control.

TACHOMETER—A small ac or dc generator, sometimes referred to as a rate generator, which converts its shaft speed into an electrical output. The tachometer is frequently used in servo systems to sense the velocity of a load.

TIME LAG—The delay in a servo system between the application of the input signal and the actual movement of the load.

TORQUE—A measure of how much load a machine can turn. This measurement is expressed either in ounce-inches for torque synchro systems or in pound-feet for heavy machinery.

TORQUE DIFFERENTIAL RECEIVER (TDR)—A type of differential synchro that takes two electrical inputs, one to the rotor and one to the stator, and produces a mechanical output. The output is the angular position of the rotor, which represents the algebraic sum or difference of the two electrical inputs.

TORQUE DIFFERENTIAL SYNCHRO SYSTEM—A synchro system containing either a TDX or a TDR. This system is used in application where it is necessary to compare two signals, add or subtract the signals, and furnish an output proportional to the sum or difference between the two signals.

TORQUE DIFFERENTIAL TRANSMITTER (TDX)—A synchro that is functionally the same as the CDX except that it is used in torque systems rather than control systems.

TORQUE RECEIVER (TR)—A type of synchro that converts the electrical input supplied to its stator back to a mechanical angular output through the movement of its rotor.

TORQUE SYNCHRO SYSTEM—A synchro system that uses torque synchros to move light loads such as dials, pointers, and other similar devices.

TORQUE TRANSMITTER (TX)—A synchro that is functionally the same as the CX except that it is used in torque synchro systems.

TORQUE VECTOR—In a gyro, a vector representing the rotary motion applied to change the direction of the rotor axis. The torque vector represents the axis about which the applied force is felt.

TRANSLATION—In a gyro, a force acting through the center of gravity of the gyro that causes no torque on the gyro rotor. Translation forces do not change the angle of the plane of rotation but move the gyroscope as a unit.

TROUBLE INDICATORS—Signal lights used to aid maintenance personnel in locating synchro troubles quickly.

TROUBLE TABLES—Tables of trouble symptoms and probable causes furnished by many manufacturers, with their equipment, to help technicians isolate synchro problems.

VELOCITY SERVO SYSTEM—A servo system that controls the speed of the load it is driving.

X-AXIS—In a gyro, the spin axis of the gyro.

Y-AXIS—In a gyro, an axis through the center of gravity and perpendicular to the spin axis.

Z-AXIS—In a gyro, an axis through the center of gravity and mutually perpendicular to both the spin (X) and Y axes.

ZEROING—The process of adjusting a synchro to its electrical zero position.

MODULE 15 INDEX

ASSIGNMENT 1

Textbook assignment: Chapter 1, “Synchros,” pages 1-1 through 1-78.

1-1. Which of the following terms accurately describes a synchro?

1. Position-sensing
2. Electromechanical
3. Rotary
4. Each of the above

1-2. What are the two general classifications of synchro systems?

1. Torque and load
2. Torque and control
3. Load and control
4. Load and lock

1-3. What is the difference in application between the two classifications of synchros?

1. Light versus heavy load
2. Mechanical versus electrical Output
3. Circular versus straight-line motion
4. High-frequency versus low-frequency operation

1-4. Which of the following types of synchro devices provides a mechanical output?

1. A control transformer
2. A torque receiver
3. A torque transmitter
4. A control transmitter

1-5. A 115-volt, 400-Hz torque transmitter with a diameter of 2.36 inches will have what military standard designation code?

1. 115 V-23CT6
2. 115 V-24TT4
3. 23TD4
4. 24TX4

1-6. A 3.5-inch diameter differential receiver will have what Navy prestandard designation code?

1. 35CR
2. 35TDR
3. 5D
4. 5DG

1-7. What does the arrow on a synchro schematic symbol indicate?

1. The direction of current flow
2. The direction of rotor movement
3. The angular position of the stator
4. The angular position of the rotor

1-8. What are the two major components of a synchro?

1. The rotor and the stator
2. The housing and the stator
3. The rotor and the shaft
4. The housing and the shaft

1-9. What type of rotor can be composed of a single winding or three Y-connected windings?

1. Salient-pole
2. Drum or wound
3. Fixed
4. "H"

1-10. How does the stator of a TX receive voltage?

1. By a physical connection with the rotor
2. By a magnetic coupling with another stator
3. By a magnetic coupling with the rotor
4. By a physical connection with a source

1-11. What part of a synchro provides a point for external connections?

1. The terminal board
2. The slip ring
3. The stator
4. The brush

1-12. Which of the following terms is defined as the amount of load a machine can turn?

1. Radian force
2. Load factor
3. Torque
4. Tension

1-13. Which of the following units should be used in measuring the amount of turning force of a synchro?

1. Ounces
2. Pounds
3. Foot-pounds
4. Ounce-inches

1-14. An overloaded synchro will probably exhibit which of the following conditions?

1. Overspeed
2. Oscillation
3. Excessive temperature
4. Noisy operation

1-15. A synchro receiver has which of the following characteristics that is NOT found in an ordinary transformer?

1. A primary that can rotate in relation to the secondary
2. A primary magnetically coupled to the secondary
3. A step-up turns ratio
4. An air core

1-16. When a synchro transmitter is in the zero-degree position, the rotor is aligned in what manner?

1. With winding S1
2. With winding S2
3. With winding S3
4. Between winding S1 and S2

1-17. Maximum voltage is induced in a stator winding of a synchro transmitter when the rotor and the stator winding have what angle between them?

1. 0 degrees
2. 30 degrees
3. 60 degrees
4. 90 degrees

1-18. Which of the following factors does NOT affect the amplitude of the voltage induced in a stator winding of a synchro transmitter?

1. The angular displacement between the rotor and stator
2. The amplitude of the primary voltage
3. The speed of data transmission
4. The turns ratio of the synchro

1-19. Damping is necessary for which of the following synchro devices?

1. Receiver
2. Transmitter
3. Control transformer
4. Differential transmitter

1-20. The primary purpose of damping is to reduce which of the following conditions in a synchro device?

1. Readings 180º out of phase
2. Overheating
3. Oscillating
4. Each of the above

1-21. What is the minimum number of synchro devices needed for a simple synchro transmission system?

1. One
2. Two
3. Three
4. Four

1-22. In a simple synchro system, what leads are connected to the source voltage?

1. R1 and R2
2. S1 and S2
3. S2 and S3
4. R1 and S1

1-23. When a synchro transmitter, and receiver are in correspondence, what is the relative value of the (a) current through the stators and (b) receiver torque?

1. (a) Maximum (b) maximum
2. (a) Maximum (b) minimum
3. (a) Minimum (b) minimum
4. (a) Minimum (b) maximum

1-24. What term applies to the angle through which a synchro transmitter rotor is rotated mechanically?

1. Lag
2. Lead
3. Gain
4. Signal

1-25. If a synchro receiver is required to rotate in a direction opposite to the rotation of the transmitter rotor, what leads should be reversed?

1. R1 and R2
2. S1 and S2
3. S2 and S3
4. S1 and S3

1-26. If a synchro receiver and transmitter are always 180 degrees out of phase with each other, what leads are reversed?

1. R1 and R2
2. S1 and S2
3. S2 and S3
4. S1 and S3

1-27. What type of synchro can accept two signals simultaneously and add or subtract?

1. Transmission
2. Differential
3. Automatic
4. Shiftless

1-28. What are the two types of synchro devices that will accept two inputs?

1. TR and TX
2. TR and TDX
3. TDR and TX
4. TDR and TDX

1-29. What types of synchro devices have (a) one electrical and one mechanical input and an electrical output; and (b) two electrical inputs and a mechanical outputs?

1. (a) TR (b) TX
2. (a) TX (b) TR
3. (a) TDX (b) TDR
4. (a) TDR (b) TDX

1-30. What determines whether a differential synchro device adds or subtracts its inputs?

1. The way it is connected in the system
2. The direction of rotor movement
3. The number of stator windings
4. The supply voltage polarity

1-31. In a TDX system, for the TR rotor to follow the TX rotor exactly, in what position must the TDX rotor be kept?

1. 0 degree position
2. 60 degree position
3. 120 degree position
4. 240 degree position

1-32. What is the angular position of a TR rotor when it is pointing to the S3 winding?

1. 0 degrees
2. 60 degrees
3. 120 degrees
4. 240 degrees

1-33. If a TDX system with standard synchro connections has the TX rotor at the 60-degree position and the TDX rotor at the 270-degree position, what is the position of the TR rotor?

1. 110 degrees
2. 150 degrees
3. 210 degrees
4. 250 degrees

1-34. For a TDX system to add its inputs rather than subtract them, what leads must be reversed between (a) the TX and TDX, and (b) the TR and TDX?

1. (a) S1 and S2 (b) R1 and R3
2. (a) S1 and S3 (b) R1 and R3
3. (a) S2 and S3 (b) R1 and R2
4. (a) S1 and S3 (b) R1 and R2

1-35. For a TDR system to add its inputs rather than subtract them, what leads must be reversed at the TDR?

1. S1 and S3
2. S1 and S2
3. R1 and R3
4. R1 and R2

1-36. If a TDR system is connected for addition and the TX rotor connected to the TDR rotor turns counterclockwise, in what direction will the TDR rotor field rotate?

1. In a direction determined by the other TX stator
2. In a direction determined by the other TX rotor
3. Counterclockwise
4. Clockwise

1-37. Which of the following types of synchros is used in a system requiring large amounts of power and high accuracy?

1. Torque
2. Control
3. Differential
4. Each of the above

1-38. What are the three types of control synchros?

1. TX, TR, CT
2. TX, CDX, CR
3. CX, CT, CR
4. CX, CT, CDX

1-39. The CX and CDX differ from the TX and TDX because the CX and CDX have which of the following characteristics?

1. Lower impedance windings
2. Higher impedance windings
3. Larger physical size
4. Smaller physical size

1-40. Which of the following is NOT a characteristic of the rotor of a control transformer (CT) rotor?

1. It is connected to a high-impedance load
2. It must be turned by an external force
3. It is connected to an ac source
4. It has a drum- or wound-type rotor

1-41. When a control transformer is at electrical zero, the rotor is perpendicular to what winding?

1. S1
2. S2
3. S3
4. R2

1-42. If a control transformer is held at electrical zero and the control transmitter is turned 90 degrees counterclockwise, what is (a) the amplitude of the induced voltage in the rotor of the control transformer, and (b) the phase relationship of this voltage and the excitation voltage to the control transmitter?

1. (a) Maximum (b) out-of-phase
2. (a) Maximum (b) in phase
3. (a) Minimum (b) out-of-phase
4. (a) Minimum (b) in phase

1-43. Which of the following terms applies to the output of a control transformer?

1. Mechanical movement
2. Deflection angle
3. Output voltage
4. Error signal

1-44. If the output of a control transformer is zero, what is the relationship of the rotors of the control transformer and the control transmitters?

1. In correlation
2. Out of correlation
3. In correspondence
4. Out of correspondence

1-45. Synchro capacitors are used to provide which of the following characteristics in a synchro system?

1. Improved accuracy
2. Reduced oscillations
3. Wider frequency response
4. Higher load-carrying capacity

1-46. Which of the following synchro devices uses a synchro capacitor?

1. TX
2. RX
3. TDR
4. CDX

1-47. What type of current is eliminated by synchro capacitors?

1. Loss
2. Rotor
3. Stator
4. Magnetizing Stator

1-48. In what configuration are synchro capacitors connected in a synchro circuit?

1. Wye, across the rotor windings
2. Delta, across the rotor windings
3. Wye, across the stator windings
4. Delta, across the stator windings

1-49. To maintain system accuracy, where are synchro capacitors physically placed in a synchro circuit?

1. Close to the TX or RX
2. Close to the TDX, CDX, or CT
3. Midway between the TX and CT
4. Far away from the TDR, CDX, or CT

1-50. Synchro systems that transmit data at two different speeds are referred to by which of the following terms?

1. Dual-speed
2. Two-speed
3. Twin-speed
4. Each of the above

1-51. Multispeed synchro systems have which of the following advantages over single-speed synchro systems?

1. Easier to troubleshoot and align
2. Fewer moving parts
3. Greater accuracy
4. All of the above

1-52. What does the gear ratio between the two transmitters in a dual-speed synchro system determine?

1. The direction of transmitter-rotation
2. The direction of receiver rotation
3. The speeds of transmission
4. The relative direction of rotation

1-53. Which of the following synchro systems, if any, should be used to transmit very large quantities?

1. Single-speed
2. Two-speed
3. Tri-speed
4. None of the above

1-54. Which of the following is a disadvantage of a double receiver as compared to two single receivers?

1. The entire unit must be replaced if one portion fails
2. It takes up much more space
3. It is much more costly
4. It is much heavier

1-55. The voltage used to prevent false synchronizations is known by what term?

1. Error voltage
2. Signal voltage
3. Source voltage
4. Stickoff voltage

1-56. What is the reference point for the alignment of all synchro units?

1. Mechanical zero
2. Electrical zero
3. Mechanical null
4. Electrical null

1-57. What is the most accurate method of aligning a synchro?

1. The dc voltmeter method
2. The ac voltmeter method
3. The synchro-tester method
4. The electric-lock method

1-58. During synchro alignment, what is the purpose of the coarse setting?

1. To ensure a setting of zero degrees rather than 180 degrees
2. To prevent the voltmeter from being overloaded
3. To keep the synchro device from overheating
4. To correct the fine setting

1-59. If a synchro receiver is properly zeroed, when do the stator windings have electrical zero voltages?

1. When the rotor is moving
2. When the rotor is stopped
3. When the rotor is at 270 degrees
4. When the rotor is at its reference position

1-60. When a 115-volt synchro transmitter is set on its coarse-zero position, approximately what voltage should be read on a voltmeter?

1. 15 volts
2. 26 volts
3. 37 volts
4. 193 volts

1-61. When a 115-volt source is used during the alignment of a differential synchro, what is the maximum time the circuit can be energized without causing damage to the synchro?

1. 1 minute
2. 2 minutes
3. 15 minutes
4. 30 minutes

1-62. After a control transformer has been zeroed and clamped down, what is the final step in the zeroing procedure?

1. Replace the fuses
2. Turn it to 270 degrees
3. Recheck the zero voltage reading
4. Disconnect all wires to the control transformer

1-63. The output voltage of a control transformer on electrical zero is which of the following relative values?

1. Equal to the supply voltage
2. Half the supply voltage
3. Maximum
4. Minimum

1-64. When a tri-speed synchro system is being zeroed, which synchro should be zeroed first?

1. Coarse
2. Medium
3. Largest
4. Fine

1-65. What method of zeroing a synchro is the fastest but NOT the most accurate?

1. The dc voltmeter method
2. The ac voltmeter method
3. The synchro-tester method
4. The electrical-lock method

1-66. The electrical-lock method of zeroing a synchro requires accessible leads and which of the following conditions?

1. A rotor free to turn
2. A stator free to turn
3. A supply voltage to the stators
4. A zero-volt potential between S1 and S2

1-67. A synchro is zeroed by the use of a synchro tester. After it is zeroed, the S1 and S3 leads are shorted together, and the synchro tester dial moves. What does this indicate?

1. The synchro is zeroed correctly
2. The synchro is not zeroed correctly
3. The supply voltage is too low
4. The supply voltage is too high

1-68. If you find that a synchro has bad bearings, which of the following actions should you take?

1. Replace the bearing
2. Lubricate the synchro
3. Replace the synchro
4. Continue to use it

1-69. Which of the following troubles is common in newly installed synchro systems?

1. Dirty brushes
2. Improper wiring
3. Worn slip rings
4. Shorted synchro windings

1-70. What type of indicating device is usually installed in the stator circuit of a torque synchro system?

1. A voltmeter indicator
2. An ohmmeter indicator
3. An overload indicator
4. A blown-fuse indicator

1-71. A synchro system with four receivers is malfunctioning. All of the receivers have incorrect readings. Which of the following is/are the most likely cause(s) of the trouble?

1. Damper failure
2. The transmitter
3. One of the receivers
4. All of the receivers

1-72. An ac voltmeter is connected between windings S1 and S3 of a synchro transmitter. Which of the following rotor positions should give a zero voltage reading?

1. 180º
2. 240º
3. 300º
4. 330º

1-73. When a synchro tester is used in place of a synchro transmitter, which of the following precautions will help to keep the tester from being overloaded?

1. Use a 26-volt supply only
2. Use a 115-volt supply only
3. Use only one syncho receiver
4. Use at least three synchro receivers

ASSIGNMENT 2

Textbook assignment: Chapter 2, “Servos,” pages 2-1 through 2-38. Chapter 3, “Gyros,” pages 3-1 through 3-27. Chapter 4, “Related Devices,” pages 4-1 through 4-12.

2-1. A servo is normally designed to move (a) what type of load to (b) what type of positions?

1. (a) Small (b) Exact
2. (a) Small (b) Approximate
3. (a) Large (b) Exact
4. (a) Large (b) Approximate

2-2. Servo systems can be found in which of the following forms?

1. Pneumatic
2. Hydraulic
3. Electromechanical
4. Each of the above

2-3. Which of the following systems are control systems?

1. Open-loop
2. Closed-loop
3. Both 1 and 2 above
4. Inductive-loop

2-4. A servo system is defined as which of the following types of control systems?

1. Open-loop
2. Closed-loop
3. Both 1 and 2 above
4. Inductive-loop

2-5. Which of the following is a basic difference between an open-loop control system and a closed-loop control system?

1. Number of loops
2. Size of the load
3. Speed of movement
4. System of feedback

IN ANSWERING QUESTIONS 2-6 THROUGH 2-8, MATCH THE FUNCTION LISTED IN COLUMN B TO THE SERVO COMPONENT LISTED IN COLUMN A THAT ACCOMPLISHES THE FUNCTION.

A. SERVO COMPONENTS	B. FUNCTIONS
2-6. Synchro control system	1. Moves the load
2-7. Servo amplifier	2. Provides power
2-8. Servo motor	3. Controls movement
	4. Converts dc to ac

2-9. In a dc position servo system, what characteristic of the error signal determines the direction in which the load is driven?

1. Amplitude
2. Frequency
3. Polarity
4. Phase

2-10. The sum point in a position servo system combines what two signals to produce an error signal?

1. Response and output
2. Feedback and Output
3. Feedback and input
4. Output and input

2-11. A position servo system exhibits a series of overtravels. This condition is known by which of the following terms?

1. Hunting
2. Overdamping
3. Undershooting
4. All of the above

2-12. A velocity servo has which of the following characteristics?

1. Senses position of the load; no error signal at correspondence
2. Senses position of the load; error signal present at correspondence
3. Senses speed of the load; no error signal at correspondence
4. Senses speed of the load; error signal present at correspondence

2-13. What device is usually used to provide feedback in a velocity servo loop?

1. Potentiometer
2. Tachometer
3. CT
4. CX

2-14. For a servo system to operate smoothly and efficiently, it must have balance between which of the following factors?

1. Acceleration and speed
2. Inertia and oscillation
3. Amplification and damping
4. Overshooting and feedback signal

2-15. When friction-clutch damping is used in a servo system, the first overshoot of the load may be characterized as

1. small
2. large
3. reversed
4. eliminated

2-16. Error-rate damping is considered to be better than friction or friction-clutch damping because of which of the following characteristics of the error-rate damping system?

1. A large error signal of short duration will not be damped
2. A small error signal of short duration will not be damped
3. A large change in the error signal causes maximum damping
4. A small change in the error signal causes maximum damping

2-17. Under what condition would a servo system that is properly designed and operating correctly have an oscillating load?

1. The input signal is large in amplitude
2. The input signal oscillates
3. Error-rate damping is used
4. Friction damping is used

2-18. A servo system is found to be "noisy." If the bandwidth of the servo amplifier were adjusted to reject the unwanted noise signals, which of the following characteristics of the servo system would be affected?

1. Amplifier gain
2. Power requirements
3. Correspondence position
4. Error-detection capability

2-19. Which of the following devices can be used as a position sensor in a servo system?

1. A summing network
2. An E-transformer
3. A potentiometer
4. A CT

2-20. Which of the following devices are magnetic error detectors?

1. CXs
2. E-transformers
3. Summing networks
4. All of the above

2-21. A dc rate generator is used in which of the following loops of a velocity servo system?

1. Prime mover
2. Feedback
3. Control
4. Error

2-22. What is the function of a modulator in a servo system?

1. To change the frequency of an ac error signal
2. To impress an ac error signal on an ac carrier
3. To convert a dc error signal to an ac error signal
4. To convert an ac error signal to a dc error signal

2-23. In a servo system that uses a modulator, what characteristic of the modulator output determines the direction of load movement?

1. Amplitude
2. Frequency
3. Polarity
4. Phase

2-24. What phase relationships between the input and reference signals are sensed by a servo demodulator?

1. 0º and 180º
2. 45º and 225º
3. 90º and 270º
4. 135º and 315º

2-25. In a properly operating servo system, what is the phase relationship between the reference voltages to the error detector and the demodulator?

1. In phase only
2. 180º out of phase only
3. Out of phase; somewhere between 0º and 180º
4. In phase or 180º out of phase, depending on the demodulator input

2-26. Which of the following should be a characteristic of a servo amplifier?

1. Narrow frequency band
2. High output impedance
3. 180º phase shift
4. Low noise level

2-27. An ac servo motor would probably be used instead of a dc servo motor in which of the following situations?

1. To move heavy loads at a constant speed
2. To move heavy loads at variable speeds
3. To move light loads at a constant speed
4. To move light loads at variable speeds

2-28. Which of the following circuits that is required in a multispeed servo system is NOT required in a single-speed servo system?

1. Position sensor
2. Error detector
3. Feedback loop
4. Synchronizer

2-29. In a two-speed servo system such as that described in the text, which of the following components controls the movement of the load at 2º but does NOT control the movement of the load at 10º?

1. Fine CT
2. Coarse CT
3. Synchronizer
4. Servoamplifier

2-30. In which of the following situations should a magnetic amplifier be used instead of a conventional amplifier?

1. When a small load is to be driven at high speeds
2. If great accuracy is required in positioning the load
3. If a dual-speed servo system is required
4. When a heavy load is to be moved

2-31. Most servo systems used in the Navy are of which of the following types?

1. Open-loop
2. Multi-loop
3. Single-loop
4. Summing-loop

2-32. Which of the following objects has gyroscopic properties?

1. A spinning top
2. A wheel on a moving bicycle
3. The moving blade assembly of an electric fan
4. Each of the above

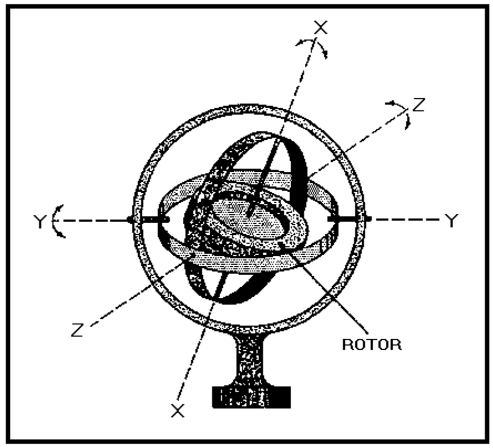


Figure 2A.—Gyro model, universally mounted.

IN ANSWERING QUESTION 2-33, REFER TO FIGURE 2A.

2-33. Which of the following axes, if any, is the gyro spin axis?

1. X-X
2. Y-Y
3. Z-Z
4. None of the above

2-34. The ability of a gyro to maintain a fixed position in space is referred to by what term?

1. Precession
2. Rigidity
3. Apparent rotation
4. Gimbal-stability

2-35. A gyro will resist all forces that attempt to change its

1. location
2. spin axis direction
3. speed of rotation
4. center of gravity

2-36. What action takes place when an outside force attempts to tilt the spin axis of a gyro?

1. The gyro precesses in the direction of the applied force
2. The gyro precesses in a direction opposite to the applied force
3. The gyro precesses in a direction at a right angle to the applied force
4. The gyro remains fixed in its original position

2-37. For a gyro to be universally mounted, it MUST have a total of how many gimbals, if any?

1. One
2. Two
3. Three
4. None

2-38. Of the following factors, which one does NOT affect rigidity?

1. Rotor speed
2. Rotor shape
3. Rotor weight
4. Rotor position

2-39. The forces that act through the center of gravity of a gyro and do NOT cause precession are referred to by what term?

1. Forces of translation
2. Forces of induction
3. Forces of isolation
4. Forces of erection

2-40. Which of the following factors determine(s) the amount of precession that will result from a given applied force?

1. Rotor speed
2. Rotor weight
3. Rotor shape
4. All of the above

2-41. Which of the following factors determine(s) the direction a gyro will precess in response to a particular force?

1. Speed of the rotor's spin
2. Shape of the rotor
3. Direction of the rotor's spin
4. All of the above

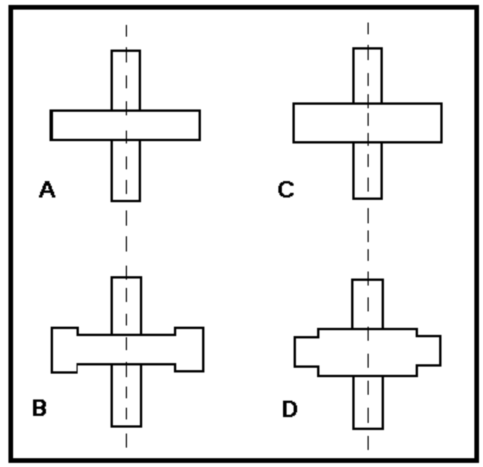

Figure 2B.—Rotors of equal weights but different shapes.

IN ANSWERING QUESTION 2-42, REFER TO FIGURE 2B.

2-42. If all of the rotors are rotated at the same speed, which one will have the greatest rigidity?

1. A
2. B
3. C
4. D

2-43. According to the right-hand rule for gyro precession, what does the thumb indicate?

1. Spin vector and axis
2. Torque vector and axis
3. Precession vector and axis
4. Axis of rotor rotation only

2-44. Which of the following is a universally mounted gyro?

1. A one-degree-of-freedom gyro
2. A two-degrees-of-freedom gyro
3. A restrained gyro
4. A rate gyro

2-45. A free gyro at the Equator appears to tilt. What is the approximate total number of degrees it will tilt in 4 hours?

1. 60º
2. 90º
3. 120º
4. 180º

2-46. Which of the following factors is NOT a cause of mechanical drift?

1. Unbalance
2. Friction
3. Apparent precession
4. Gimbal inertia

2-47. Which of the following is a purpose of a gyro-erection system?

1. To precess the gyro to its operating position
2. To prevent a gyro from precessing once the rotor is up to speed
3. To establish a vertical position to which the gyro position may be compared
4. Each of the above

2-48. Which of the following is an advantage that the mercury ballistic erection system has over the mercury erection system?

1. Greater sensitivity
2. Faster response time
3. Spin axis aligns in any desired position
4. Spin axis aligns north-south

2-49. What is the principal purpose of rate gyros?

1. To serve as gyroscopes
2. To serve as reference elements
3. To measure acceleration
4. To measure angular rates

2-50. In what maximum number of directions is a rate gyro free to precess?

1. One
2. Two
3. Three
4. Four

2-51. The amount of precession of a rate gyro is proportional to what input factor?

1. Rate of gyro case rotation
2. Amount of gyro case rotation
3. Rate of linear displacement
4. Amount of total movement

2-52. The operation of an accelerometer is based on what physical property?

1. Heat
2. Inertia
3. Gravity
4. Precession

2-53. Accelerometers find their greatest use in what type of system?

1. Navigation
2. Communication
3. Weapons control
4. Direction-indicating

2-54. Pulse-counting accelerometers are designed for use only with what type of equipment?

1. Radar sensors
2. Electronic compasses
3. Analog indicators
4. Digital computers

2-55. Which of the following is NOT a difference between IC synchros and standard synchros?

1. Amount of torque available
2. Construction of the stator
3. Construction of the rotor
4. Principle of operation

USE THE FOLLOWING INFORMATION IN ANSWERING QUESTIONS 2-56 AND 2-57. A SYNCHRO SYSTEM USING AN IC TRANSMITTER HAS THE REQUIREMENT THAT THE RECEIVER TURN IN THE OPPOSITE DIRECTION FROM THE TRANSMITTER.

2-56. If an IC receiver were used, what winding of the receiver would be connected to winding R1 of the IC transmitter?

1. R1
2. R3
3. S1
4. S1

2-57. If a standard synchro receiver were used, what winding of the receiver would be connected to winding R3 of the IC transmitter?

1. R1
2. R3
3. S1
4. S3

2-58. Angular data is to be transmitted and dc is the only power available. Which of the following systems should be used?

1. Resolver system
2. IC synchro system
3. Step-transmission system
4. Servo system using a CT and a dc servo motor

2-59. A step-transmission system is to be built in which the steps are to be smaller than the steps in the system shown on page 4-3 of the text. What must be done to the system shown in the text to accomplish this change?

1. Increase the number of coils
2. Decrease the number of coils
3. Increase the supply voltage
4. Decrease the supply voltage

2-60. Which of the following is an advantage that a step-transmission system has over a standard synchro system?

1. Smaller changes in data can be transmitted
2. Transmitted data is "smoother"
3. Synchronizing is not needed
4. Cost is considerably less

2-61. A resolver performs which of the following mathematical functions?

1. Differentiation
2. Trigonometric
3. Integration
4. Algebraic

2-62. Resolvers are used aboard a ship to keep a gun mount steady regardless of the pitch and roll of the ship. What characteristic of the resolver makes it especially useful for this application?

1. Provides instant solutions with constantly changing inputs
2. Provides higher power gain for greater accuracy
3. Uses error-rate damping for smoother solutions
4. Uses ac for greater efficiency

2-63. The (a) rotor and (b) stator of a resolver are best described by which of the following?

1. (a) A single coil
   (b) Three coils, wye-connected
2. (a) Two coils in parallel
   (b) Two coils in series
3. (a) Two coils in series
   (b) Two coils in parallel
4. (a) Two coils at right angles
   (b) Two coils at right angles

PREFACE

By enrolling in this self-study course, you have demonstrated a desire to improve yourself and the Navy. Remember, however, this self-study course is only one part of the total Navy training program. Practical experience, schools, selected reading, and your desire to succeed are also necessary to successfully round out a fully meaningful training program.

COURSE OVERVIEW: To introduce the student to the subject of Test Equipment who needs such a background in accomplishing daily work and/or in preparing for further study.

THE COURSE: This self-study course is organized into subject matter areas, each containing learning objectives to help you determine what you should learn along with text and illustrations to help you understand the information. The subject matter reflects day-to-day requirements and experiences of personnel in the rating or skill area. It also reflects guidance provided by Enlisted Community Managers (ECMs) and other senior personnel, technical references, instructions, etc., and either the occupational or naval standards, which are listed in the *Manual of Navy Enlisted Manpower Personnel Classifications and Occupational Standards,* NAVPERS 18068.

THE QUESTIONS: The questions that appear in this course are designed to help you understand the material in the text.

VALUE: In completing this course, you will improve your military and professional knowledge. Importantly, it can also help you study for the Navy-wide advancement in rate examination. If you are studying and discover a reference in the text to another publication for further information, look it up.

Sailor's Creed

"I am a United States Sailor.

I will support and defend the Constitution of the United States of America and I will obey the orders of those appointed over me.

I represent the fighting spirit of the Navy and those who have gone before me to defend freedom and democracy around the world.

I proudly serve my country's Navy combat team with honor, courage and commitment.

I am committed to excellence and the fair treatment of all."

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

INSTRUCTIONS FOR TAKING THE COURSE

ASSIGNMENTS

The text pages that you are to study are listed at the beginning of each assignment. Study these pages carefully before attempting to answer the questions. Pay close attention to tables and illustrations and read the learning objectives. The learning objectives state what you should be able to do after studying the material. Answering the questions correctly helps you accomplish the objectives.

SELECTING YOUR ANSWERS

Read each question carefully, then select the BEST answer. You may refer freely to the text. The answers must be the result of your own work and decisions. You are prohibited from referring to or copying the answers of others and from giving answers to anyone else taking the course.

SUBMITTING YOUR ASSIGNMENTS

To have your assignments graded, you must be enrolled in the course with the Nonresident Training Course Administration Branch at the Naval Education and Training Professional Development and Technology Center (NETPDTC). Following enrollment, there are two ways of having your assignments graded: (1) use the Internet to submit your assignments as you complete them, or (2) send all the assignments at one time by mail to NETPDTC.

Grading on the Internet: Advantages to Internet grading are:

- you may submit your answers as soon as you complete an assignment, and
- you get your results faster; usually by the next working day (approximately 24 hours).

In addition to receiving grade results for each assignment, you will receive course completion confirmation once you have completed all the assignments. To submit your assignment answers via the Internet, go to:

https://courses.cnet.navy.mil

COMPLETION TIME

Courses must be completed within 12 months from the date of enrollment. This includes time required to resubmit failed assignments.

PASS/FAIL ASSIGNMENT PROCEDURES

If your overall course score is 3.2 or higher, you will pass the course and will not be required to resubmit assignments. Once your assignments have been graded you will receive course completion confirmation.

If you receive less than a 3.2 on any assignment and your overall course score is below 3.2, you will be given the opportunity to resubmit failed assignments. **You may resubmit failed assignments only once.** Internet students will receive notification when they have failed an assignment—they may then resubmit failed assignments on the web site. Internet students may view and print results for failed assignments from the web site. Students who submit by mail will receive a failing result letter and a new answer sheet for resubmission of each failed assignment.

COMPLETION CONFIRMATION

After successfully completing this course, you will receive a letter of completion.

STUDENT FEEDBACK QUESTIONS

We value your suggestions, questions, and criticisms on our courses. If you would like to communicate with us regarding this course, we encourage you, if possible, to use e-mail.

NAVAL RESERVE RETIREMENT CREDIT

If you are a member of the Naval Reserve, you may earn retirement points for successfully completing this course, if authorized under current directives governing retirement of Naval Reserve personnel. For Naval Reserve retirement, this course is evaluated at 5 points. (Refer to *Administrative Procedures for Naval Reservists on Inactive Duty,* BUPERSINST 1001.39, for more information about retirement points.)

THIS PAGE LEFT BLANK INTENTIONALLY.

CHAPTER 1

TEST EQUIPMENT ADMINISTRATION AND USE

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions included are based on the objectives. By successfully completing the NRTC, you indicate that you have met the objectives and have learned the information.

Upon completing this chapter, you should be able to:

1. Describe the Ship Configuration and Logistic Support Information System (SCLSIS).
2. State the differences between calibration and repair.
3. Explain the various calibration status labels used by the Navy.
4. List the procedures for obtaining repairs to test equipment.
5. Describe the Metrology Automated System for Uniform Recall and Reporting (MEASURE) System and the purpose of the Metrology Equipment Recall and Reporting (METER) card and recall schedule.
6. Describe major test equipment references available to you.
7. Explain the purposes and benefits of testing.
8. State the safety precautions involved in working with test equipment.
9. List three precautions you should observe to avoid damaging electric measuring instruments.
10. State the correct procedures for using a safety shorting probe.
11. Describe resistance, voltage, and current measurements in terms of purposes, methods, and instruments used.
12. Describe how capacitance and inductance are measured.
13. Explain the operation of bridges in the measurement of unknown resistances, capacitances, and inductances.

INTRODUCTION

One purpose of this chapter is to acquaint you with the practical use of test equipment. The presence of adequate test equipment in your shop is not in itself a "cure-all" for making repairs to complex electronic equipment. You must know how to best use the equipment available. First, however, you must understand the basis of electronic theory and be able to apply it to the system under repair.

Another purpose of this chapter is to introduce you to calibration and repair procedures, and basic voltage and current measurements. You will also learn how ac bridges are used for precise measurements of resistance, capacitance, and inductance.

Much of the theory of operation and practical applications of the basic types of test instruments used in electrical and electronic circuits are found in the instruction books and technical manuals that accompany various equipments. You should read and understand these books before you attempt to use any test instrument. You should also know the established safety precautions to ensure your safety and safe equipment operating procedures to protect equipment from damage.

TEST EQUIPMENT IDENTIFICATION

One of the first things you must learn as a maintenance technician is how to identify the various electronic equipment and components by their appropriate nomenclatures. You will find that several methods are used to identify test equipment used; this may be somewhat confusing to you at first. For example, a Tektronix Model 541A oscilloscope can also be identified as a CBTV-541A. The Joint Electronics Type Designation System (JETDS) is used by all branches of the military to identify equipment by a system of standardized nomenclatures.

Q-1. What system is currently used by all branches of the military to identify test equipment?

ELECTRONIC TEST EQUIPMENT CLASSIFICATION

The Electronic Test Equipment Classification Board was established in 1973 to control the increased use of undesirable electronic test equipment (ETE) in fleet and shore activities. The board classifies electronic test equipments as GENERAL PURPOSE (GPETE) or SPECIAL PURPOSE (SPETE) and assigns responsibility for their management. Items classified as general purpose are managed by the Space and Warfare Systems Command (SPAWARSYSCOM). Items classified as special purpose are managed by the individual systems command that generates the requirement.

GPETE is test equipment that has the capability, without modification, to generate, modify, or measure a range of parameters of electronic functions required to test two or more equipments or systems of basically different design.

Special-purpose electronic test equipment (SPETE) is specifically designed to generate, modify, or measure a range of parameters of electronic functions of a specific or peculiar nature required to test a single system or equipment. These special test equipments are procured by the systems command that has the responsibility for the system/equipment requiring the SPETE for maintenance.

Q-2. Name the two classes of test equipment.

Q-3. What test equipment is designed to generate, modify, or measure a range of parameters of electronic functions of a specific nature required to test a single system or equipment?

Until the ETE classification board was established, the uncontrolled increase in use of nonstandard GPETE had resulted in loss of inventory control and increased support costs. NESEA has the responsibility for evaluating requests to purchase nonstandard GPETE and for recommending its approval or disapproval to NAVSEA. NAVSEA will then forward its final decision to the originating command for such requests.

SHIP CONFIGURATION AND LOGISTIC INFORMATION SYSTEM (SCLSIS) PROGRAM

The Navy must maintain, update, and calibrate thousands of pieces of equipment. To do this, the SHIP CONFIGURATION AND LOGISTIC SUPPORT INFORMATION SYSTEM (SCLSIS) program was designed to keep track of all installed and portable equipment in the fleet. SCLSIS is used to keep up with the existence, location, and changes made to equipment. The SCLSIS program seeks to improve the quality of equipment reporting, provide information needed by other Navy management systems, and reduce record keeping. It is also designed to assist Navy supply systems that furnish spares, documentation, and training necessary to support installed and portable equipment.

Therefore, the inventory of assigned test equipment on board ship is directly related to SCLSIS records. Properly maintained SCLSIS records also show the complete inventory of test equipment on board by quantity, serial number, and location. The SCLSIS program has two basic elements: (1) VALIDATION, to establish a baseline data inventory, and (2) INVENTORY UPDATING, to correct errors or omissions and to document configuration changes.

Q-4. Name the two basic elements of the SCLSIS program.

CALIBRATION AND REPAIR PROCEDURES

The difference between the terms *calibration* and *repair* needs to be addressed before we proceed further. Calibration is little more than checking, adjusting, or systematically aligning a test instrument to a known standard. To do this, you must ensure that the equipment you send to the calibration lab is in working order.

The calibration lab is where actual repair work becomes important. Obvious problems, such as open power cords, burned components, broken meters, and missing hardware, should be repaired or replaced before sending equipment to the calibration lab. Most calibration labs with which you will deal will be part of an intermediate maintenance activity (IMA) on board a tender.

CALIBRATION STATUS

You can determine the calibration status of any test equipment by checking the calibration label or tag located on the equipment. These calibration labels or tags advise you as to whether the item is usable and within its calibration interval. Tags and labels to be used in the METROLOGY CALIBRATION (METCAL) coordination program are listed in the following paragraphs. No other calibration labels or tags are authorized to be placed on test equipment.

Calibrated Label

The CALIBRATED label, shown in view A of figure 1-1, has black lettering and a white background and comes in two sizes. It is the most commonly used label in the METCAL program. This label indicates that the instrument to which it is attached is within its applicable tolerance on all parameters. If there are any qualifying conditions for use of the instrument, one of the other labels described in the next paragraphs should be used.

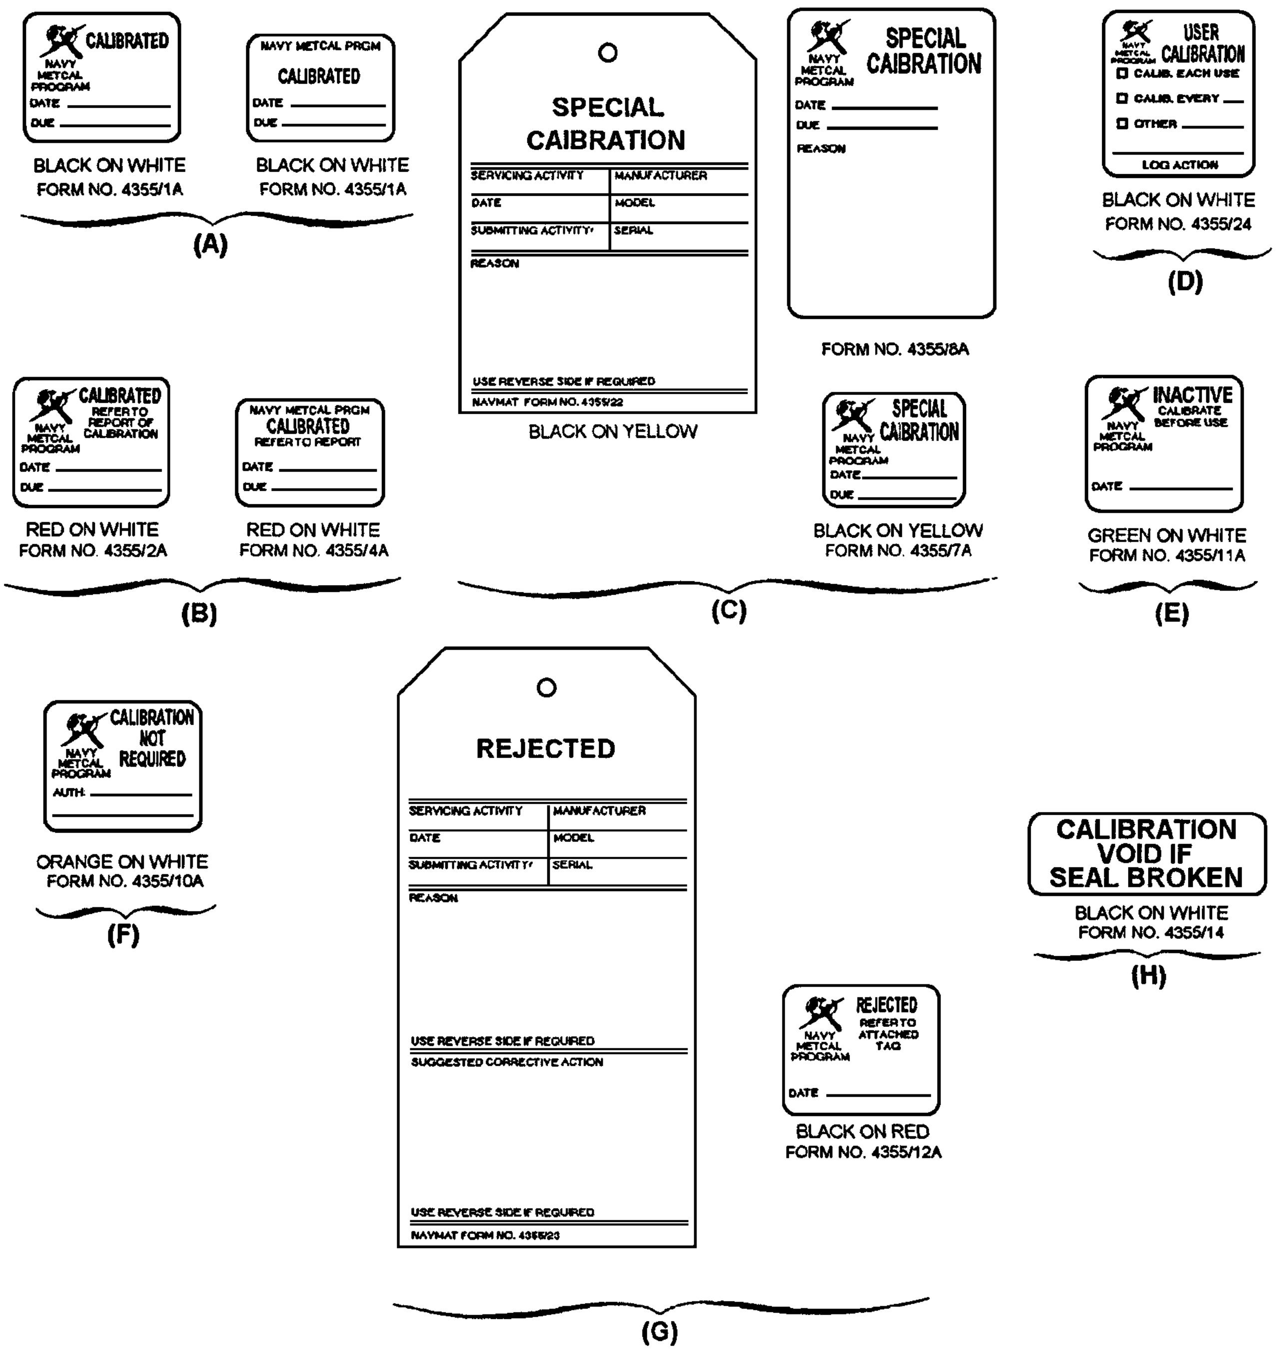

Figure 1-1.—Calibration labels and tags.

Calibrated—Refer to Report Label

The CALIBRATED—REFER TO REPORT label, shown in view B of figure 1-1, has red lettering and a white back ground. It comes in two sizes and is used when you must know the actual measurement values to use the instrument.

Q-5. What calibration label is used when actual measurement values must be known to use the test equipment?

Special Calibration Labels

Two SPECIAL CALIBRATION labels are shown in view C of figure 1-1 that have black lettering and a yellow background; the size and content of the labels are different. A SPECIAL CALIBRATION tag (figure 1-1, view C) is used with the smaller of the two labels. These labels or tag are used when some unusual or special condition in the calibration should be drawn to your attention.

Such special conditions may be deviations from usual calibration tolerances, multiple calibration intervals, or a requirement for in-place calibration. The special condition that resulted in the SPECIAL CALIBRATION label should be described on the large label when sufficient space is available on the instrument or on the tag when the small label is used. Brief descriptions of special conditions are provided in the following paragraphs.

Q-6. An instrument that must be calibrated in place requires what type of calibration label?

In cases where you do not require full instrument capability, the calibration can be performed with reduced tolerances or cover less than all ranges and parameters. This approach is often used when the instrument does not meet full calibration tolerances on certain ranges or parameters, but can still meet user requirements. On the other hand, the special calibration may be for higher accuracy than usual on a short-term basis upon your specific request.

MULTIPLE CALIBRATION INTERVALS.—Some instruments have components that require calibration less frequently than the rest of the instrument. For example, the attenuator in a signal generator may require calibration every 12 months, whereas the rest of the instrument parameters should be calibrated every 4 months. Since the attenuator calibration is time consuming and may require unavailable standards, use of the multiple-interval approach can save considerable time (man-hours) as well as permit the more frequent calibration to be performed at a lower level laboratory.

When a specific instrument has been designed for multiple calibration intervals, such information is provided in the applicable calibration procedure. The SPECIAL CALIBRATION label or tag is annotated with the words MULTIPLE INTERVAL, and the type of calibration performed is indicated; for example, partial 1 of 2, 2 of 2, complete calibration, and so forth. The calibration due date reflects the due date of the next partial or complete calibration.

CALIBRATION IN-PLACE.—Some instruments should be calibrated in-place. Annotation on the SPECIAL CALIBRATION label or tag will alert both you and the calibrator that the instrument should not be removed, but should be calibrated in-place.

User Calibration Label

Some test and measuring equipment (T&ME) should be calibrated by you instead of your referring the instrument to a calibration facility. For example, some instruments, such as hardness testers and densitometers, are provided with their own standards and should be calibrated each time used, or at least very frequently. Some instruments, such as oscillographic recorders, may require calibration before, during, and after each use.

Other automatic test equipment (ATE) have self-calibration tests that should be performed each time used or each day of use. Still other instruments are calibrated as part of checkout procedures performed daily or weekly and recorded in maintenance logs. Whenever recognized, the requirement for calibration by the user and the calibration interval (each use—daily, weekly, every 100 hours—each overhaul, and so forth) is indicated in the Metrology Requirements List (METRL).

The USER CALIBRATION label, shown in view D of figure 1-1, has black lettering and a white background and is affixed when the calibration is performed by the user; however, this label is not replaced at each calibration. When the label is first attached to the instrument, it is annotated as to the appropriate calibration interval. Records of calibrations performed, when other than each time used, should be by normal maintenance practices; that is, in the maintenance log, on maintenance action forms, and so forth.

Inactive—Calibrate Before Use Label

In the event that an individual instrument due for recalibration will not be used for some time in the future, you may indefinitely postpone the recalibration by affixing an inactive label to the instrument. As shown in view E of figure 1-1, the INACTIVE—CALIBRATE BEFORE USE label has green lettering and a white background. The INACTIVE label remains on the instrument until it is recalibrated. The instrument is not to be used while bearing this label.

Calibration Not Required Label

Test equipment standards and T&ME not requiring calibration are shown as CALIBRATION NOT REQUIRED. This label, shown in view F of figure 1-1, has orange letters and a white background. It is attached to and should remain on the instrument indefinitely unless its calibration requirements change. If the instrument is not listed in METRL, you should use the following criteria when placing instruments in the CALIBRATION NOT REQUIRED category:

- Instrument does not make quantitative measurements nor provide quantified outputs.
- The device is "fail-safe"; that is, operation beyond specified tolerances will be apparent to the user.
- All measurement/stimulus circuits are monitored during use by calibrated instruments or are dependent on external known or calibrated sources for performance within required limits. (When determining that an instrument falls into the CALIBRATION NOT REQUIRED category, you should annotate the label as to the authority for the decision, such as METRL, technical manual, letter or message from higher authority.)

Rejected—refer To Attached Tag Label

In the event that an instrument fails to meet the acceptance criteria during calibration and cannot be adequately repaired, a REJECTED—REFER TO ATTACHED TAG label is placed on the instrument and all other servicing labels removed. This label, as shown in view G of figure 1-1, has black letters and a red background. In addition to the REJECTED label, a REJECTED tag, giving the reason for rejection and other information as required, is attached to the instrument. Both the label and tag remain on the instrument until it is repaired and recalibrated. The instrument is not to be used while bearing a REJECTED label.

Calibration Void If Seal Broken Label

The CALIBRATION VOID IF SEAL BROKEN label, shown in view H of figure 1-1, has black letters and a white background. It is placed over readily accessible (usually exterior) adjustments to prevent tampering by the user when such tampering could affect the calibration. The label should not be used to cover adjustments or controls that are part of the normal use and operation of the instrument. This label may also be used to prevent removal and/or interchange of plug-ins, modules, subassemblies, and so forth, when such removal or interchange would affect the calibration.

REPAIR PROCEDURES

If you are unable to replace a known failed component with onboard spares, you can often locate the replacement component from other supply sources. The replacement component can then be delivered, along with the inoperative equipment, to the IMA. So by sending the repair part along with the equipment, you can reduce repair time considerably. This is particularly true when your unit is getting under way and no time is available for you to complete the repair before calibration. Most operational commands have a higher supply priority for purchase of repair parts than the IMA can use.

"No Reject" Policy

IMAs have a "no reject" policy on test equipment to provide operational test equipment in a more timely manner. The "no reject" policy says, in effect, that test equipment submitted to the IMA for calibration, which is later found to require repair, will be repaired by the repair department of the IMA. Before this policy, any equipment found inoperative by the calibration lab was marked REJECTED, the reasons stated, and the equipment returned uncalibrated to the ship for repairs. The "no reject" policy does not relieve you of your responsibility to ensure your equipment is in working order prior to submitting it for calibration. Its purpose is to streamline the procedure and cut down delays in returning your equipment to you calibrated and ready to use.

Responsibility for Repair and Maintenance of Test Equipment

Generally, the responsibility for repair and maintenance of test equipment is placed on maintenance personnel. In some cases, however, maintenance personnel are not authorized to make repairs. Then the test instrument must be sent to a shore repair/calibration facility.

Q-7. Responsibility for repair and maintenance of test equipment generally rests with what group of personnel?

When test equipment is sent for calibration and repair, all accessories, such as probes, adapters, and calibration sheets, should be included. Only in emergencies or special situations should partial repair or calibration be attempted on test equipment designated as nonrepairable. Such emergency repairs should be noted on a tag attached to the unit and an entry made on the MEASURE card (discussed shortly). The equipment should then be sent at the earliest opportunity to an authorized facility so that permanent repairs can be made and the unit calibrated.

STOWAGE AND HANDLING OF TEST EQUIPMENT

Most electronic test equipment is precision equipment. Such equipment must be handled with care to properly perform its designed functions. Rough handling, excessive heat, moisture, and dust all affect the useful life of the equipment. Bumping or dropping a test instrument may ruin the calibration of a meter, cause short circuits, or damage electronic elements inside the case. Sharp bends, creases, or dents in coaxial test cables can alter the expected attenuating effect and cause false meter readings or measurements. Forced air cooling, dust filters, and heaters are used in many pieces of equipment. This test equipment requires clean air filters for proper ventilation and a warm-up period that permits units in the equipment to maintain calibrated standards.

Electronic test equipment should be stowed in a dry location with the dust cover (if provided) in place. Dust covers for spare plug-in units should be constructed for such stowage. For ease in performing maintenance, the test equipment should be stowed at a location convenient to equipment spaces. If possible, related test equipment should be mounted in the equipment spaces. This reduces the problem of finding adequate stowage space elsewhere.

In stowage spaces, individual pieces of test equipment should be held in place by stretch seat-belt-type straps. If bars are used to hold equipment on shelves, meters and control knobs should be protected by blocking the equipment to prevent it from rolling and sliding on the shelf. Test equipment too large for shelf stowage should be kept in stowage cases and tie-downs provided to secure the cases. Refer to *Stowage Guide for Portable Test Equipment*, NAVSEA ST000-AB-GYD-010/GPETE, to determine adequate stowage space and proper weight support requirements.

THE METROLOGY AUTOMATED SYSTEM FOR UNIFORM RECALL AND REPORTING (MEASURE)

For the sake of simplicity, we will use the more commonly used acronym MEASURE instead of the full name to describe this system in the next discussion.

MEASURE is a data processing system designed to provide a standardized system for the recall and scheduling of test, measurement, and diagnostic equipment (TMDE) into calibration facilities. It also provides for the documentation of data pertaining to the calibration actions performed by these facilities.

The primary reference document that describes the operation of the MEASURE system is *Metrology Automated System for Uniform Recall and Reporting (MEASURE) Users Manual*, OP 43P6A. The Chief of Naval Operations oversees this program and establishes policy and guidelines.

Q-8. What Navy office oversees the MEASURE program?

Each naval activity must ensure that the test equipment for which it has been assigned primary responsibility is submitted on a timely basis to a calibration activity for required calibration.

The MEASURE program is designed to assist these naval activities in the fulfillment of this responsibility. MEASURE does this by providing for the automatic scheduling and recall of all such test equipment for calibration.

Each activity submits an initial inventory, using the form shown in figure 1-2, to its Metrology Calibration Representative (METCALREP) for approval. The METCALREP then forwards the inventory to the Measure Operational Control Center (MOCC). The MOCC, based on the information contained on these inventory report forms, provides the necessary preprinted Metrology Equipment Recall and Reporting (METER) card. Figure 1-3 illustrates a MEASURE METER card.

Figure 1-2.—MEASURE TMDF Inventory report form.

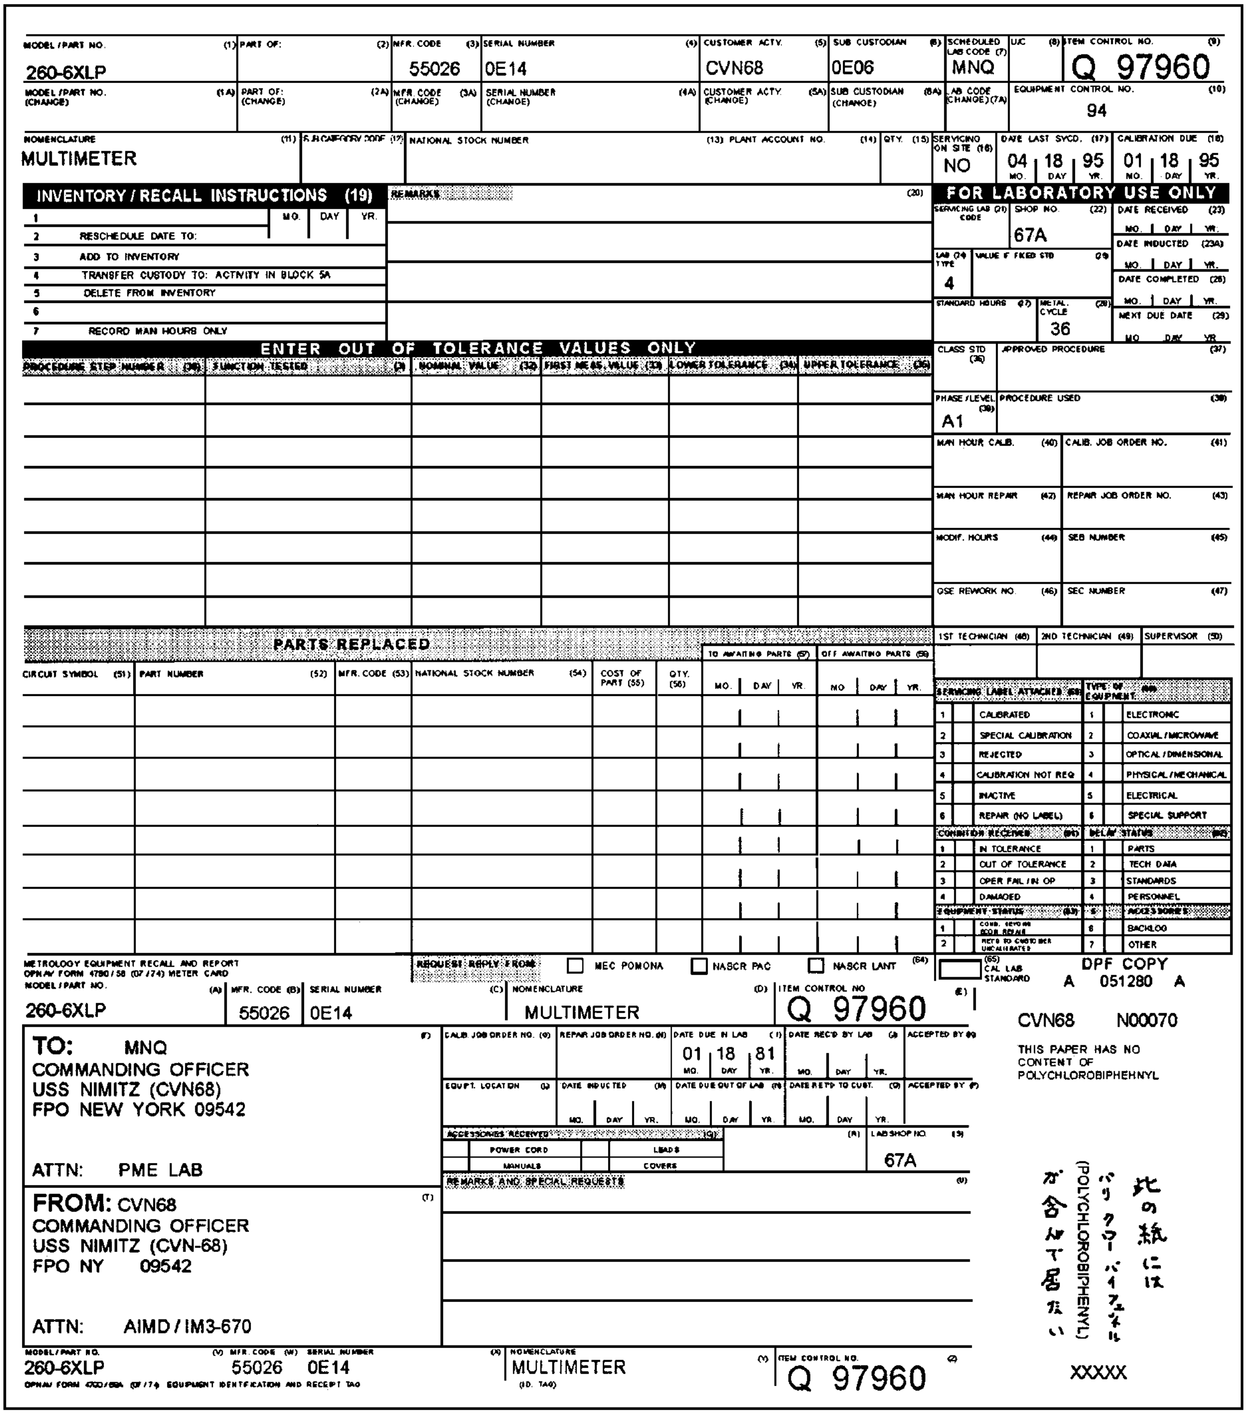

Figure 1-3.—MEASURE METER card.

In part, the METER card is preprinted with information taken from the initial inventory data submitted on the inventory report forms together with such updated data as may appear on any prior METER card. The remaining information required is entered on the card by the user of the equipment or the calibration activity, as appropriate.

The METER card is used to report changes, additions, or deletions to the user activity's inventory. It is also used to report changes in custody of the item of test equipment. The procedure for filling out the METER card is outlined in the appendixes of the *MEASURE Users Manual*. Blank METER cards can be obtained through the responsible METCALREP.

A computer printout recall schedule is also generated by the MEASURE system. The purpose of this printout is to list those items of equipment that are due for calibration. Each recall schedule is composed of a set of four identical copies. One set is provided to the calibration activity as an aid to workload planning; a second set is sent to the user's activity. The recall schedule is one of several products/formats sent automatically by the MEASURE Operation Control Center to the user activity on a regular basis. The MOCC automatically distributes the following products to user activities at the intervals shown:

DOCUMENT TITLE	TYPE DOCUMENT	INTERVAL
Format 215	Unmatched listing	As required
Format 310	Test equipment inventory	Monthly
Format 350	Test equipment inventory in sub-custodian order	Monthly
Format 804	Recall schedule for on-site equipment	Monthly/Quarterly
Replenishment cards	Preprinted METER card	As required
Blank METER cards		Initial issue

TEST EQUIPMENT REFERENCES

Several publications that contain information concerning test equipment are required to be maintained aboard ship by type commander instructions. These requirements are usually found in the inspection checkoff list. Other publications, while not required by directive, are necessary to you as reference and study material so you will be able to administer an effective test equipment program. Technicians should become familiar with the publications/directives listed in appendix II of this module.

INTRODUCTION TO TROUBLESHOOTING

Our military forces increasingly rely on electrical and electronic equipment to help perform their mission. The effectiveness of our tactical forces depends on many types of electronic systems, such as communications systems, detection systems, and fire control systems. The reliability of such equipment is determined by many factors; however, the primary factors are the quality of the equipment in use, the availability of spare parts, and the ability of maintenance personnel to perform adequate maintenance.

Maintenance is work done to correct, reduce, or counteract wear, failure, and damage to equipment. Maintenance of electrical and electronic equipment is divided into two main categories: PREVENTIVE (routine) and CORRECTIVE maintenance. Preventive maintenance consists of mechanical, electrical, and electronic checks to determine whether equipment is operating properly. It also consists of visual inspections of cabling and equipment for damage and to determine if lubrication is needed. Corrective maintenance isolates equipment failure by means of test techniques and practices; it also replaces defective parts and realigns or readjusts equipment to bring it back to proper performance.

Q-9. What are the two main categories of maintenance?

Q-10. What type of maintenance involves isolating equipment troubles and replacing defective parts?

Testing and troubleshooting are the areas of maintenance that require the greatest technical skill. Testing procedures are referred to as **measurements**, **tests**, and **checks**. The definitions of these terms often overlap, depending on their use and the results obtained. For example, a power measurement and a frequency check could constitute a test of the operation of the same radio transmitter.

Troubleshooting is a term which we in the electronics field use daily. But what does it mean? Troubleshooting is sometimes thought to be the simple repair of a piece of equipment when it fails to function properly. This, however, is only part of the picture. In addition to repair, you, as a troubleshooter, must be able to evaluate equipment performance. You evaluate performance by comparing your knowledge of how the equipment should operate with the way it is actually performing. You must evaluate equipment both before and after repairs are accomplished.

Equipment performance data, along with other general information for various electronic equipments, is available to help you in making comparisons. This information is provided in performance standards books for each piece of equipment. It illustrates what a particular waveform should look like at a given test point or what amplitude a voltage should be, and so forth. This data aids you in making intelligent comparisons of current and baseline operating characteristics for the specific equipment assigned to you for maintenance. ("Baseline" refers to the initial operating conditions of the equipment on installation or after overhaul when it is operating according to design.)

Remember, *maintenance* refers to all actions you perform on equipment to retain it in a serviceable condition or to restore it to proper operation. This involves inspecting, testing, servicing, repairing, rebuilding, and so forth. Proper maintenance can be performed only by trained personnel who are thoroughly familiar with the equipment. This familiarity requires a thorough knowledge of the theory of operation of the equipment.

A logical and systematic approach to troubleshooting is of the utmost importance in your performance of electronics maintenance. Many hours have been lost because of time-consuming "hit-or-miss" (often referred to as "easter-egging") methods of troubleshooting.

GENERAL TEST EQUIPMENT INFORMATION

In any maintenance training program, one of your most important tasks is to learn the use of test equipment in all types of maintenance work. To be effective in maintenance work, you must become familiar not only with the common types of measuring instruments, but also with the more specialized equipment. Some examples of common types of typical measuring instruments are the ammeter, voltmeter, and ohmmeter; examples of specialized test equipment are the spectrum analyzer, dual-trace oscilloscope, and power and frequency meters.

TEST EQUIPMENT SAFETY PRECAUTIONS

The electrical measuring instruments included in test equipment are delicately constructed and require certain handling precautions to prevent damage and to ensure accurate readings. In addition, to prevent injury to personnel, you must observe precautions while using test equipment. You can find a list of applicable instructions in appendix II of this module.

Instrument Precautions

To prevent damage to electrical measuring instruments, you should observe the precautions relating to three hazards: mechanical shock, exposure to magnetic fields, and excessive current flow.

MECHANICAL SHOCK.—Instruments contain permanent magnets, meters, and other components that are sensitive to shock. Heavy vibrations or severe shock can cause these instruments to lose their calibration accuracy.

EXPOSURE TO STRONG MAGNETIC FIELDS.—Strong magnetic fields may permanently impair the accuracy of a test instrument. These fields may impress permanent magnetic effects on permanent magnets, moving-coil instruments, iron parts of moving-iron instruments, or in the magnetic materials used to shield instruments.

EXCESSIVE CURRENT FLOW.—This includes various precautions, depending on the type of instrument. When in doubt, use the maximum range scale on the first measurement and shift to lower range scales only after you verify that the reading can be made on a lower range. If possible, connections should be made while the circuit is de-energized. All connections should be checked to ensure that the instrument will not be overloaded before the circuit is reenergized.

Other Instrument Precautions

Precautions to be observed to prevent instrument damage include the following:

- Keep in mind that the coils of wattmeters, frequency meters, and power meters may be carrying large quantities of current even when the meter pointer is on scale.
- Never open secondaries of current transformers when the primary is energized.
- Never short-circuit secondaries of potential transformers the primary is energized.
- Never leave an instrument connected with its pointer off-scale or deflected in the wrong direction.
- Ensure that meters in motor circuits can handle the motor starting current. This may be as high as six to eight times the normal running current.
- Never attempt to measure the internal resistance of a meter movement with an ohmmeter since the movement may be damaged by the current output from the ohmmeter.
- Never advance the intensity control of an oscilloscope to a position that causes an excessively bright spot on the screen; never permit a sharply focused spot to remain stationary for any period of time. This results in burn spots on the face of the cathode-ray tube (CRT).
- In checking electron tubes with a tube tester that has a separate "short test," always make the short test first. If the tube is shorted, no further test should be made.
- Before measuring resistance, always discharge any capacitors in the circuit to be tested. Note and record any points not having bleeder resistors or discharge paths for capacitors.
- Always disconnect voltmeters from field generating or other highly inductive circuits before you open the circuit.

Q-11. Which quantity (voltage or current) determines the intensity of an electrical shock?

Situations can arise during the use of test equipment that are extremely dangerous to personnel. For example, you may have an oscilloscope plugged into one receptacle, an electronic meter plugged into another, and a soldering iron in still another. Also, you may be using an extension cord for some equipments and not others or may be using other possible combinations. Some of the hazards presented by situations such as these include contact with live terminals or test leads. In addition, cords and test leads may be cross connected in such a manner that a potential difference exists between the metal cases of the instruments. This potential difference may cause serious or fatal shocks.

Test leads attached to test equipment should, if possible, extend from the back of the instruments away from the observer. If this is not possible, they should be clamped to the bench or table near the instruments.

At times, you may use instruments at locations where vibration is present, such as near a diesel engine. At such times, the instruments should be placed on pads of folded cloth, felt, or similar shock-absorbing material.

WORKING ON ENERGIZED CIRCUITS

Insofar as is practical, you should NOT undertake repair work on energized circuits and equipment. However, it could become necessary, such as when you make adjustments on operating equipment. In such cases, obtain permission from your supervisor, then proceed with your work, but carefully observe the following safety precautions:

- DO NOT WORK ALONE.
- Station an assistant near the main switch or circuit breaker so the equipment can be immediately de-energized in case of an emergency.
- Someone qualified in first aid for electrical shock should be standing by during the entire operation.
- Ensure that you have adequate lighting. You must be able to see clearly if you are to perform the job safely and properly.
- Be sure that you are insulated from ground by an approved rubber mat or layers of dry canvas and/or wood.
- Where practical, use only one hand, keeping the other either behind you or in your pocket.
- If you expect voltage to exceed 150 volts, wear rubber gloves.
- DO NOT work on any type of electrical apparatus when you are wearing wet clothing or if your hands are wet.
- DO NOT wear loose or flapping clothing.
- The use of thin-soled shoes and shoes with metal plates or hobnails is prohibited.
- Flammable articles, such as celluloid cap visors, should not be worn.

- Remove all rings, wristwatches, bracelets, and similar metal items before working on the equipment. Also ensure that your clothing does not contain exposed metal fasteners, such as zippers, snaps, buttons, and pins.

- Do not tamper with interlock switches; that is, do not defeat their purpose by shorting them or blocking them open.

- Ensure that equipment is properly grounded before energizing.

- De-energize equipment before attaching alligator clips to any circuit.

- Use only approved meters and other indicating devices to check for the presence of voltage.

- Observe the following procedures when measuring voltages in excess of 300 volts:

  - Turn off the equipment power.

  - Short-circuit or ground the terminals of all components capable of retaining a charge.

  - Connect the meter leads to the points to be measured.

  - Remove any terminal grounds previously connected.

  - Turn on the power and observe the voltage reading.

  - Turn off the power.

  - Short circuit or ground all components capable of retaining a charge.

  - Disconnect the meter leads.

- On all circuits where the voltage is in excess of 30 volts and where decks, bulkheads, or workbenches are made of metal, you should insulate yourself from accidental grounding by using approved insulating material. The insulating material should have the following qualities:

  - It should be dry, without holes, and should not contain conducting materials.

  - The voltage rating for which it is made should be clearly marked on the material. The proper material should be used so that adequate protection from the voltage can be supplied.

  - Dry wood may be used or, as an alternative, several layers of dry canvas, sheets of phenolic (resin or plastic) insulating material, or suitable rubber mats.

  - Care should be exercised to ensure that moisture, dust, metal chips, and so forth, which may collect on insulating material, are removed at once. Small deposits of such materials can become electrical hazards.

  - All insulating materials on machinery and in the area should be kept free of oil, grease, carbon dust, and so forth, since such deposits destroy insulation.

SAFETY SHORTING PROBE

A representative shorting probe is shown in figure 1-4. An approved shorting probe is shown in NAVSEA 0967-LP-000-0100, EIMB, *General*, Section 3.

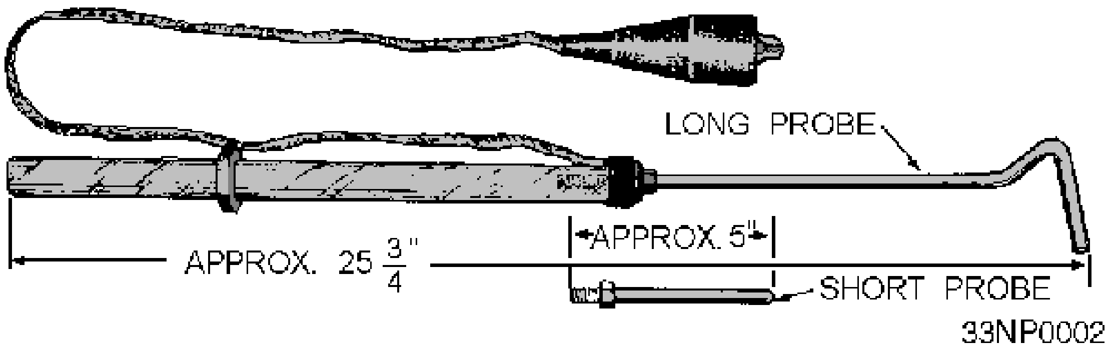

Figure 1-4.—Representative safety shorting probe.

CAUTION

Capacitors and cathode-ray tubes may retain their charge for a considerable period of time after having been disconnected from the power source.

Always assume there is a voltage present when working with circuits having high capacitance, even when the circuit has been disconnected from its power source.

An approved type of shorting probe should be used to discharge capacitors and cathode-ray tubes individually.

When using the safety shorting probe, always be sure to first connect the test clip to a good ground (if necessary, scrape the paint off the grounding metal to make a good contact). Then hold the safety shorting probe by the insulated handle and touch the probe end of the shorting rod to the point to be shorted out. The probe end is fashioned so that it can be hooked over the part or terminal to provide a constant connection by the weight of the handle alone. Always take care not to touch any of the metal parts of the safety shorting probe while touching the probe to the exposed "hot" terminal. It pays to be safe; use the safety shorting probe with care.

Some equipments are provided with walk-around shorting devices, such as fixed grounding studs or permanently attached grounding rods. When that is the case, the walk-around shorting devices should be used rather than the safety shorting probe.

Q-12. What tool is used to de-energize capacitors in a circuit that has been disconnected from its power source?

WORKING ON DE-ENERGIZED CIRCUITS

When any electronic equipment is to be repaired or overhauled, certain general safety precautions should be observed. They are as follows:

- Remember that electrical and electronic circuits often have more than one source of power. Take time to study the schematics or wiring diagrams of the entire system to ensure that all sources of power have been disconnected

- If pertinent, inform the remote station regarding the circuit on which work will be performed.

- Use one hand when turning switches on or off.

- Safety devices, such as interlocks, overload relays, and fuses, should never be altered or disconnected except for replacement. In addition, they should never be changed or modified in any way without specific authorization.

- Fuses should be removed and replaced only after the circuit has been de-energized. When a fuse "blows," the replacement should be of the same type and have the same current and voltage ratings. A fuse puller should be used to remove and replace cartridge fuses.

- All circuit breakers and switches from which power could possibly be supplied should be secured (locked if possible) in the OPEN or OFF (safe) position and danger tagged in accordance with procedures in the *Standard Organization and Regulations of the U.S. Navy*, OPNAVINST 3120.32.

- After the work has been completed, the tag (or tags) should be removed **only** by the same person who signed it (them) when the work began.

- Keep clothing, hands, and feet dry if at all possible. When you must work in wet or damp locations, place a rubber mat or other nonconductive material on top of a dry, wooden platform or stool; then use the platform or stool to sit and stand on. Use insulated tools and insulated flashlights of the molded type when you are required to work on exposed parts.

GROUNDING OF POWER TOOLS AND EQUIPMENT

The possibility of electrical shock can be reduced by ensuring that all motor and generator frames, metal bases, and other structural parts of electrical and electronic equipment are at ground potential.

Normally, on steel-hull vessels, such grounds are inherently provided because the metal cases or frames of the equipment are in contact with one another and with the metal structure of the vessel. In some instances where such inherent grounding is not provided by the mounting arrangements, such as equipment supported on shock mounts, suitable ground connections must be provided.

The grounding wire used for this purpose is generally made of flexible material (copper or aluminum) that provides sufficient current-carrying capacity to ensure an effective ground. In this manner, equipment cases and frames that are not intended to be above ground potential are effectively grounded; also, the possibility of electrical shock to personnel coming in contact with metal parts of the equipment is minimized. The secondary purpose of grounding equipment is to improve the operation and continuity of service of all equipments.

Paint, grease, or other foreign matter can interfere with the positive metal-to-metal contact at the ground connection point. Therefore, all bonding surfaces (connection points or metallic junctions) must be securely fastened and free of such matter. In all instances where equipment grounding is provided, certain general precautions and preventive maintenance measures must be taken. A few of these precautions are listed below:

- Periodically clean all strap-and-clamp connectors to ensure that all direct metal-to-metal contacts are free from foreign matter.

- Check all mounting hardware for mechanical failure or loose connections.

- Replace any faulty, rusted, or otherwise unfit grounding strap, clamp, connection, or component between the equipment and the ground to the ship's hull.

- When replacing a part of the ground connection, make certain that the metallic contact surfaces are clean and that electrical continuity is re-established.

- After completing the foregoing steps, recheck to be sure that the connection is securely fastened with the correct mounting hardware. Paint the ground strap and hardware in accordance with current procedures.

Because of the electrical shock hazards that could be encountered aboard ship, plugs and convenience outlets for use with portable equipment and power tools normally are standard three-prong type. Both plugs and outlets are keyed so that the plug must be in the correct position before it can be inserted into the receptacle. To ensure that the safety factors incorporated in these devices are in serviceable condition and are safe for use, you must perform the following precautions and inspections:

- Inspect the pins of the plug to see that they are firmly in place and are not bent or damaged.

- Check the wiring terminals and connections of the plug. Loose connections and frayed wires on the plug surface must be corrected and any foreign matter removed before the plug is inserted into the receptacle.

- Use a meter to ensure that the ground pin has a resistance of less than 1 ohm equipment ground.

- Do not attempt to insert a grounded-type plug into a grounded receptacle without first aligning the plug properly.

CAUTION

Never use a power tool or a piece of portable test equipment unless you are absolutely sure that it is equipped with a properly grounded conductor.

BASIC MEASUREMENTS

Electronic measurements involve the fundamental electrical quantities of voltage and current and the inherent characteristics of resistance, capacitance, and inductance. In circuits being tested, voltage and current are dependent upon resistance, capacitance, and inductance for their distribution; therefore, voltage and current measurements are valuable aids in determining circuit component conditions and in the evaluation of symptoms. Practically any reading obtained from the use of test equipment will depend on these basic measured quantities of resistance, capacitance, and inductance.

VOLTAGE AND CURRENT MEASUREMENTS

Voltage measurements may be made as part of either preventive or corrective maintenance. These measurements are made using a voltmeter. When compared with voltage charts, these measurements are a valuable aid in locating a trouble quickly and easily. However, if the sensitivity of the test voltmeter differs from that of the voltmeter used in preparing the chart, the voltage measurements must be evaluated before the true circuit conditions can be determined. (Sensitivity in voltmeters was discussed in NEETS, Module 3, *Introduction to Circuit Protection, Control, and Measurement*.)

Since many of the troubles you find in equipments and systems are the result of abnormal voltages, voltage measurements are a valuable aid in locating trouble. You can measure voltage with a voltmeter without interrupting circuit operation.

Point-to-point voltage measurement charts, usually found in equipment technical manuals, contain the normal operating voltages found in the various stages of the equipment. These voltages are usually measured between indicated points and ground unless otherwise stated. When you begin recording voltage measurements, it is a smart and safe practice to set the voltmeter on the highest range before measuring. This ensures that excessive voltages existing in the circuit will not cause overloading of the meter.

Q-13. On what range should you set the voltmeter prior to taking a voltage measurement?

To increase accuracy, you should then set the voltmeter to the appropriate range for the proper comparison with the expected voltage in the voltage charts. When checking voltages, remember that a voltage reading can be obtained across a resistance, even if that resistance is open. The resistance of the meter itself forms a circuit resistance when the meter probes are placed across the open resistance. Therefore, the voltage across the component may appear to be normal or near-normal as you read the meter, but may actually be abnormal when the meter is disconnected from the circuit.

If the internal resistance of the voltmeter is approximately the same value as the resistance being tested, it will indicate a considerably lower voltage than the actual voltage present when the meter is removed from the circuit. The sensitivity (in ohms per volt) of the voltmeter used to prepare the voltage charts is provided on those charts. If a meter of similar sensitivity is available, you should use it to reduce the effects of loading.

The following precautions are general safety measures that apply to the measurement of voltages. Remember that nearly all voltages are dangerous and have often proved fatal to careless technicians. When measuring voltages, be sure to observe the following precautions:

- Set test equipment to the HIGHEST range.
- Make sure safety observer knows where to secure power for the equipment under test.
- Connect the ground lead of the voltmeter first.
- Use only one hand to take measurements (when possible), and put the other hand in your pocket or behind your back.
- If the voltage to be measured is less than 300 volts, place the end of the test probe on the point to be tested; use the polarity switch to select positive or negative readings.

- If the voltage to be measured is more than 300 volts, proceed as follows:

  1. Shut off circuit power.
  2. Discharge all filter capacitors with a shorting probe.
  3. Temporarily ground the point to be measured.
  4. Connect (clip on) the proper test lead to the high-voltage point.
  5. Move away from the voltmeter.
  6. Turn on circuit power and read the voltmeter.
  7. Turn off circuit power.
  8. Discharge all capacitors before disconnecting the meter.

Q-14. When taking a voltage measurement, which lead of the voltmeter should you connect to the circuit first?

Current measurements are not often taken in the course of preventive maintenance or testing. This is because the ammeter (or other current-measuring instrument) must become an actual part of the equipment being tested. The circuit must be opened (desoldered) to connect the ammeter in series with the circuit being tested. Usually, you can take a voltage measurement and use this factor to calculate the circuit current by applying Ohm's law.

Q-15. Is an ammeter connected in series or in parallel with the circuit under test?

RESISTANCE MEASUREMENTS

Resistance measurements are a valuable aid to you in locating defective circuits and components during corrective maintenance. Maintenance handbooks for the equipment can often be used to help you take these measurements. These handbooks often contain resistance charts that are referenced to accessible test points within the equipment. Without these charts, taking resistance measurements in a complex circuit is a slow process. The process is slow because one side of the circuit component must often be desoldered to get a true resistance measurement. However, resistance tolerances vary so widely that approximate resistance readings are adequate for most jobs.

Once the most accessible test point is found, an ohmmeter is usually used to take the resistance measurement. Because of the degree of accuracy needed when an ohmmeter is used, proper calibration and understanding of the meter scales is a must. (Topic 2 of this module will discuss these requirements in detail.) When using an ohmmeter, you must observe the following precautions:

- The circuit being tested must be completely de-energized.

- Any meters or transistors which can be damaged by the ohmmeter current must be removed before any measurement is made.

Q-16. What must be done to a circuit before you can use an ohmmeter for testing?

CAPACITANCE MEASUREMENTS

Capacitance measurements are usually taken with a capacitance meter. Capacitance tolerances vary even more widely than resistance tolerances. Capacitance tolerances depend on the type of capacitor, the value of capacitance, and the voltage rating. The actual measurement of capacitance is very simple; however, you must make the important decision of whether to reject or to continue to use the capacitor after it has been tested.

The POWER FACTOR of a capacitor is important because it is an indication of the various losses of a capacitor. Power losses can be traced to the dielectric, such as current leakage and dielectric absorption. Current leakage is of considerable importance, especially in electrolytic capacitors.

Q-17. What is the term used to refer to the losses which can be traced to the dielectric of a capacitor?

INDUCTANCE MEASUREMENTS

Inductance measurements are seldom required in the course of troubleshooting. However, inductance measurements are useful in some cases; therefore, bridges (discussed in the next section) are available for making this test. You will find that many capacitance test sets can be used to measure inductance. Most capacitance test sets are furnished with inductance conversion charts if the test equipment scale is not calibrated to read the value of inductance directly.

CAPACITANCE, INDUCTANCE, AND RESISTANCE BRIDGES

You can measure capacitance, inductance, and resistance for precise accuracy by using ac bridges. These bridges are composed of capacitors, inductors, and resistors in a wide variety of combinations. These bridges are operated on the principle of a dc bridge called a WHEATSTONE BRIDGE.

Wheatstone Bridge

The Wheatstone bridge is widely used for precision measurements of resistance. The circuit diagram for a Wheatstone bridge is shown in figure 1-5. Resistors R1, R2, and R3 are precision, variable resistors. The value of R_x is an unknown value of resistance that must be determined. After the bridge has been properly balanced (galvanometer G reads zero), the unknown resistance may be determined by means of a simple formula. The galvanometer (an instrument that measures small amounts of current) is inserted across terminals **b** and **d** to indicate the condition of balance. When the bridge is properly balanced, no difference in potential exists across terminals **b** and **d**; when switch S2 is closed, the galvanometer reading is zero.

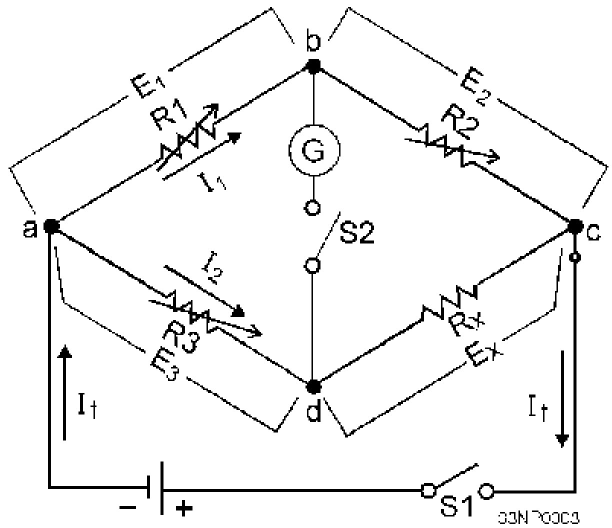

Figure 1-5.—Wheatstone bridge.

The operation of the bridge is explained in a few logical steps. When the battery switch S1 is closed, electrons flow from the negative terminal of the battery to point **a**. Here the current divides as it would in any parallel circuit. Part of it passes through R1 and R2; the remainder passes through R3 and R_x. The two currents, I_1 and I_2, unite at point **c** and return to the positive terminal of the battery. The value of I_1 depends on the sum of resistance R1 and R2, and the value of I_2 depends on the sum of resistances R3 and R_x. In each case, according to Ohm's law, the current is inversely proportional to the resistance.

R1, R2, and R3 are adjusted so that when S1 is closed, no current flows through **G**. When the galvanometer shows no deflection, there is no difference of potential between points **b** and **d**. All of I_1 follows the **a b c** path and all I_2 follows the **a b c** path. This means that a voltage drop E_1 (across R1 between points **a** and **b**) is the same as voltage drop E_3 (across R3 between points a and d). Similarly, the voltage drops across R2 and R_x (E_2 and E_x) are also equal. Expressed algebraically,

$$E_1 = E_3$$
$$I_1R1 = I_2R3$$

and

$$E_2 = E_X$$
$$I_1R2 = I_2R_X$$

With this information, we can figure the value of the unknown resistor R_x. Divide the voltage drops across R1 and R3 by their respective voltage drops across R2 and R_x as follows:

$$\frac{I_1R1}{I_1R2} = \frac{I_2R3}{I_2R_X}$$

We can simplify this equation:

$$\frac{R1}{R2} = \frac{R3}{R_X}$$

then we multiply both sides of the expression by R_x to separate it:

$$R_X = \frac{R2R3}{R_X}$$

For example, in figure 1-5, we know that R1 is 60 ohms, R2 is 100 ohms, and R3 is 200 ohms. To find the value of R_x, we can use our formula as follows:

$$R_X = \frac{R2R3}{R1}$$

$$R_X = \frac{100 \times 200}{60}$$

$$R_X = \frac{20{,}000}{60}$$

$$R_X = 333.33 \text{ ohms}$$

Use of ac Bridges

A wide variety of ac bridge circuits (such as the Wheatstone) may be used for the precision measurement of ac resistance, capacitance, and inductance. Let's look at ac bridges in terms of functions they perform.

RESISTANCE BRIDGE.—An ac signal generator, as shown in figure 1-6, is used as the source of voltage. Current from the generator passes through resistors R1 and R2, which are known as the ratio arms, and through R_s and R_x. Again, R_x is known as resistance. R_s has a standard value and replaces R3 in figure 1-6. When the voltage drops across R2 and R_s are equal, the voltage drops across R2 and R_x are also equal; no difference of potential exists across the meter and no current flows through it. As we discovered with the Wheatstone bridge, when no voltage appears across the meter, the following ratio is true:

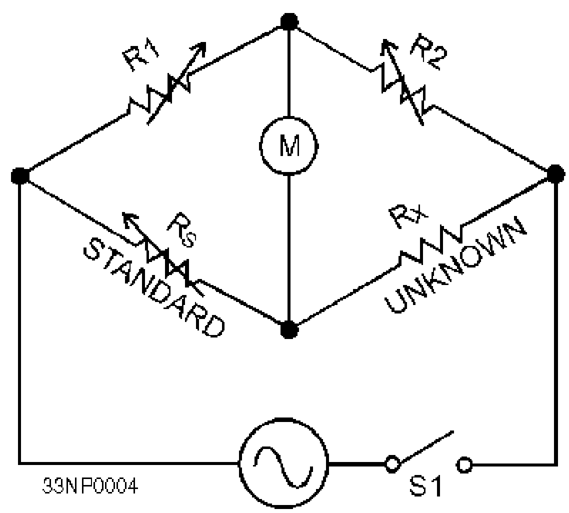

Figure 1-6.—Resistance bridge (ac).

For example, if in figure 1-6 we know that R1 is 20 ohms, R2 is 40 ohms, and R_s is 60 ohms, we can find the value of R_x using our formula as follows:

$$R_X = \frac{R2R_S}{R1}$$

$$R_X = \frac{40 \times 60}{20}$$

$$R_X = \frac{2,400}{20}$$

$$R_X = 120 \text{ ohms}$$

With the ac signal applied to the bridge, R1 and R2 are varied until a zero reading is seen on the meter. Zero deflection indicates that the bridge is balanced. (**NOTE**: In actual practice, the variables are adjusted for a minimum reading since the phase difference between the two legs will not always allow a zero reading.)

CAPACITANCE BRIDGE.—Because current varies inversely with resistance and directly with capacitance, an inverse proportion exists between the four arms of the bridge in figure 1-7; the right side of our expression is inverted from the resistance bridge expression as follows:

$$\frac{R1}{R2} = \frac{C_X}{C_S}$$

or

$$C_X = \frac{R1C_S}{R2}$$

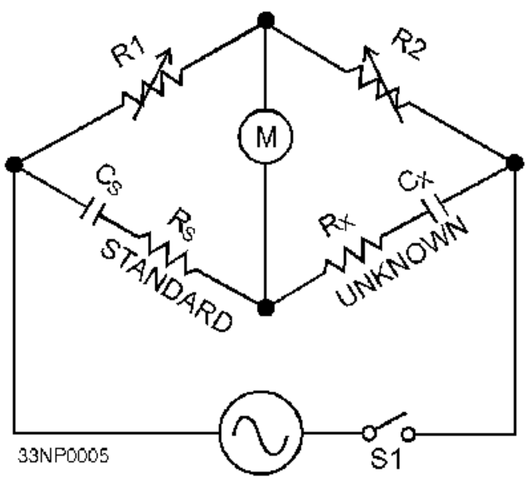

Figure 1-7.—Capacitance bridge.

Q-18. What effect does an increase in capacitance have on a capacitor's opposition to current flow?

Because R1 and R2 are expressed in the same units, the equation R1/R2 becomes a simple multiplication factor. This equation provides a numerical value for C_x and will be in the same units as C_s (farad, microfarad, and so forth).

Similarly, the following resistance ratio exists between the four arms of the bridge, just as in the resistance bridge expression discussed earlier:

$$\frac{R1}{R2} = \frac{R_S}{R_X}$$

or

$$R_X = \frac{R2R_S}{R1}$$

Thus, both the unknown resistance and capacitance, R_x and C_x, can be estimated in terms of known resistance R1, R2, R_s, and known capacitance C_s.

In figure 1-7, for example, we know that R1 is 20 ohms, R2 is 40 ohms, R_s is 60 ohms, and C_s is 10 microfarads. We can find the values of C_x and R_x by using the respective formulas as follows:

$$C_X = \frac{R1C_S}{R2}$$

$$C_X = \frac{20 \times 10}{40}$$

$$C_X = \frac{200}{40}$$

$$C_X = 5 \text{ microfarads}$$

and

$$R_X = \frac{R2R_S}{R1}$$

$$R_X = \frac{40 \times 60}{20}$$

$$R_X = \frac{2{,}400}{20}$$

$$R_X = 120 \text{ ohms}$$

Q-19. When a bridge is used to measure resistance, what is the value of R_x if R1 equals 80 ohms, R2 equals 120 ohms, and R3 equals 280 ohms?

INDUCTANCE BRIDGE.—The value of the unknown inductance L_x may be determined by means of the simple bridge circuit shown in figure 1-8. Ratio arms R1 and R2 are accurately calibrated resistors. L_s is a standard inductor with a known inductance; R_s is the known resistance, and R_x represents the resistance of the unknown inductor.

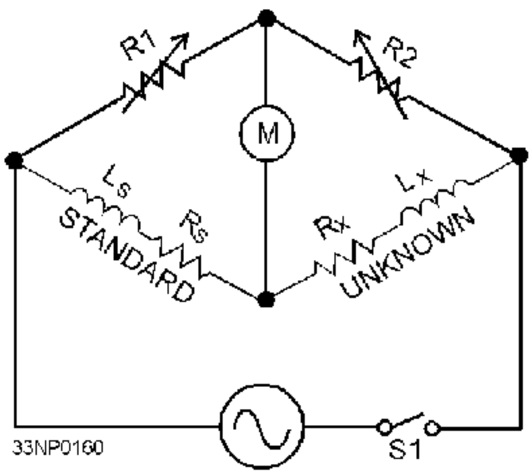

Figure 1-8.—Inductance bridge.

The ac signal is applied to the bridge, and variable resistors R1 and R2 are adjusted for a minimum or zero deflection of the meter, indicating a condition of balance. When the bridge is balanced, the following formulas may be used to find L_x.

(NOTE: The right side of this expression is NOT inverse as it was in the capacitance bridge.)

$$\frac{R1}{R2} = \frac{L_S}{L_X}$$

$$\frac{R2L_S}{R1} = L_X$$

and

$$\frac{R1}{R2} = \frac{R_S}{R_X}$$

or

$$R_X = \frac{R2R_S}{R1}$$

In figure 1-8, for example, the values of R1, R2, and R_s are 20, 40, and 60 ohms, respectively. The value of L_s is 10 millihenries. We can find the values of R_x and L_x by using their respective formulas as follows:

$$L_X = \frac{R2L_S}{R1}$$

$$L_X = \frac{40 \times 10}{20}$$

$$L_X = \frac{400}{20}$$

$$L_X = 20 \text{ millihenries}$$

and

$$R_X = \frac{R2R_S}{R1}$$

$$R_X = \frac{40 \times 60}{20}$$

$$R_X = \frac{2,400}{20}$$

$$R_X = 120 \text{ ohms}$$

Thus, both the unknown resistance and inductance can be estimated in terms of the known values for R1, R2, R_s, and L_s.

Q-20. When an unknown capacitance is tested with a bridge, what is the value of C_x if R1 equals 70 ohms, R2 equals 150 ohms, and C_s equals 550 microfarads?

SUMMARY

The important points of this chapter are summarized in the following paragraphs:

The **JETDS SYSTEM** is jointly used by all branches of the military to identify equipments by a system of standardized nomenclatures.

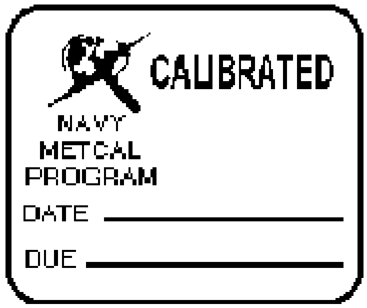
GPETE is test equipment that has the capability, without modifications, to generate, modify, or measure a range of parameters of electronic functions required to test two or more equipments or systems of basically different design. All GPETE are listed in *Standard General Purpose Electronic Test Equipment*, MIL-STD-1364 (series).

SPETE is test equipment that is specifically designed to generate, modify, or measure a range of parameters of electronic functions of a specific or peculiar nature required to test a single equipment or system.

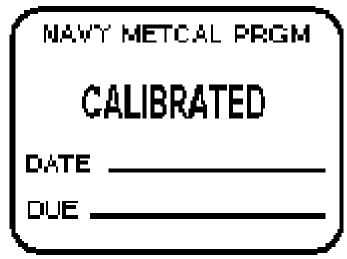
The **SHIP CONFIGURATION AND LOGISTICS INFORMATION SYSTEM (SCLSIS)** program is designed to keep track of equipment configuration changes in the fleet.

The **SCLSIS** program has two basic elements, VALIDATION and INVENTORY UPDATING.

The **CALIBRATION STATUS** of any items of test equipment can be determined by the information recorded on the calibration label or tag located on the equipment.



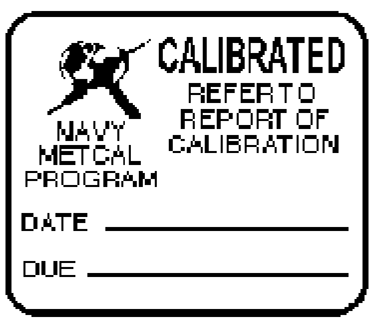
BLACK ON WHITE
FORM NO. 4355/1A



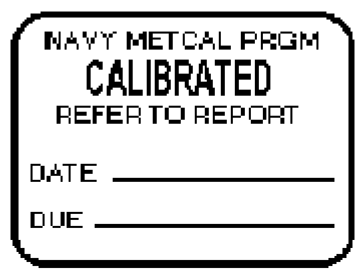
BLACK ON WHITE
FORM NO. 4355/3A

The **CALIBRATED** label, with black lettering on a white background, indicates the instrument to which it is attached is within tolerance on all scales.

The **CALIBRATED—REFER TO REPORT** label, with red lettering on a white background, is used when actual measurement values must be known to use the instrument.

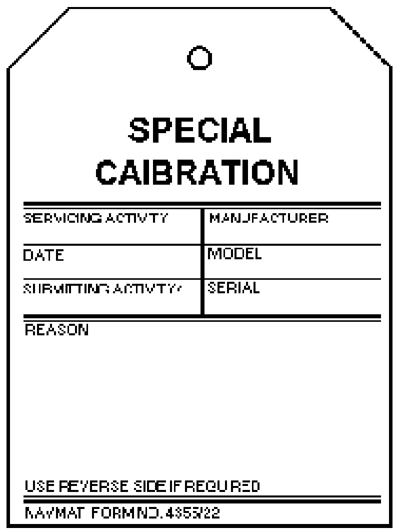


RED ON WHITE
FORM NO. 4355/2A

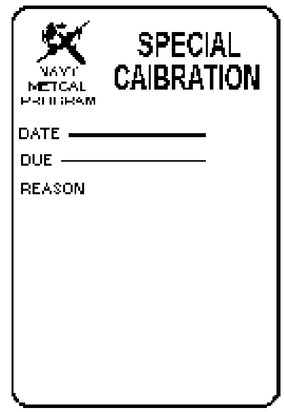


RED ON WHITE
FORM NO. 4355/4A

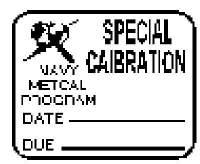
The **SPECIAL CALIBRATION** label, with black lettering on a yellow background, is used when some unusual or special condition in the calibration should be drawn to your attention.



BLACK ON YELLOW

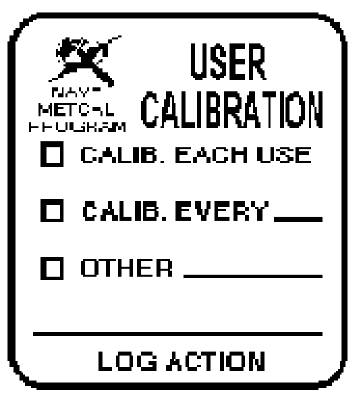


FORM NO. 4355/8A



BLACK ON YELLOW
FORM NO. 4355/7A

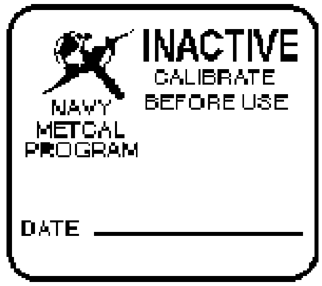
The **USER CALIBRATION** label indicates that you should calibrate the test and measuring instrument instead of sending the instrument to a calibration facility.



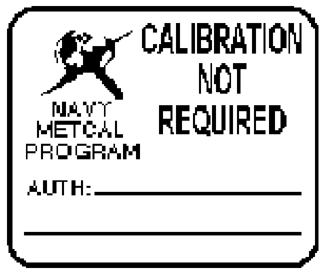
BLACK ON WHITE
FORM NO. 4355/24

The **INACTIVE—CALIBRATE BEFORE USE** label is used when a piece of test equipment due for recalibration will not be used for some time in the future.

The **CALIBRATION NOT REQUIRED** label is used on test instruments listed in the Metrology Requirements List (METRL) as not requiring calibration.

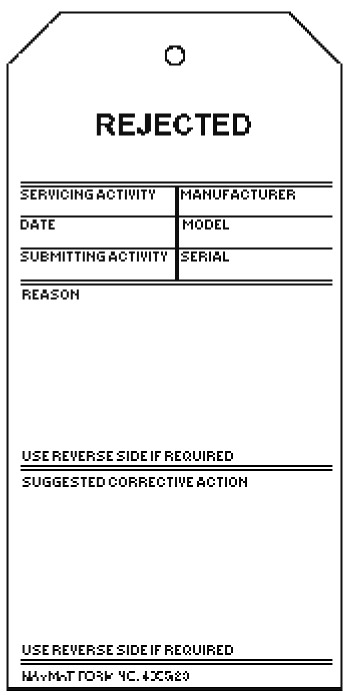


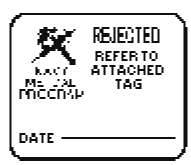
GREEN ON WHITE
FORM NO. 4355/11A



ORANGE ON WHITE
FORM NO. 4355/10A

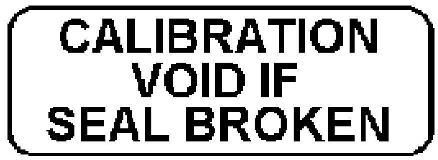
The **REJECTED** label is attached to a test instrument that fails to meet the acceptance criteria during calibration and cannot be repaired.





BLACK ON RED
FORM NO. 4355/12A

The **CALIBRATION VOID IF SEAL BROKEN** label is placed over readily accessible adjustments to prevent tampering by the user when such tampering could affect the calibration.



BLACK ON WHITE
FORM NO. 4355/14

The **MEASURE** system is designed to standardize the recall and scheduling of test, measurement, and diagnostic equipment into calibration facilities and for the documentation of actions performed by the calibration facility.

MAINTENANCE is work done to correct, reduce, or counteract wear and damage to equipment.

PREVENTIVE MAINTENANCE consists of checks to determine weather equipment is functioning properly. It also consists of visual inspections of cabling and equipment for damage and to determine if lubrication is needed.

CORRECTIVE MAINTENANCE is used to isolate troubles by means of test techniques and practices that realign or readjust equipment or otherwise bring the equipment back up to proper performance.

SENSITIVITY of the voltmeter is always given on the voltage charts for a particular piece of equipment. You should always use a voltmeter of similar sensitivity to the equipment to diminish the effects of circuit loading.

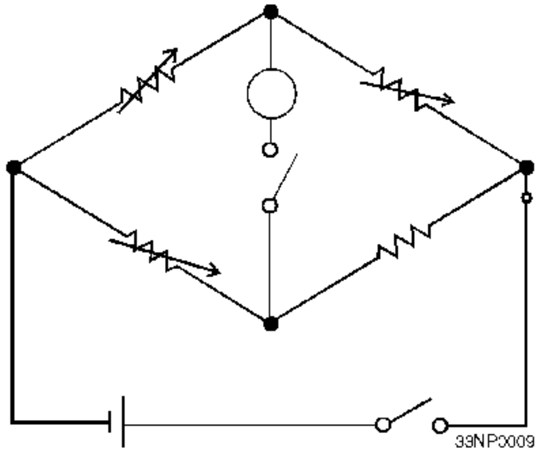
CURRENT MEASUREMENTS are not often taken in the course of testing because the ammeter (or other current measuring device) must become an actual part of the equipment being tested. The circuit must be opened for necessary connection of the meter. Usually you can use a voltage measurement to calculate the circuit current by applying Ohm's law.

You should observe the following PRECAUTIONS when using an ohmmeter:

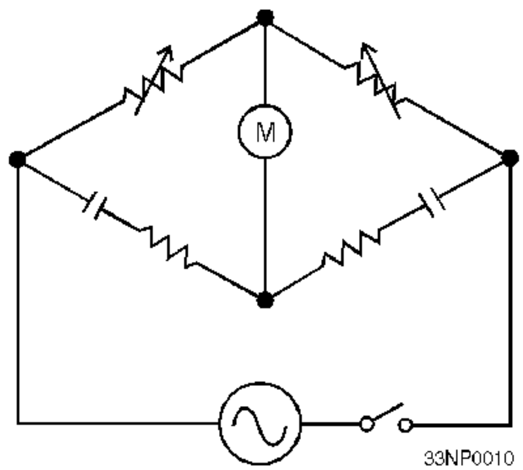
1. The circuit being tested must be completely de-energized.

2. Any circuit components which can be damaged by ohmmeter current must be removed before any measurement is made.

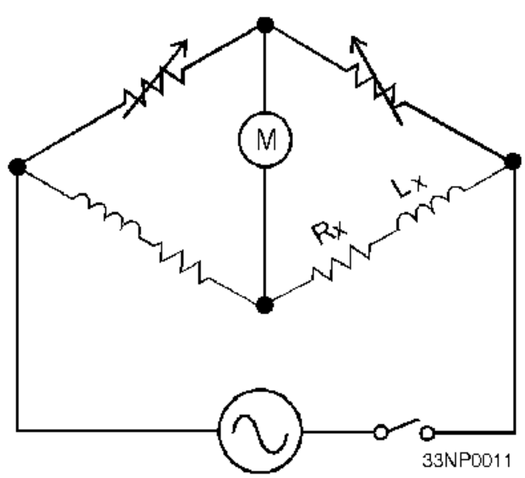
The **WHEATSTONE BRIDGE** is used for precise measurement of resistance.



The **CAPACITANCE BRIDGE** is used for measuring an unknown capacitance.



An **INDUCTANCE BRIDGE** is used to find the value of an unknown inductance.



ANSWERS TO QUESTIONS Q1. THROUGH Q20.

A-1. Joint Electronics Type Designation System (JETDS).

A-2. General-purpose electronic test equipment (GPETE) and special-purpose electronic test equipment (SPETE).

CHAPTER 2

MISCELLANEOUS MEASUREMENTS

LEARNING OBJECTIVES

Upon completing this chapter, you should be able to:

1. Define and explain the use of the terms "dB" and "dBm" as they apply to power measurements.
2. Describe the use of resistive loads, bolometers, and thermocouples in power measurements.
3. Explain the measurement of mechanical rotation using the tachometer, stroboscope, and the strobotac.
4. Explain the measurement of frequency in various ranges using vibrating reeds, tuned circuits, heterodyne frequency meters, absorption wavemeters, cavity wavemeters, and frequency counters.
5. Describe the use of frequency-measurement devices, oscilloscopes, and spectrum analyzers in waveform analysis and maintenance.
6. Describe semiconductor testing and applicable terms in maintenance.

INTRODUCTION

In chapter 1, you studied test equipment administration and the basic measurements that all technicians are responsible for performing. Chapter 2 presents miscellaneous measurements that are fairly common; keep in mind, however, that you may not routinely perform these measurements in your particular job. This chapter introduces you to several test instruments and components found in those test instruments. It will also serve as a review of some of the basics of electronic theory related to test equipment.

POWER MEASUREMENTS

You may be required to check the power consumption and the input-signal power levels of electronic equipment. The determination of dc power is fairly simple; recall that the unit of power, the **watt**, is the product of the potential in volts and the current in amperes ($P = E \times I$).

As discussed in NEETS, Module 2, *Introduction to Alternating Current and Transformers*, the phase angle of the voltage and current must be considered for accurate ac power measurements. The measurement of ac power is further complicated by the frequency limitations of various power meters. If there is no phase angle difference, you can compute ac power in the same manner as dc power; that is, by determining the effective value of the product of the voltage and current.

For equipments that operate in the audio-frequency (af) range, power levels have to be determined in the performance of routine checks and during corrective maintenance procedures.

Power measurements for af circuits are usually indicated in terms of decibels (dB) or decibels referenced to 1 milliwatt (dBm). Because the actual calculation of decibel measurements is seldom required, the following explanation is somewhat simplified. Most test equipment is designed to measure and indicate decibels directly. This eliminates the need for you to perform complicated calculations. Nevertheless, a basic explanation of the decibel measurement system is necessary for you to understand the significance of dB readings and amplifier-gain ratings that are expressed in decibels.

THE DECIBEL SYSTEM

The basic unit of measurement in the system is not the decibel; it is the **bel**. The bel is a unit that expresses the logarithmic ratio between the input and the output of any given component, circuit, or system. It may be expressed in terms of voltage, current, or power. Most often, it is used to show the ratio between input and output power to figure gain. You can express the power gain of the amplifier (N) in bels by dividing the output (P_1) by the input (P_2) and taking the base 10 logarithm of the resulting quotient. The formula for determining this gain is:

$$\log_{10}\frac{P_1}{P_2}$$

If an amplifier doubles the input power, the quotient of P_1 to P_2 will be 2. If you consult a logarithm table, you will find that the base 10 logarithm of 2 is 0.3, making the power gain of the amplifier 0.3 bel.

Q-1. What is the logarithmic ratio between the input and output of a given circuit called?

Experience has shown that because the bel is a rather large unit, it is difficult to apply. A more practical unit, and one that can be used more easily, is the decibel (1/10 bel). You can convert any figure expressed in bels to decibels by multiplying that figure by 10 or simply by moving the decimal point one place to the right. Applying this rule, we find that the above ratio of 0.3 bel is equal to 3 decibels.

The decibel (dB) cannot be used to represent actual power; only the ratio of one power compared to another. To say that an amplifier has a 3 dB gain means that the output power is twice the input power. This gives no indication of the actual power represented. You must be able to state the input power for it to be meaningful. In many **applications**, a mathematical expression represents the actual power, not a power ratio. One standard reference is the dBm.

The dBm is an abbreviation used to represent power levels above or below 1 milliwatt. Negative dBm (−dBm) represents power levels below 1 milliwatt, and positive dBm (+dBm) represents power levels above 1 milliwatt. In other words, a dBm value is a specific amount of power; 0 dBm is equal to 1 milliwatt. Briefly stated, the amount of power in a given value of dBm is the power which results if 1 milliwatt is amplified or attenuated by that dB value. For example, 40 dBm represents an actual power level (watts or milliwatts) that is 40 dB above 1 milliwatt, whereas −10 dBm represents a power level that is 10 dB below 1 milliwatt. The formula for finding dBm is a variation of the dB power formula:

$$\text{dBm} = 10\ \log\frac{\text{actual power } (P_2)}{.001 \text{ watt } (P_1)}$$

Q-2. What term is used to represent power levels above or below a 1-milliwatt reference?

You do not need to use the formula in most applications. The following shows conversions of dBm to mW:

+20dBm	=	100mW
+10dBm	=	10mW
+7dBm	=	5mW
+6dBm	=	4mW
+4dBm	=	2.5mW
+3dBm	=	2mW
0dBm	=	1mW
-3dBm	=	.5mW
-10dBm	=	.1mW

For a +10 dBm level, start with the 1 milliwatt reference and move the decimal point one place to the right (+10 dBm = 10 mW). Another 10 dB increment brings the power level to +20 dBm, thereby moving the decimal point another place to the right (+20 dBm = 100 mW). For a –10 dBm level, again start with 1 milliwatt, but this time move the decimal point one place to the left (–10 dBm = .1 mW). An additional 10 dB decrease results in another decimal point shift to the left (–20 dBm = .01 mW).

For a 3 dB increase, you double the power. For a 3 dB decrease, you reduce the power by one-half (+3 dBm = 2 mW and –3 dBm = .5 mW). A +6 dBm level is an additional 3 dB change from +3 dBm. In this case, you just double the power level of the +3 dBm (+6 dBm = 4 mW).

Q-3. What milliwatt value is equal to +6 dBm?

The dB change can be made in either direction. For example, +7 dBm is a decrease from +10 dBm. Reducing the +10 dBm power by one-half, we have +7 dBm, or 5 mW. A +4 dBm power level is a 3 dB decrease from +7 dBm (+4 dBm – 2.5 mW). By using this simple method, you can quickly find any power level that corresponds to a given dBm.

Some test instruments you will be using are calibrated in decibels and have a 1 milliwatt zero reference level. Figure 2-1 illustrates such an instrument. Notice that this is an ac voltmeter in which the upper scale of the meter indicates ac voltage and the lower scale indicates decibels. The zero power-level indicator on the decibel scale is located at, or near, center scale. If the power in the line being measured is more than the reference value, the meter will indicate a value to the right of the zero mark (+dB). If the power is less than the reference value, the meter will indicate a value to the left of the zero mark (–dB). Such meters are useful when recording measurements where a direct indication in decibels is desired. However, you must remember that this meter is still a voltmeter and that power measurements are not meaningful unless the circuit impedance is known. If you feel the need to review how to calculate power in ac circuits, refer to NEETS, Module 2.

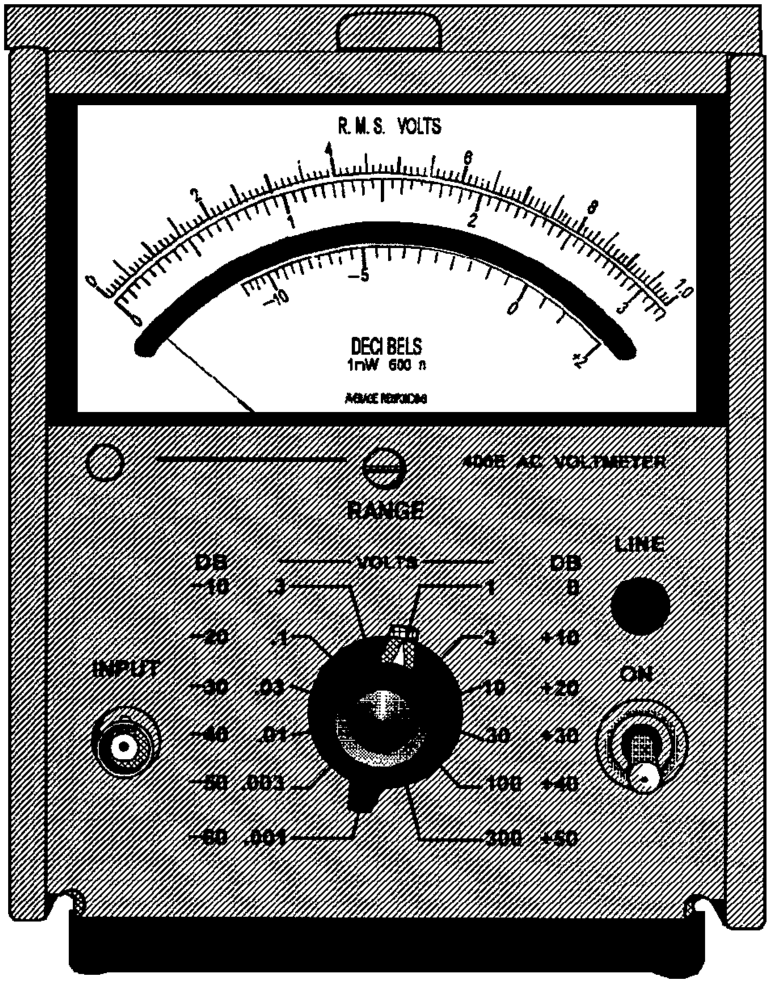

Figure 2-1.—Ac voltmeter.

MEASUREMENT METHODS

At radio frequencies below the UHF range, power is usually determined by voltage, current, and impedance measurements. One common method used to determine the output power of radio-frequency (rf) oscillators and radio transmitters consists of connecting a known resistance to the equipment output terminals. Current flowing through this resistance is then measured and the power is calculated as the product of I^2R.

Because power is proportional to the current squared, the meter scale can be calibrated to indicate power units directly. A THERMOCOUPLE AMMETER can be used in this manner for measuring rf power. The resistor used to replace the normal load is specially designed to have low reactance and the ability to dissipate the required amount of power. Such resistors are commonly called DUMMY LOADS or DUMMY ANTENNAS.

Q-4. What name is given to a resistor used to replace the normal load in a circuit?

In the UHF and SHF frequency ranges, accurately measuring the voltage, current, and resistance is difficult. These basic measurements can vary greatly, depending on where in the circuit the measurements are made. They are also affected by small changes in parts placement in the vicinity of tuned circuits.

To measure the output of microwave radio or radar transmitters, you can use test instruments that convert rf power to another form of energy, such as light or heat. These instruments can be used to indirectly measure the power. A method used to measure the effect of a resistor load on a stream of passing air can also be used to indirectly measure power. Accurate measurement of large-magnitude power also can be achieved by measuring the temperature change of a water load. The most common type of power meter for use in this frequency range employs a BOLOMETER.

Bolometer

The bolometer is a loading device that undergoes changes of resistance as changes in dissipated power occur. The two types of bolometers are the BARRETTER and the THERMISTOR. The barretter is characterized by an increase in resistance as the dissipated power rises. The thermistor decreases in resistance as the power increases. In either case, resistance is measured before and after the application of rf power. If the same change in resistance is then produced by a variable dc source of power, then the rf power is equal to the measured dc power. This relationship makes possible the direct calibration of a bridge circuit in units of power. In other words, one condition of balance exists when no rf power is applied; but in the presence of power, a second condition of balance exists because of the resistance changes of the bolometer. It is this change of resistance that is calibrated in power.

Q-5. What are the two types of bolometers?

BARRETTER.—The construction of a typical barretter is shown in figure 2-2. The fine wire (usually tungsten) is extremely small in diameter. This thin diameter allows the rf current to penetrate to the center of the wire. The wire is supported in an insulating capsule between two metallic ends, which act as connectors. Because of these physical characteristics, the barretter resembles a cartridge-type fuse. The enclosure is a quartz capsule made in two parts. One part is an insert cemented in place after the tungsten wire has been mounted. In operation, the barretter is matched to the rf line after power is applied.

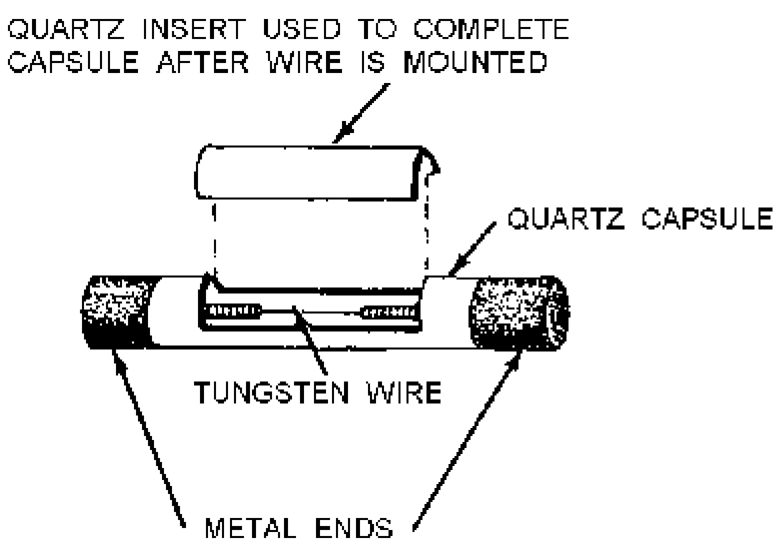

Figure 2-2.—Typical barretter.

THERMISTOR.—A high degree of precision is made possible by the thermistor; therefore, it is widely used. Figure 2-3 shows the typical construction of a bead-type thermistor. The negative-temperature coefficient comes from the use of a semiconductor as the active material. Notice that the active material is shaped in the form of a bead. It is supported between two pigtail leads by connecting wires. The pigtail ends are embedded in the ends of the surrounding glass capsule.

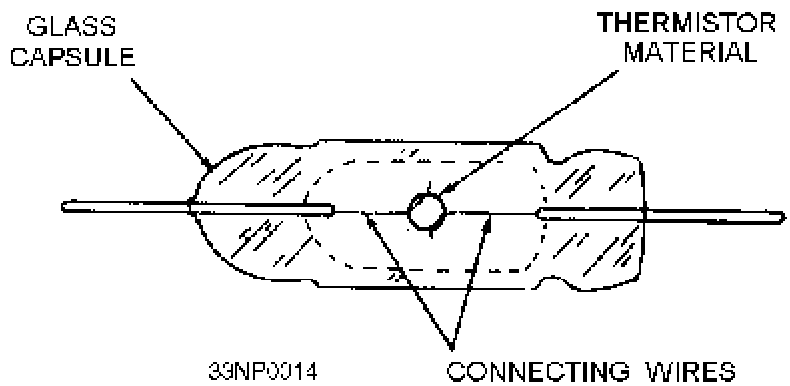

Figure 2-3.—Bead-type thermistor.

The negative-resistance temperature coefficient of thermistors is desirable. This is because excessive power has the effect of changing the resistance of the thermistor to an extent that causes a pronounced rf mismatch. The resulting decrease in power transfer reduces the likelihood of burnout.

Thermistor Bridge

Figure 2-4, views A and B, is an example of a THERMISTOR BRIDGE used for rf power measurements. A thermistor bridge circuit includes other thermistor elements, referred to as *compensating thermistors*. These thermistors respond to fluctuations in ambient temperature so that the bridge balances and calibration are maintained over a wide temperature range. Compensating thermistors are usually in disc form so that they can be mounted on a flat metal surface, such as a chassis or a waveguide. The thermistor bridge in view B is located in the terminating section of a waveguide and contains RT-2, a bead thermistor, and two compensating thermistors, RT-1 and RT-3, on the outside of the waveguide (view A). RA-1 in view B, a calibrated attenuator, controls the amount of rf energy applied to RT-2.

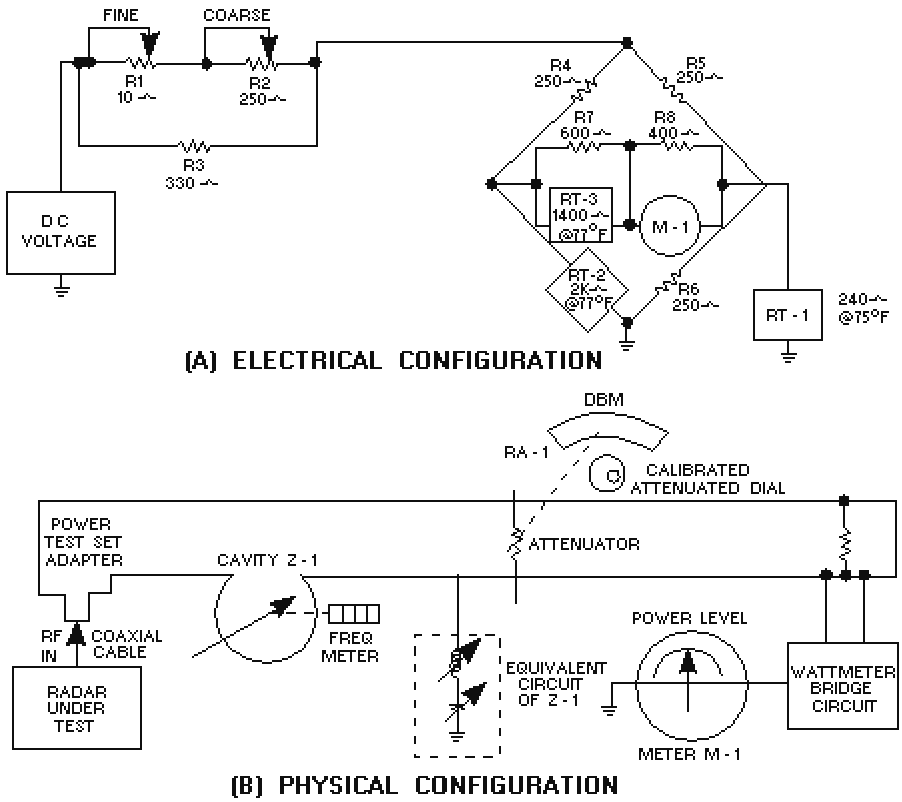

Figure 2-4.—Thermistor bridge.

Before power is applied, R1 and R2 in view A of figure 2-4 are used to adjust the current through RT-2. When the resistance of RT-2 reaches the equivalent parallel resistance of R6 and RT1 (122.4 ohms), the bridge is balanced. Meter M-1 reads 0 at this time. The rf signal being measured is connected to the test set and applied via the calibrated attenuator to RT-2. This causes the temperature of RT-2 to increase, thus reducing its resistance. The bridge becomes unbalanced, causing meter M-1 to deflect an amount proportional to the decrease in resistance of RT-2. Meter M-1, because of the operation of RT-2, reads average power.

Q-6. As the dissipated power increases, what effect does this have on the resistance of a thermistor?

If the ambient temperature rises, the resistance of RT-1 decreases. This shunts more current around the bridge network and allows RT-2 to cool. The resistance of RT-3 decreases, maintaining meter sensitivity independent of temperature changes. Cavity Z-1 in view B of figure 2-4 is an ABSORPTION-TYPE FREQUENCY METER. This type of meter will be discussed later.

FREQUENCY MEASUREMENTS

Frequency measurements are an essential part of preventive and corrective maintenance for electric and electronic equipment. Some examples of the various frequency measurements follow:

- Rotation frequencies of some electro-mechanical devices, such as electric motors, must be determined.

- The output frequency of electric power generators is checked when the engine is started and during preventive maintenance routines.

- Equipment that operates in the af range must be adjusted to operate at the correct frequencies.

- Radio transmitters must be accurately tuned to the assigned frequencies to provide reliable communications and to avoid interference with radio circuits operating on other frequencies.

- Radar sets must be properly tuned to obtain satisfactory performance.

As you can see from the above examples, frequency measurement does indeed play a valuable role in maintenance. These measurements can be divided into two broad categories: MECHANICAL-ROTATION FREQUENCY measurement and ELECTRICAL-OUTPUT FREQUENCY measurement. Depending upon your job and/or the type of command to which you are assigned, you may be tasked with performing one or both of these types of measurements.

MECHANICAL-ROTATION FREQUENCY MEASUREMENT

The rotating frequency (speed in revolutions per minute) of armatures in electric motors and engine-driven generators, as well as the blade speed in turbines, is measured with devices called TACHOMETERS, STROBOSCOPES, and STROBOTACS.

Tachometer

A tachometer is an instrument that measures the rate at which a shaft is turning. Although tachometers are installed on machinery, such as generators and engines, you may need to determine the speed of a rotating machine that is not equipped with a tachometer. In these instances, you will be required to use a PORTABLE TACHOMETER. Portable hand-held tachometers measure speed by direct contact with the shaft of the measured unit. Portable tachometers are for use only during testing and should not be used continuously. The common types of portable tachometers are the CENTRIFUGAL and the CHRONOMETRIC.

CENTRIFUGAL TACHOMETER.—A centrifugal-type tachometer is illustrated in figure 2-5, view A. View B shows the internal arrangement of the centrifugal tachometer; refer to view B in this discussion. In the centrifugal tachometer, centrifugal force acts upon fly weights that are connected by links to upper and lower collars. The upper collar is affixed to a drive shaft; the lower collar is free to move up and down the shaft. A spring, which fits over the shaft, connects the upper and lower collars.

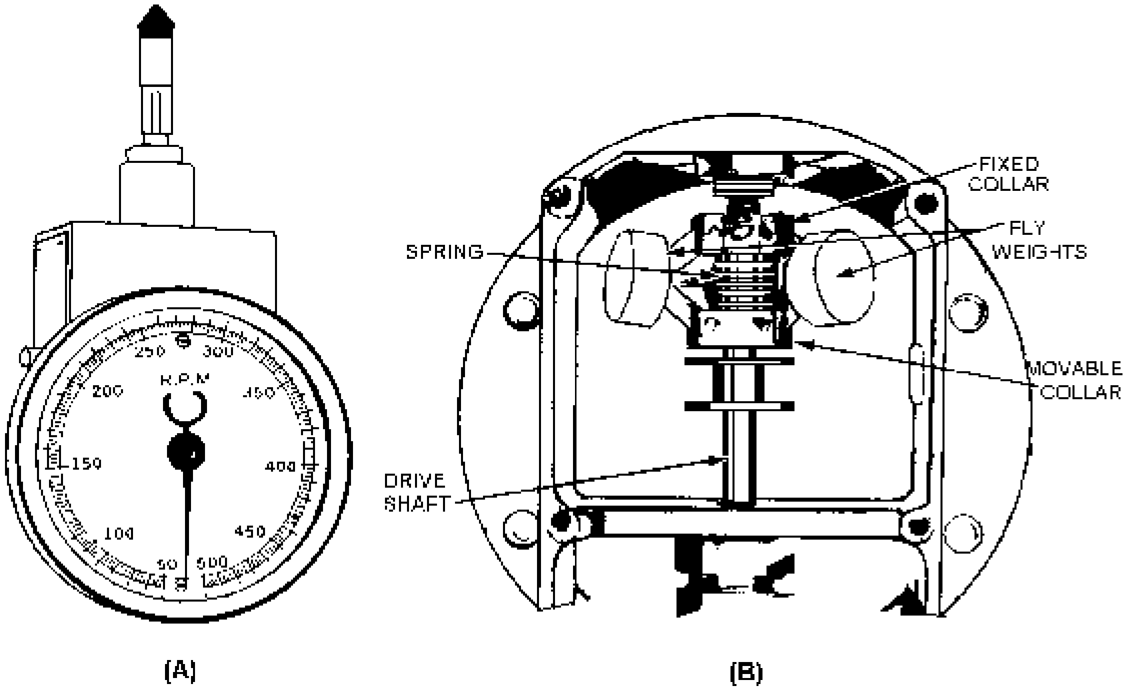

Figure 2-5.—Centrifugal tachometer.

Each portable centrifugal tachometer has a small rubber-covered wheel and a number of hard rubber tips. You fit the appropriate tip or wheel on the end of the tachometer drive shaft, and hold it against the shaft to measure speed of rotation. As the drive shaft begins to rotate, the fly weights rotate with it. Centrifugal force tends to pull the fly weights away from the center, causing the lower collar to rise and compress the spring. The lower collar is attached to a pointer, and its upward motion, restricted by the spring tension, causes an increase in the indication on the dial face.

When properly used, a centrifugal tachometer will indicate correct shaft speed as long as it is in contact with the machine shaft under test. A portable centrifugal tachometer has three ranges: low (50 to 500 rpm), medium (500 to 5,000 rpm), and high (5,000 to 50,000 rpm).

CHRONOMETRIC TACHOMETER.—The chronometric tachometer (figure 2-6) is a combination watch and revolution counter. It measures the average number of revolutions of a shaft per minute. The chronometric tachometer also comes with hard rubber tips, which must be inserted over the drive shaft.

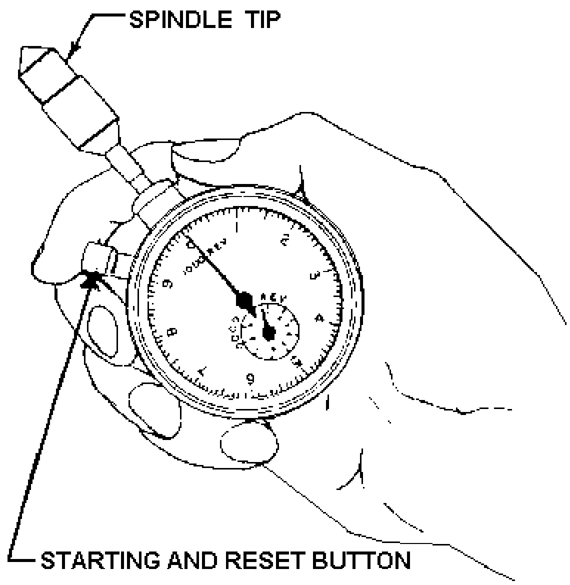

Figure 2-6.—Chronometric tachometer.

When applied to a rotating shaft, the outer drive shaft of this tachometer runs free until a starting button is depressed to start the timing element. In figure 2-6, note the starting button beneath the index finger. The chronometric tachometer retains readings on its dial after its drive shaft has been disengaged from a rotating shaft and until the pointers are returned to 0 by the reset button (usually the starting button). The range of a chronometric tachometer is usually from 0 to 10,000 rpm and from 0 to 3,000 feet per minute (fpm).

Stroboscope

The rotation frequencies of recording devices and teletypewriter motors can be measured by the use of a STROBOSCOPE. The stroboscope is an instrument that allows you to view rotating or reciprocating objects intermittently and produces the optical effect of a slowing down or stopping motion. For example, electric fan blades revolving at 1,800 rpm will appear stationary if you look at them under a light that flashes uniformly 1,800 times per minute. At 1,799 flashes per minute, the blades will appear to rotate forward at 1 rpm; at 1,801 flashes per minute, they will appear to rotate backward at 1 rpm.

When the flashing rate of the light is adjustable, you can calibrate the control in flashes (or revolutions) per minute. The stationary image you see when the rate of the lamp and the rotational rate of a shaft are equal lets you record a very precise speed measurement.

Strobotac

The STROBOTAC (figure 2-7) is an electronic flash device in which the flash duration is very short (a few millionths of a second). (Table 2-1 contains a description of the controls and indicators shown on the strobotac in figure 2-7.) Because of this short flash duration, the strobotac can measure very rapid motion. The box contains a swivel mount with a STROBOTRON LAMP in a reflector, an electronic pulse generator to control the flashing rate, and a power supply that operates from the ac power line. The flashing rate is controlled by the large knob; the corresponding speed (rpm) is indicated on an illuminated dial that is viewed through windows in the knob.

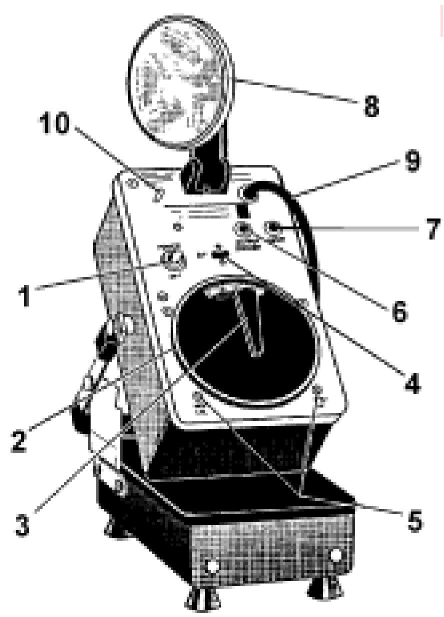

Figure 2-7.—Electronic strobotac.

Table 2-1.—Strobotac Controls and Indicators

	CONTROLS AND INDICATORS (see figure 2-7)	
NO	**NAME**	**USE**
1.	POWER switch	Turns power on and off.
2.	RPM control	Controls the flashing rate of light as the fluted rim is rotated. Dial is calibrated directly in revolutions per minute (rpm).
3.	Range switch	Selects any of three rpm (internal oscillator) ranges, plus three external-input positions: Rpm ranges Intensity External input 110-690 rpm High 700 rpm max 170-4170 rpm Med 4000 rpm max* 4000-25,000 rpm Low 25,000 rpm max
4.	CALibration indicator lamp	Indicates the correct setting of CALibration adjustments for calibrating the RPM dial to power-line frequency.
5.	HIGH CAL, LOW CAL	Calibration adjustments used to calibrate the RPM dial.
6.	OUTPUT TRIGGER jack	A trigger pulse is available at this jack for strobotac types 1531, 1538, stroboslave type 1539, and strobolume type 1532.
7.	INPUT jack	Used for connecting the stroboscope to an external synchronizing signal from the electrical device or mechanical contactor.
8.	Reflector-lamp assembly	Produces and aims the flashing light.
9.	Power cord	A permanently attached 6-foot power cord. For storage, the cord is wound clockwise around the range-switch knob and reflector. The plug is secured by sliding it onto the holding pin.
10.	Holder pin	Used to secure the plug-end of the power cord when unit is to be stored in its case.

* Flashes at 3600 rpm until external signal is plugged in.

The normal speed range is from 110 to 25,000 rpm. At speeds below 600 rpm, "flicker" becomes a problem because the human eye cannot retain successive images long enough to create the illusion of continuous motion. The life of the strobotron lamp is approximately 250 hours if used at flashing speeds of less than 5,000 rpm, or 100 hours if used at higher speeds.

ELECTRICAL OUTPUT FREQUENCY

All alternating voltage sources are generated at a set frequency or range of frequencies. A FREQUENCY METER provides a means of measuring this frequency. The electrical output frequency of ac power generators can be measured by a vibrating reed, a tuned circuit, or by a crossed-coil, iron-vane type meter. The vibrating-reed device is the simplest type of frequency meter. It has the advantage of being rugged enough to be mounted on generator control panels.

A simplified diagram of a vibrating-reed frequency meter is shown in figure 2-8, views A through D. In view A, you can see that the current to be measured flows through the coil and exerts maximum attraction on the soft-iron armature twice during each cycle. The armature is attached to the bar, which is mounted on a flexible support. Reeds of suitable dimensions to have natural vibration frequencies of 110, 112, 114, and so forth, up to 130 hertz are mounted on the bar (view B). The reed with a frequency of 110 hertz is marked 55 hertz; the one with a frequency of 112 hertz is marked 56 hertz; the one with a frequency of 120 hertz is marked 60 hertz, and so forth.

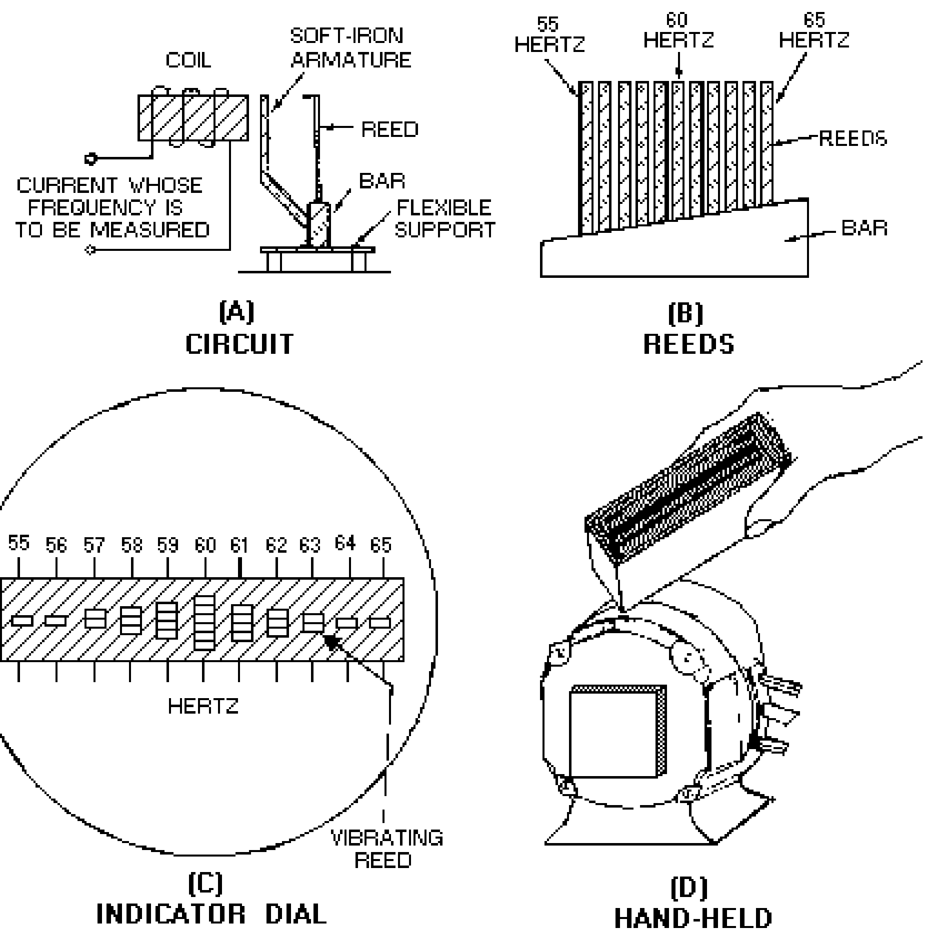

Figure 2-8.—Vibrating-reed frequency meter.

When the coil is energized by a current with a frequency between 55 and 65 hertz, all the reeds are vibrated slightly; but, the reed having a natural frequency closest to that of the energizing current vibrates through a larger amplitude. The frequency is read from the scale value opposite the reed having the greatest amplitude of vibration.

In some instruments, the reeds are the same length; but they are weighted by different amounts at the top so they will have different natural rates of vibration. An end view of the reeds in the indicator is shown in view C. If the energizing current has a frequency of 60 hertz, the reed marked 60 will vibrate the greatest amount, as shown. View D shows a hand-held vibrating-reed frequency meter mounted on the casing of a motor-generator.

Tuned Circuits

TUNED CIRCUITS are used as filters for the passage or rejection of specific frequencies. BANDPASS FILTERS and BAND-REJECT FILTERS are examples of this type. Tuned circuits have certain characteristics that make them ideal for certain types of filters, especially where a high degree of selectivity is desired. A series-tuned circuit offers a low impedance to currents of the particular frequency to which the circuit is tuned and a relatively high impedance to currents of all other frequencies. A parallel-tuned circuit, on the other hand, offers a very high impedance to currents of its natural, or resonant, frequency and a relatively low impedance to others. If you feel you need to review the subject of tuned circuits at this time, refer to NEETS, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*, for more information on these circuits and their applications.

AUDIO FREQUENCIES

Frequency measurements in the af range can be made by the comparison method or the direct-reading frequency meter. Frequency comparisons can be made by the use of a calibrated af generator in conjunction with either an oscilloscope or a modulator and a zero-beat indicating device. Direct-reading frequency measurements can be made by instruments using series, frequency-selective electrical networks, bridge test sets having null indicators, or counting-type frequency meters.

Heterodyne Frequency Meters

Heterodyne frequency meters are available in several varieties. They measure the frequency of the unknown signal by matching the unknown signal with a locally generated signal of the same frequency obtained from a calibrated, precision oscillator. This method is normally referred to as *zero beating*. When a perfect frequency match is obtained, it is indicated by the absence of a beat note (zero beat). The technician generally uses a set of headphones to detect a zero-beat condition in the equipment being tested.

The basic heterodyne meter (figure 2-9) is a calibrated variable oscillator, which heterodynes against the frequency to be measured. Coupling is accomplished between the frequency meter and the output of the equipment under test. (NOTE: This coupling should be in accordance with the step-by-step procedures listed in the technical manual for the frequency meter.) The calibrated oscillator is then tuned so that the difference between the oscillator frequency and the unknown frequency is in the af range. This difference in frequency is known as the BEAT FREQUENCY. As the two frequencies are brought closer to the same value, the tone in the headset will decrease in pitch until it is replaced by a series of rapid clicks. As the process is continued, the clicks will decrease in rapidity until they stop altogether. This is the point of zero beat; that is, the point at which the frequency generated in the oscillator of the frequency meter is equal to the frequency of the unknown signal being measured.

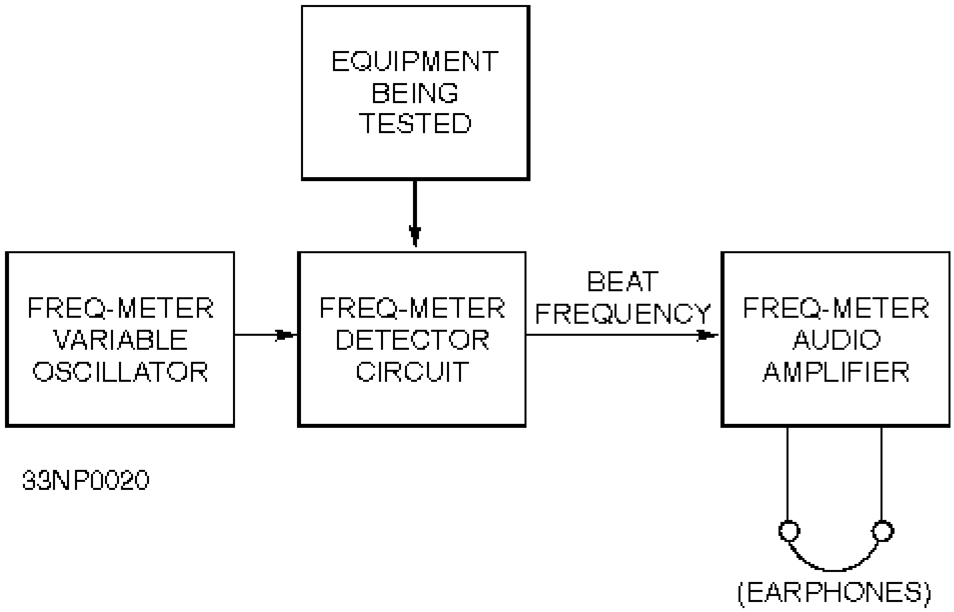

Figure 2-9.—Basic heterodyne meter (block diagram).

Q-7. In a heterodyne-type frequency meter, what is the difference between the oscillator frequency and the unknown frequency?

For all practical purposes, the point of zero beat can be assumed when the clicks are heard at infrequent intervals. Figure 2-10 illustrates the zero-beat concept. Maintaining a condition of absolute silence in the earphones is extremely difficult when you are making this measurement. When the incoming signal is strong, the clicks are sharp and distinct. When the signal is weak, the zero-beat condition is evidenced by a slowly changing "swishing" or "rushing" sound in the headset. After the zero beat is obtained, the dial reading corresponds to the frequency measured.

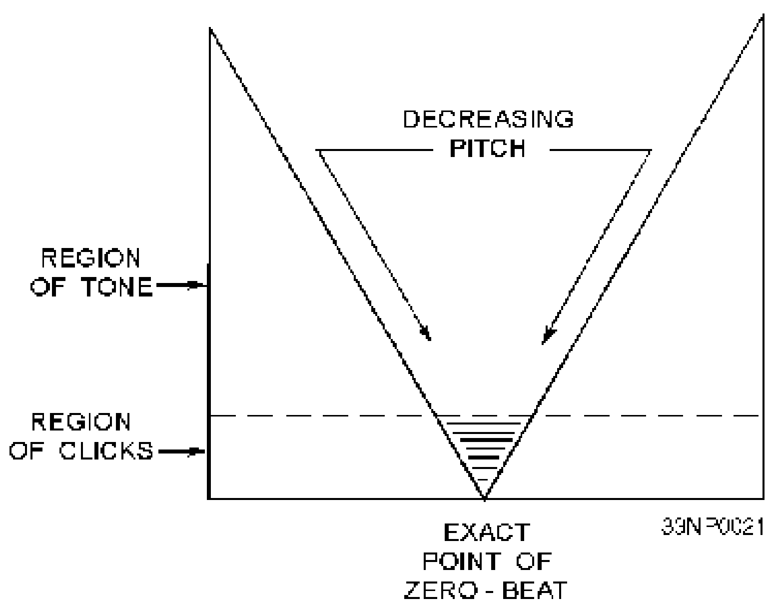

Figure 2-10.—Graph of sound heard in earphone when zero beating.

The manufacturer's calibration book is a very important part of the frequency meter package; in fact, the book is so important that it bears the same serial number as the heterodyne-type frequency meter itself. Contained in this book is a list of the dial settings and the corresponding frequencies produced by that meter at those dial settings. Operating instructions for the meter are also included.

Absorption Wavemeter

WAVEMETERS are calibrated resonant circuits used to measure frequency. The accuracy of wavemeters is not as high as that of heterodyne-type frequency meters; however, they have the advantage of being comparatively simple and can be easily carried.

Q-8. What equipment uses a calibrated resonant circuit to measure frequency?

Any type of resonant circuit can be used in wavemeter applications. The exact kind of circuit used depends on the frequency range for which the meter is intended. Resonant circuits consisting of coils and capacitors are used for VLF through VHF wavemeters.

The simplified illustration of an absorption wavemeter, shown in figure 2-11, consists of a pickup coil, a fixed capacitor, a lamp, a variable capacitor, and a calibrated dial. When the wavemeter's components are at resonance, maximum current flows in the loop, illuminating the lamp to maximum brilliance. The calibrated dial setting is converted to a frequency by means of a chart, or graph, in the instruction manual. If the lamp glows very brightly, the wavemeter should be coupled more loosely to the circuit. For greatest accuracy, the wavemeter should be coupled so that its indicator lamp provides only a faint glow when tuned to the resonant frequency.

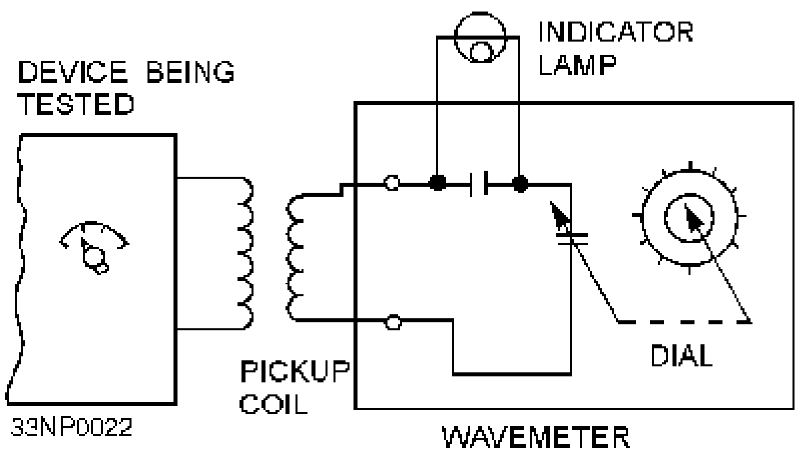

Figure 2-11.—Absorption wavemeter circuit.

FREQUENCIES ABOVE THE AUDIO RANGE

The signal frequencies of radio and radar equipments that operate in the UHF and SHF ranges can be measured by resonant, cavity-type wavemeters or resonant, coaxial-line-type wavemeters. When properly calibrated, resonant-cavity and resonant-coaxial line wavemeters are more accurate and have better stability than wavemeters used for measurements in the LF to VHF ranges. These frequency-measuring instruments are often furnished as part of the equipment. They are also available as general-purpose test sets.

Although many wavemeters are used in performing various functions, the cavity-type wavemeter is the type most commonly used. Only this type is discussed in some detail.

Cavity Wavemeter

Figure 2-12 shows a typical CAVITY WAVEMETER. The wavemeter is of the type commonly used for the measurement of microwave frequencies. The device uses a resonant cavity. The resonant frequency of the cavity is varied by means of a plunger, which is mechanically connected to a micrometer mechanism. Movement of the plunger into the cavity reduces the cavity size and increases the resonant frequency. Conversely, an increase in the size of the cavity (made by withdrawing the plunger) lowers the resonant frequency. The microwave energy from the equipment being tested is fed into the wavemeter through one of two inputs, **A** or **B**. The crystal rectifier then detects (rectifies) the signal. The rectified current is indicated on current meter **M**.

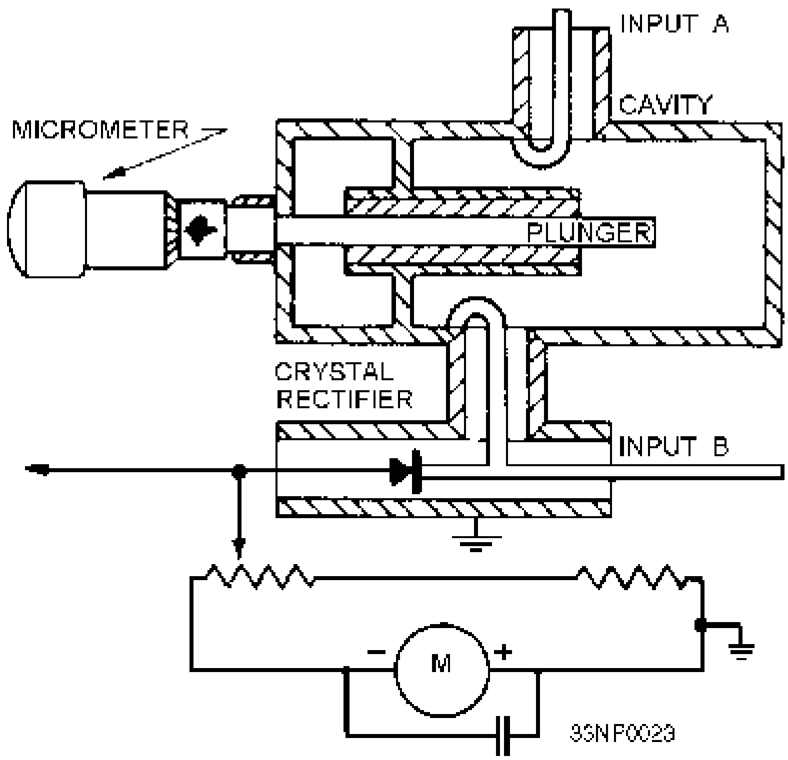

Figure 2-12.—Typical cavity wavemeter.

Electronic Frequency Counters

Another device used to measure frequencies above the audio range is the ELECTRONIC FREQUENCY COUNTER. Since this instrument will be covered in detail in a later chapter, only a brief description is provided at this time.

The electronic frequency counter is a high-speed electronic counter with an accurate, crystal-controlled time base. This combination provides a frequency counter that automatically counts and displays the number of events occurring in a precise time interval. The frequency counter itself does not generate any signal; it merely counts the recurring pulses fed to it.

WAVEFORM ANALYSIS

WAVEFORM ANALYSIS can be made by observing displays of voltage and current variations with respect to time or by harmonic analysis of complex signals. Waveform displays are particularly valuable for adjusting and testing pulse-generating, pulse-forming, and pulse-amplifying circuits. The waveform visual display is also useful for determining signal distortion, phase shift, modulation factor, frequency, and peak-to-peak voltage.

Waveform analysis is used in various electrical and electronic equipment troubleshooting. This section will briefly discuss the oscilloscope and spectrum analyzer to provide you with basic knowledge of this test equipment.

Q-9. Name two instruments used to analyze waveforms.

USE OF THE OSCILLOSCOPE

The CATHODE-RAY OSCILLOSCOPE (CRO or O-SCOPE) is commonly used for the analysis of waveforms generated by electronic equipment. Several types of cathode-ray oscilloscopes are available for making waveform analysis. The oscilloscope required for a particular test is determined by characteristics such as input-frequency response, input impedance, sensitivity, sweep rate, and the methods of sweep control. The SYNCHROSCOPE is an adaptation of the cathode-ray oscilloscope. It features a wide-band amplifier, triggered sweep, and retrace blanking circuits. These circuits are desirable for the analysis of pulse waveforms.

Oscilloscopes are also part of some harmonic analysis test equipments that display harmonic energy levels. To effectively analyze waveform displays, you must know the correct wave shape. The maintenance instructions manual for each piece of equipment illustrates what waveforms you should observe at the various test points throughout the equipment. Waveforms that will be observed at any one selected test point will differ; each waveform will depend on whether the operation of the equipment is normal or abnormal.

The display observed on a cathode-ray oscilloscope is ordinarily one similar to those shown in figure 2-13. Views A and B show the instantaneous voltage of the wave plotted against time. Elapsed time (view A) is indicated by horizontal distance, from left to right, across the etched grid (graticule) placed over the face of the tube. The amplitude (view B) of the wave is measured vertically on the graph.

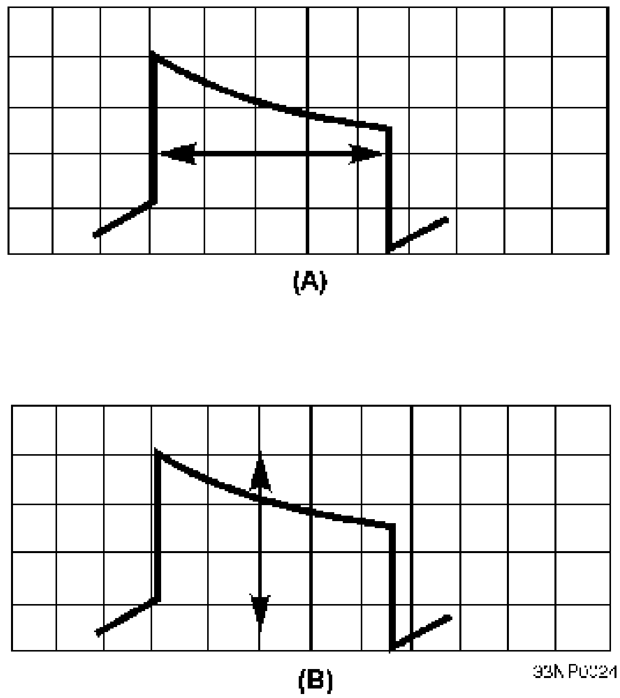

Figure 2-13.—Typical waveform displays.

The oscilloscope is also used to picture changes in quantities other than simply the voltages in electric circuits. For example, if you need to see the changes in waveform of an electric current, you must first send the current through a small resistor. You can then use the oscilloscope to view the voltage wave across the resistor. Other quantities, such as temperatures, pressures, speeds, and accelerations, can be translated into voltages by means of suitable transducers and then viewed on the oscilloscope. A detailed discussion of the oscilloscope is presented in chapter 6 of this module.

USE OF THE SPECTRUM ANALYZER

The SPECTRUM ANALYZER is a device that sweeps over a band of frequencies to determine (1) what frequencies are being produced by a specific circuit under test and (2) the amplitude of each frequency component. To accomplish this, the spectrum analyzer first presents a pattern on a display. Then the relative amplitudes of the various frequencies of the spectrum of the pattern are plotted (see figure 2-14). On the vertical, or Y axis, the **amplitudes** are plotted; on the horizontal, or X axis, the frequencies (time base) are plotted. The overall pattern of this display indicates the proportion of power present at the various frequencies within the SPECTRUM (fundamental frequency with sideband frequencies).

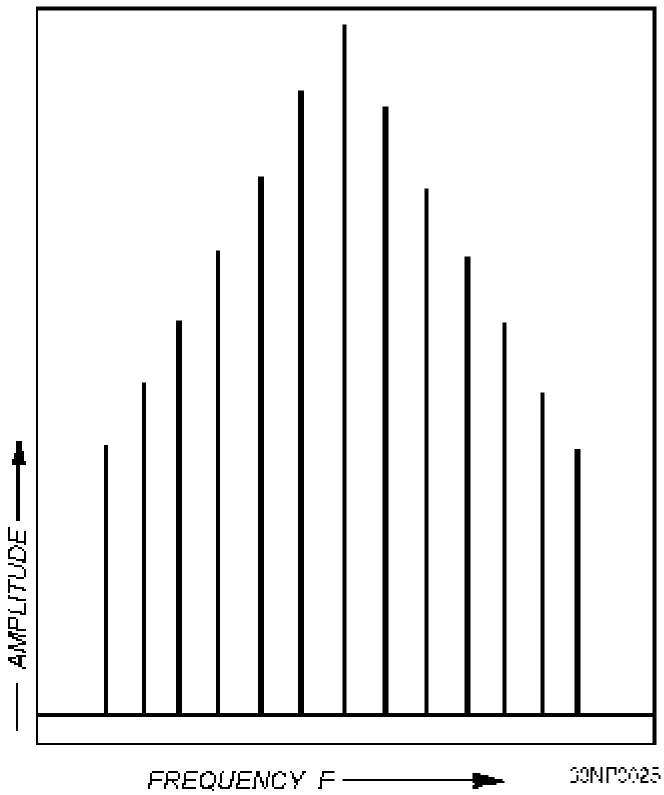

Figure 2-14.—Spectrum analyzer pattern.

Q-10. What device sweeps a band of frequencies to determine frequencies and amplitudes of each frequency component?

The spectrum analyzer is used to examine the frequency spectrum of radar transmissions, local oscillators, test sets, and other equipment operating within its frequency range. Proper interpretation of the displayed frequency spectrum enables you to determine the degree of efficiency of the equipment under test. With experience, you will be able to determine definite areas of malfunctioning components within equipment. In any event, successful spectrum analysis depends on the proper operation of a spectrum analyzer and your ability to correctly interpret the displayed frequencies. Later, in chapter 6, we will discuss the various controls, indicators, and connectors contained on the spectrum analyzer.

TESTING SEMICONDUCTOR DEVICES

Because of the reliability of semiconductor devices, servicing techniques developed for transistorized equipment differ from those normally used for electron-tube circuits. Electron tubes are usually considered to be the circuit component most susceptible to failure and are normally the first components to be tested. Transistors, however, are capable of operating in excess of 30,000 hours at maximum rating without failure. They are often soldered in the circuit in much the same manner as resistors and capacitors. Therefore, they are NOT so quickly removed for testing as tubes.

Substitution of a semiconductor diode or transistor known to be in good condition is one method of determining the quality of a questionable semiconductor device. This method should be used only after you have made voltage and resistance measurements. This ensures the circuit has no defect that might damage the substitute semiconductor device. If more than one defective semiconductor is present in the equipment section where trouble has been localized, the semiconductor replacement method becomes cumbersome. Several semiconductors may have to be replaced before the trouble is corrected. To determine which stage(s) failed and which semiconductors are not defective, you must test all the removed semiconductors. You can do this by observing whether the equipment operates correctly as you reinsert each of the removed semiconductor devices into the equipment.

TESTING DIODES

Semiconductor diodes, such as general-purpose germanium and silicon diodes, power silicon diodes, and microwave silicon diodes, can be tested effectively under actual operating conditions. However, crystal-rectifier testers are available to determine dc characteristics that provide an indication of crystal-diode quality.

A common type of crystal-diode test set is a combination ohmmeter-ammeter. Measurements of forward resistance, back resistance, and reverse current can be made with this equipment. Using the results of these measurements, you can determine the relative condition of these components by comparing their measured values with typical values obtained from test information furnished with the test set or from the manufacturer's data sheets. A check that provides a rough indication of the rectifying property of a diode is the comparison of the back-and-forward resistance of the diode at a specified voltage. A typical back-to-forward-resistance ratio is on the order of 10 to 1, and a forward-resistance value of 50 to 80 ohms is common.

Q-11. What is the typical back-to-forward resistance ratio of a good-quality diode?

Testing Diodes with an Ohmmeter

A convenient test for a semiconductor diode requires only an ohmmeter. The back-and-forward resistance can be measured at a voltage determined by the battery potential of the ohmmeter and the resistance range at which the meter is set. When the test leads of the ohmmeter are connected to the diode, a resistance will be measured that is different from the resistance indicated if the leads are reversed. The smaller value is called the FORWARD RESISTANCE, and the larger value is called the BACK RESISTANCE. If the ratio of back-to-forward resistance is greater than 10 to 1, the diode should be capable of functioning as a rectifier. However, keep in mind that this is a very limited test that does not take into account the action of the diode at voltages of different magnitudes and frequencies. (**NOTE**: This test should never be used to test crystal mixer diodes in radars. It will destroy their sensitivity.)

Testing Diodes with Oscilloscopes

An oscilloscope can be used to graphically display the back-and-forward resistance characteristics of a crystal diode. A circuit used in conjunction with an oscilloscope to make this test is shown in figure 2-15. This circuit uses the oscilloscope line-test voltage as the test signal. A series circuit (composed of resistor R1 and the internal resistance in the line-test circuit) decreases a 3-volt, open-circuit test voltage to a value of approximately 2 volts peak to peak.

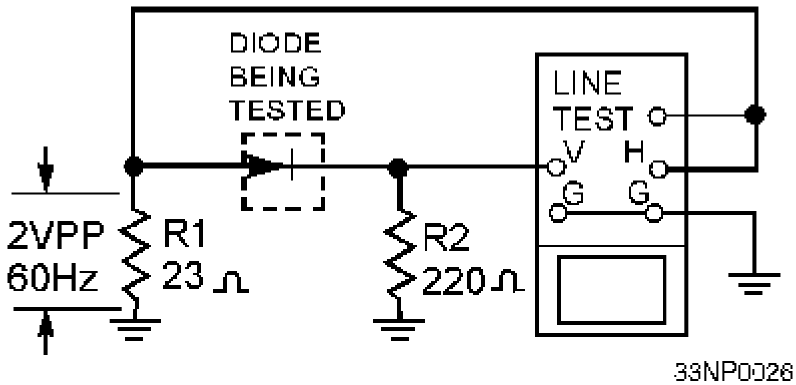

Figure 2-15.—Testing semiconductor diodes with an oscilloscope.

The test signal applied to the crystal diode is also connected to the horizontal input of the oscilloscope. The horizontal sweep represents the voltage applied to the diode under test. The voltage developed across current-measuring resistor R2 is applied to the vertical input of the oscilloscope. Because this voltage is proportional to the current through the diode being tested, the vertical deflection will indicate crystal current. The resulting oscilloscope trace for a normal diode is similar to the curve shown in figure 2-16.

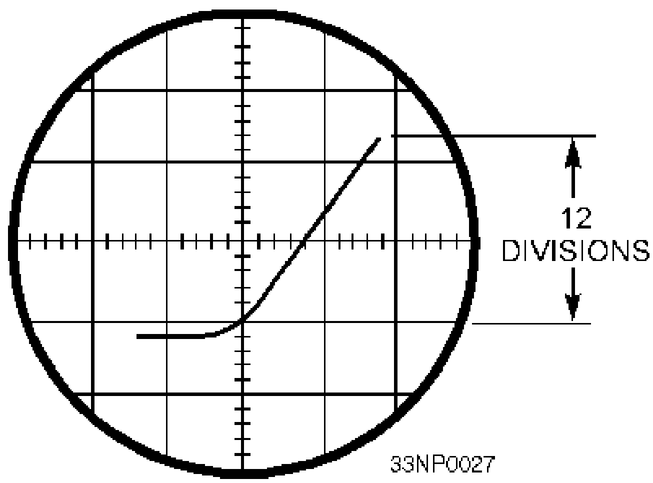

Figure 2-16.—Characteristic curve of a semiconductor diode.

To test Zener diodes, you must use a higher voltage than the oscilloscope line-test signal. This test can be made with a diode test set or with the circuit shown in figure 2-17. In this circuit, rheostat R1 is used to adjust the input voltage to a suitable value for the Zener diode being tested. Resistor R2 limits the current through the diode. The signal voltage applied to the diode is also connected to the horizontal input of the oscilloscope. The voltage developed across current-measuring resistor R3 is applied to the vertical input of the oscilloscope. The horizontal sweep represents the applied voltage, and the vertical deflection indicates the current through the diode being tested. Figure 2-18 shows the characteristic pattern of a Zener diode. Note the sharp increase in current at the Zener voltage (avalanche) point. For the Zener diode to be usable, this voltage must be within limits specified by the manufacturer.

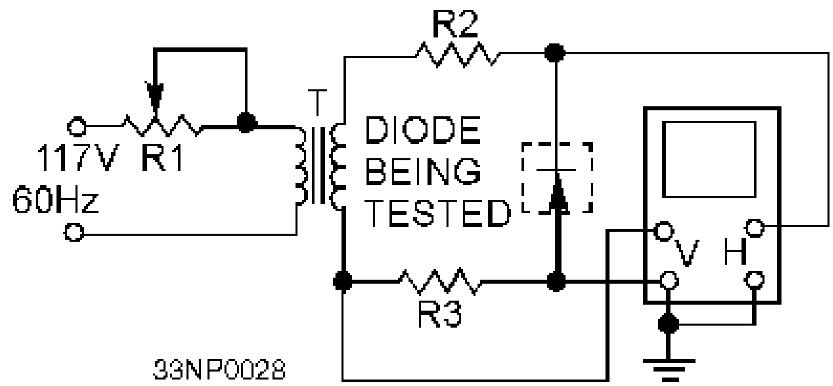

Figure 2-17.—Testing a Zener diode.

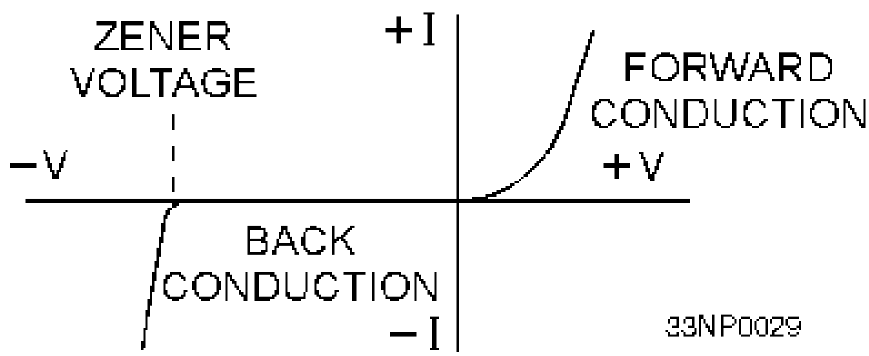

Figure 2-18.—Zener diode characteristic curve.

TESTING TRANSISTORS

Most transistorized equipments use printed circuit boards on which components are neatly arranged. This arrangement makes the transistors and other components easy to reach while you are troubleshooting and servicing the equipment. While investigating with test probes, however, you must be careful to prevent damage to the printed wiring.

One of the outstanding advantages of transistors is their reliability. Tube failures account for over 90 percent of the failures in electron-tube equipments. Transistors, however, are long lived. This factor, among others, decreases maintenance required to keep transistorized equipment operating. The techniques used in testing transistorized equipment are similar to those for maintaining electron-tube circuits. Basically, these techniques include several checks and inspections.

Power Supply Checks

When using test equipment to localize a trouble, you should check the power supply to see that its output voltages are present and of the correct values. Improper power supply voltages can cause odd effects. You will prevent many headaches by checking the power supply first.

Visual Inspection

Visual inspection is a good maintenance technique. Occasionally, you will find loose wires or faulty connections, making extensive voltage checks unnecessary.

Transistor Checks

Transistors can be checked by substitution. Transistors, however, have a characteristic known as *leakage current*, which may affect the results obtained when the substitution method is used.

The leakage current may influence the current gain or amplification factor of the transistor. Therefore, a particular transistor might operate properly in one circuit and not in another. This characteristic is more critical in certain applications than in others. As the transistor ages, the amount of leakage current tends to increase. One type of transistor checker used is the semiconductor test set. This test set can be used either for in-circuit or out-of-circuit tests or for collector leakage current or current gain. You should use extreme care when substituting transistors. More and more transistors have specific current and breakdown voltage requirements that may affect how they operate within a given circuit.

Q-12. As a transistor ages, what happens to the leakage current?

Voltage Checks

Voltage measurements provide a means of checking circuit conditions in a transistorized circuit just as they do in checking conditions in a tube circuit. The voltages, however, are much lower than in a tube circuit. The bias voltage between the base and emitter, for instance, is usually 0.05 to 0.20 volts. When making checks, observe polarity.

Resistance Checks

Transistors have little tendency to burn or change value because of low voltage in their circuits. They can, however, be permanently damaged by high-voltage conditions that occur when the collector voltage is increased. They can also be permanently damaged when the ambient temperature increases and causes excessive collector current flow. Transistors are easily damaged by high current; therefore, resistance measurements must not be taken with an ohmmeter that provides a maximum current output in excess of 1 milliampere. If you are not sure that the range of ohmmeter you want to use is below the 1 milliampere level, connect the ohmmeter to a milliammeter and check it. See figure 2-19 for a method of measuring the current from an ohmmeter.

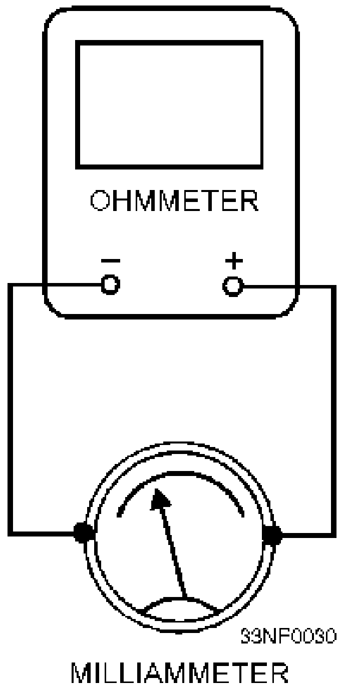

Figure 2-19.—Measuring current passed by an ohmmeter.

Resistance measurements usually are not made in transistorized circuits, except when you are checking for open windings in transformers and coils. When a resistance check is required, the transistors are usually removed from the circuit. Resistance checks cannot test all the characteristics of transistors, especially transistors designed for high frequencies or fast switching. The ohmmeter is capable of making simple transistor tests, such as open and short tests.

Refer to NEETS, Module 7, *Introduction to Solid-State Devices and Power Supplies*, for a review of transistor and semiconductor terms and theory.

SUMMARY

The important points of this chapter are summarized in the following paragraphs:

The **BEL** is a unit that expresses the logarithmic ratio between the input and output of any given component, circuit, or system and can be expressed in terms of voltage, current, or power.

Any figure expressed in bels can be converted to DECIBELS by multiplying the figure by 10. The decibel cannot be used to represent actual power, only a ratio of one power to another.

The abbreviation dBm is used to represent power levels above or below a 1 milliwatt reference level.

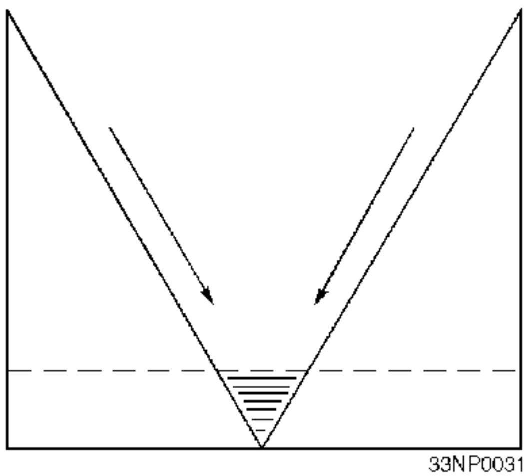
A **BOLOMETER** is a device that undergoes changes in resistance as changes in dissipated power occur. The two types of bolometers most often used are the barretter and the thermistor.

FREQUENCY MEASUREMENTS can be divided into two broad categories: mechanical-rotation frequency and electrical-output frequency measurements.

MECHANICAL ROTATION frequency is measured using a device called a TACHOMETER. Three basic tachometers are used for measuring mechanical rotation frequency—the CENTRIFUGAL tachometer, the CHRONOMETRIC tachometer, and the STROBOSCOPIC tachometer.

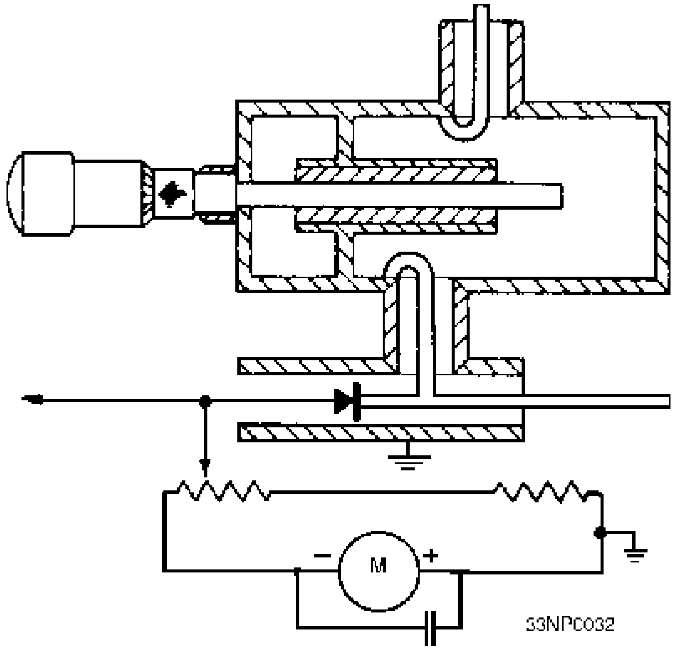
ELECTRICAL-OUTPUT frequencies of ac generators can be measured by VIBRATING-REED devices or TUNED CIRCUITS.

AUDIO FREQUENCIES can be measured by a process known as ZERO BEATING. This is done by matching an unknown signal with a locally generated signal of the same frequency obtained from a calibrated high-precision oscillator. As the two frequencies are brought closer to the same value, they reach a point of zero beat. This is when the frequency generated in the oscillator is equal to the frequency of the unknown signal being measured. Another term for zero beating is HETERODYNING.



WAVEMETERS are calibrated resonant circuits used to measure frequency. Any type of resonant circuit can be used in wavemeter applications. The type used depends on the frequency range for which the meter is intended.

For measuring frequencies in the microwave range, the CAVITY WAVEMETER is the type most commonly used.



The **CATHODE-RAY OSCILLOSCOPE** and the SPECTRUM ANALYZER are used to perform WAVEFORM ANALYSIS.

A typical **BACK-TO-FORWARD-RESISTANCE** ratio for a diode is 10 to 1.

ANSWERS TO QUESTIONS Q1. THROUGH Q12.

A-1. Bel.

A-2. dBm.

A-3. 4 mW.

A-4. Dummy load or dummy antenna.

A-5. Barretter and thermistor.

A-6. It increases.

A-7. Beat frequency.

A-8. Wavemeter.

A-9. Oscilloscope and spectrum analyzer.

A-10. Spectrum analyzer.

A-11. 10-to-1 ratio.

A-12. It tends to increase.

CHAPTER 3

BASIC METERS

LEARNING OBJECTIVES

Upon completing this chapter, you should be able to:

1. Describe the basic theory of the galvanometer.
2. Describe the basic theory of the D'Arsonval meter movement.
3. State the proper procedure for connecting an ammeter to a circuit.
4. Define ammeter sensitivity.
5. State the proper procedure for connecting a voltmeter to a circuit.
6. Describe possible effects on a circuit caused by the connection of a voltmeter.
7. Define voltmeter sensitivity.
8. Describe the internal operation of an ohmmeter with the use of a block diagram.
9. Describe the operating procedure for using a megohmmeter.
10. Describe the use of the electrodynamometer-type meter as a voltmeter, ammeter, and wattmeter.
11. Describe the factors that limit wattmeter capability.
12. Describe an open circuit, a ground, a short, and the tests used to check for these conditions.

INTRODUCTION

When troubleshooting, testing, or repairing electronic equipment, you will use various meters and other types of test equipment to check for proper circuit voltages, currents, resistances, and to determine if the wiring is defective. You may be able to connect these test instruments to a circuit and take readings without knowing just *how* the instruments operate. However, to be a competent technician, you need to be able to do more than merely read a test instrument. You need a basic knowledge of how test instruments operate. This chapter discusses the operating principles of some of the test instruments you will use in equipment troubleshooting.

METERS

The best and most expensive measuring instrument is of no use to you unless you know what you are measuring and what each reading indicates. Remember that the purpose of a meter is to measure quantities existing within a circuit. For this reason, when the meter is connected to the circuit, it must not change the condition of the circuit.

METER POWER SOURCE

Meters are either SELF-EXCITED or EXTERNALLY EXCITED. Self-excited meters operate from their own power sources. Externally excited meters get their power from the circuit to which they are connected. Most common meters (voltmeters, ammeters, and ohmmeters) that you use in your work operate on the electromagnetic principle. All measuring instruments must have some form of indicating device, usually a meter, to be of any use to you. The most basic indicating device used in instruments that measure current and voltage operates by using the interaction between the magnetic fields associated with current flow in the circuit. Before continuing, you might want to review the properties of magnetism and electromagnetism in NEETS, Module 1, *Introduction to Matter, Energy, and Direct Current*.

Q-1. What meters operate from their own power sources?

BASIC METER MOVEMENT

A stationary, permanent-magnet, moving-coil meter is the basic meter movement used in most measuring instruments used for servicing electrical equipment. When current flows through the coil, a resulting magnetic field reacts with the magnetic field of the permanent magnet and causes the movable coil to rotate. The greater the intensity of current flow through the coil, the stronger the magnetic field produced; the stronger the magnetic field produced, the greater the rotation of the coil. The GALVANOMETER is an example of one type of stationary, permanent-magnet, moving-coil measuring instrument.

Galvanometer

The galvanometer is used to measure very low currents, such as those in bridge circuits. In modified form, the galvanometer has the highest sensitivity of any of the various types of meters in use today. A simplified diagram of a galvanometer is shown in figure 3-1. It is different from other instruments used for the same purpose because its movable coil is suspended by means of metal ribbons instead of a shaft and jewel-bearing arrangement often used in other instruments.

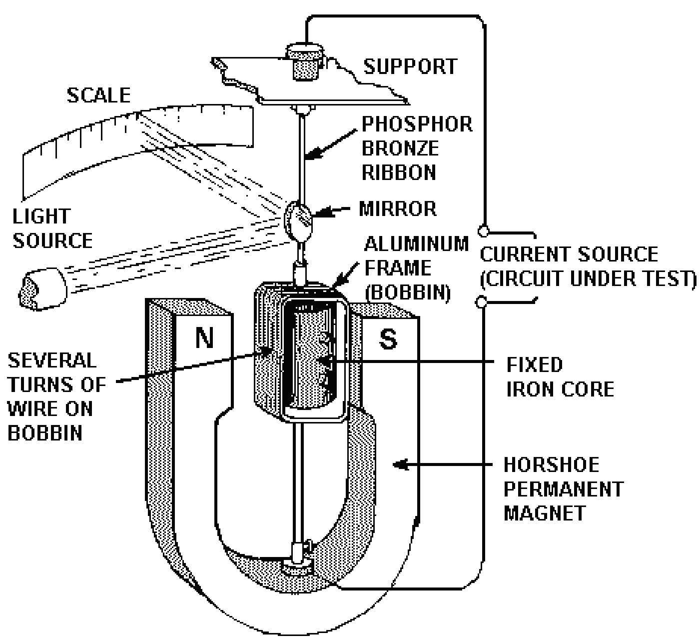


Figure 3-1.—Simplified galvanometer.

The movable coil is wrapped around the aluminum frame of the galvanometer. The coil is suspended between the poles of the magnet by means of thin, flat ribbons of phosphor bronze. These ribbons provide a conduction path for the current between the circuit being tested and the movable coil. The ribbons allow the coil to twist in response to the interaction of the applied current through the coil and the magnetic field of the permanent magnet. They also provide the restoring force for the coil. Basically, the restoring force is that force necessary to return the movable frame to its resting position after a reading. The ribbons restrain or provide a counterforce to the magnetic force acting on the coil. When the driving force of the coil current is removed, the restoring force provided by the ribbons returns the coil to its zero position.

Q-2. What physical component of a galvanometer provides the restoring force for the coil?

To determine the amount of current flow, we must have a means to indicate the amount of coil rotation. Either of two methods may be used: (1) the **POINTER** arrangement or (2) the **LIGHT AND MIRROR** arrangement.

Q-3. In a galvanometer, what two methods are used to indicate the amount of coil rotation?

In the pointer arrangement, one end of the pointer is mechanically connected to the rotating coil; as the coil moves, the pointer also moves. The other end of the pointer moves across a graduated scale and indicates the amount of current flow. The overall simplicity of this arrangement is its main advantage. However, a disadvantage of this arrangement is that it introduces a mechanical coil balancing problem, especially if the pointer is long.

Q-4. What is the primary disadvantage of the pointer arrangement for indicating coil rotation?

In the light and mirror arrangement, the use of a mirror and a beam of light simplifies the problem of coil balance. When this arrangement is used to measure the turning of the coil, a small mirror is mounted on the supporting ribbon, as shown in figure 3-1. An internal light source is directed to the mirror and then reflected to the scale of the meter. As the movable coil turns, so does the mirror. This causes the light reflection to move across the graduated scale of the meter. The movement of the reflection is proportional to the movement of the coil; therefore, the intensity of the current being measured by the meter is accurately indicated.

If the beam of light and mirror arrangement is used, the beam of light is swept to the right or left across a translucent screen (scale). The translucent screen is divided uniformly with the zero reading located at center scale. If the pointer arrangement is used, the pointer is moved in a horizontal plane to the right or left across a scale that is divided uniformly with the zero reading at the center. The direction in which the beam of light or the pointer moves depends on the direction (polarity) of current through the coil.

D'Arsonval Meter Movement

Most dc instruments use meters based on some form of the D'Arsonval meter movement. In D'Arsonval-type meters, the length of the conductor and the strength of the field between the poles of the magnet are fixed. Therefore, any change in current causes a proportional change in the force acting on the coil. Figure 3-2 is a simplified diagram showing the principle of the D'Arsonval movement.

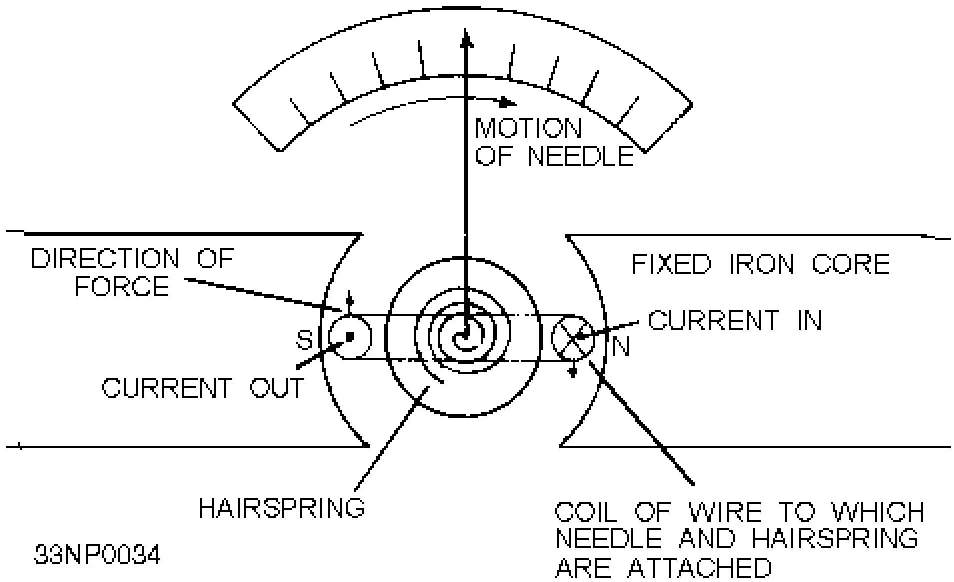

Figure 3-2.—D'Arsonval meter movement.

In the figure, only one turn of wire is shown; however, in an actual meter movement, many turns of fine wire would be used, each turn adding more effective length to the coil. The coil is wound on an aluminum frame (bobbin) to which the pointer is attached. Oppositely wound hairsprings (only one is shown in the figure) are also attached to the bobbin, one at either end. The circuit to the coil is completed through the hairsprings. In addition to serving as conductors, the hairsprings serve as the restoring force that returns the pointer to the zero position when no current flows.

Q-5. What component of the D'Arsonval meter movement completes the circuit for current flow to the coil?

COIL MOVEMENT.—As we discussed previously, the deflecting (moving) force on the coil is proportional to the current flowing through the coil. This deflecting force tends to cause the coil to rotate against the restraining force of the hairsprings. When the deflecting force and the restraining force are equal, the coil and the pointer stop moving. As we have just stated, the deflecting force is proportional to the current in the coil, the angle (amount) of rotation is proportional to the deflecting force; therefore, the angle of rotation is proportional to the current through the coil. When current stops flowing through the coil, the deflecting force stops, and the restoring force of the springs returns the pointer to the zero position.

Q-6. What component supplies restoring force to the coil of the D'Arsonval meter movement?

DIRECTION OF FORCE.—The current through the single turn of wire is in the direction indicated in the figure (away from you on the right-hand side and toward you on the left-hand side). If we apply the right-hand motor rule, the direction of force is upward on the left-hand side and downward on the right-hand side; therefore, the direction of motion of the coil and pointer is clockwise. If the current were reversed in the wire, the direction of motion of the coil and pointer would be reversed. For a review of the right-hand rule for motors, refer to NEETS, Module 5, *Introduction to Generators and Motors*.

PRINCIPLE OF OPERATION.—A more detailed view of the basic D'Arsonval movement, as it is used in ammeters and voltmeters, is shown in figure 3-3. The principle of operation is the same as that discussed in the simplified version. The iron core is rigidly supported between the pole pieces; it serves to concentrate the flux in the narrow space between the iron core and the pole piece. Current flows into one hairspring, through the coil, and out the other hairspring. The restoring forces of the spiral springs return the pointer to the normal zero position when the current through the coil is interrupted. Conductors connect the hairsprings with the outside terminals of the meter. If the instrument is not DAMPED to absorb the energy of the moving element, the pointer will oscillate (vibrate) for a period of time before coming to a stop in its final position. Damping is an energy-absorbing system that prevents this.

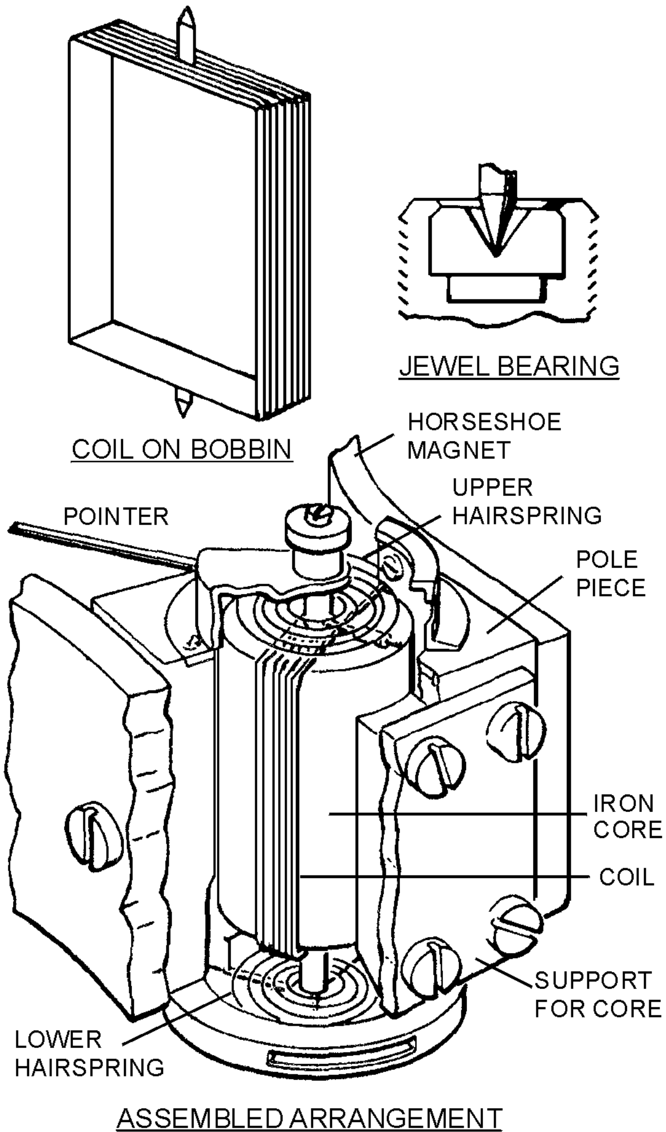

Figure 3-3.—Detailed view of the basic D'Arsonval meter movement.

DAMPING.—This is accomplished in many D'Arsonval movements by means of the motion of the aluminum bobbin on which the coil is wound. As the bobbin rotates in the magnetic field, an electromotive force is induced into it as it cuts through the lines of force. Induced currents flow in the bobbin in a direction opposite to the motion; this causes the bobbin to go beyond its final position only once before stopping. The overall sensitivity of the meter can be increased by the use of a lightweight rotating assembly (bobbin, coil, and pointer) and by the use of jewel bearings, as shown in figure 3-3.

POLE CONSTRUCTION.—Note that the pole pieces in figures 3-2 and 3-3 have curved faces. You can see the advantage of this type of construction if you remember that lines of force enter and leave a magnetic field in the air gap at right angles to the coil, regardless of the angular position of the coil. Because of this type of construction, a more linear scale is possible than if the pole faces were flat.

Q-7. What advantage is gained by using pole pieces with curved faces in the D'Arsonval meter movement?

DC AMMETER

The movable coil of the D'Arsonval meter movement we have been discussing up to now uses small-size wire in its windings. This small-size wire places limits on the amount of current that can be safely passed through the coil. Therefore, the basic D'Arsonval movement discussed can be used to indicate or measure only very small currents. Certain circuit changes must be made to the basic D'Arsonval meter movement for it to be practical in everyday use. To measure large currents, you must use a SHUNT with the meter.

Shunts

A shunt is a physically large, low-resistance conductor connected in parallel (shunt) with the meter terminals. It is used to carry the majority of the load current. Such a shunt is designed with the correct amount of resistance so that only a small portion of the total current flows through the meter coil. The meter current is proportional to the total load current. If the shunt is of such a value that the meter is calibrated in milliamperes, the instrument is called a MILLIAMMETER. If the shunt has such a value that the meter must be calibrated in terms of amperes, it is called an AMMETER.

Q-8. What structurally large, low-resistance conductor is connected in parallel with the meter movement to prevent damage?

SHUNT RESISTANCE.—A single, standardized meter movement is normally used in all ammeters, no matter what the range is for a particular meter. For example, meters with working ranges of 0 to 10 amperes, 0 to 5 amperes, or 0 to 1 ampere all use the same meter movement. The various ranges are achieved through the use of different values of shunt resistance with the same meter movement. The designer of the ammeter simply calculates the correct shunt resistance required to extend the range of the meter movement to measure any desired value of current. This shunt is then connected across the meter terminals. Shunts may be located inside the meter case (internal shunts) with the proper switching arrangements for changing them. They may also be located outside the meter case (external shunts) with the necessary leads to connect them to the meter.

EXTERNAL SHUNTS.—An external-shunt circuit is shown in figure 3-4, view A. Typical external shunts are shown in view B. View C shows a meter movement mounted within the case. The case provides protection against breakage, magnetic shielding in some cases, and portability.

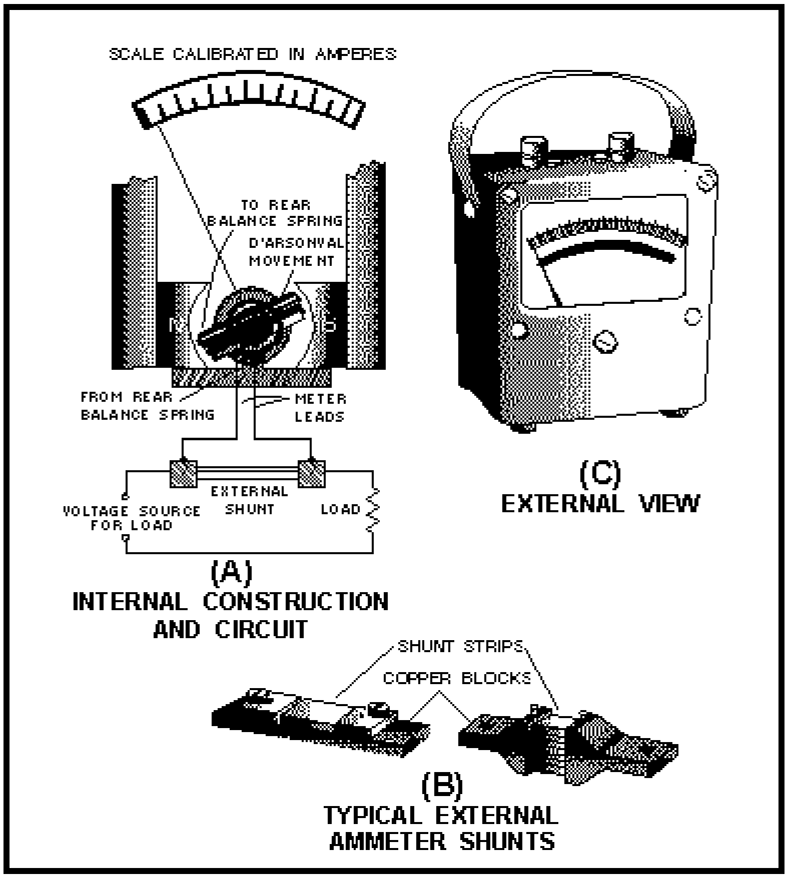

Figure 3-4.—Dc ammeter using the D'Arsonval movement with external shunts.

SHUNT CONSTRUCTION.—The shunt strips (view B of figure 3-4) are usually made of the alloy *Manganin*. Manganin has a temperature coefficient of almost zero. The zero-temperature coefficient property is desirable because of the heavy currents that often flow through shunts producing heat. A zero-temperature coefficient material is not affected by this heat; therefore, it remains stable in temperature. Most other materials increase their resistance as they are heated. If shunts were made of these materials, they would carry less current. More and more current would flow through the meter movement, and the chances of damage would increase. Using shunts constructed with zero-temperature coefficient materials eliminates this problem.

Q-9. What type of temperature coefficient material does not produce increased heat in response to increased current flow?

The ends of the shunt strips are embedded in heavy copper blocks. The blocks are attached to the meter coil leads and the line terminals. To ensure accurate readings, you should not interchangeably use the meter leads for a particular ammeter with those for a meter of a different range. Slight changes in lead length and size may vary the resistance of the meter circuit. If this happens, current will also change and cause incorrect meter readings. External shunts are generally used where currents greater than 50 amperes must be measured.

SHUNT SELECTION.—When using an external-shunt ammeter, you should select a suitable shunt so that the scale deflection can be easily read. For example, if the scale has 150 divisions and the load current you want to measure is known to be between 50 and 100 amperes, a 150-ampere shunt would be the correct choice. Under these conditions, each division of the scale represents 1 ampere. In other words, a full-scale deflection of the pointer would rest on the 150th division mark, indicating that 150 amperes of load current is flowing. At half-scale deflection, the pointer would rest on the 75th division mark, indicating that 75 amperes of load current is flowing.

A shunt having exactly the same current rating as the expected normal load current should **never** be selected. If you were to select such a shunt, higher than normal load currents could possibly drive the pointer off scale and damage the meter movement. A good choice of shunt values will place the indicating needle somewhere near the midscale indication when the load current you are reading is normal. For example, assume that the meter scale is divided into 100 equal divisions and you want to measure a current of 60 amperes. The shunt to use would be a 100-ampere shunt. This would make each division of the scale equal to 1 ampere. The meter indication would fall on the 60th division showing that 60 amperes of load current is flowing. Therefore, an allowance (40 amperes) remains for unexpected surge currents.

Q-10. A good choice of shunt resistance will place the indicating pointer near what part of the meter scale with a normal load?

INTERNAL SHUNTS FOR METERS IN THE 0- TO 50-AMPERE RANGE.—When measuring current ranges below 50 amperes, you will most often use internal shunts (R_{shunt}). In this way, you can easily change the range of the meter by means of a switching arrangement. A switch will select the correct internal shunt with the necessary current rating and resistance. Before you can calculate the required resistance of the shunt for each range, the total resistance of the meter movement must be known. For example, suppose you desire to use a 100-microampere D'Arsonval meter with an internal coil resistance of 100 ohms to measure line currents up to 1 ampere. The meter will deflect to its full-scale position when the current through the deflection coil is 100 microamperes.

Since the coil resistance is 100 ohms, you can calculate the coil's voltage (E_{coil}) by using Ohm's law, as follows:

$$\begin{aligned} E_{coil} &= I \times R_{coil} \\ &= 0.0001 \text{ amperes} \times 100 \text{ ohms} \\ &= 0.01 \text{ volt} \end{aligned}$$

When the pointer is deflected to full scale, 100 microamperes of current flows through the coil and 0.01 volt drops across it. Remember, 100 microamperes is the maximum safe current for this meter movement. Exceeding this value will damage the meter. The shunt must carry any additional load current.

The meter coil has a 0.01 volt drop across it, and, because the shunt and coil are in parallel, the shunt also has a voltage drop of 0.01 volt. The current that flows through the shunt is the difference between the full-scale meter current and the line current being fed into the shunt. In this case, meter current is 100 microamperes. Full-scale deflection is desired only when the total current is 1 ampere. Therefore, the shunt current must equal 1 ampere minus 100 microamperes, or 0.9999 ampere. Ohm's law is again used to provide the approximate value of required shunt resistance (R_{shunt}), as follows:

$$\begin{aligned} R_{shunt} &= \frac{E}{I} \\ &= \frac{0.01 \text{ volt}}{0.999 \text{ ampere}} \\ &= 0.01 \text{ ohm} \end{aligned}$$

To increase the range of the 100-microampere meter to 1 ampere (full-scale deflection), place a 0.01-ohm shunt in parallel with the meter movement.

You can convert the 100-microampere instrument to a 10-ampere meter by using a proper shunt. The voltage drop for a full-scale deflection is still 0.01 volt across the coil and the shunt. The meter current is still 100 microamperes. The shunt current must therefore be 9.9999 amperes under full-scale deflection. Again, this is an approximate figure found by the application of Ohm's law.

You can also convert the same instrument to a 50-ampere meter by using the proper shunt resistance, as follows:

$$\begin{aligned} R_{shunt} &= \frac{E}{I} \\ &= \frac{0.01 \text{ volt}}{49.999 \text{ amperes}} \\ &= 0.0002 \text{ ohm} \end{aligned}$$

INTERNAL SHUNTS FOR METERS IN THE MILLIAMPERE RANGE.—The above method of computing the shunt resistance is satisfactory in most cases; however, it can only be used when the line current is in the ampere range and the meter current is relatively small compared to the load current. In such cases, you can use an approximate value of resistance for the shunt, as was done above. However, when the line current is in the milliampere range and the coil current becomes an appreciable percentage of the line current, a more accurate calculation must be made. For example, suppose you desire to use a meter movement that has a full-scale deflection of 1 milliampere and a coil resistance of 50 ohms to measure currents up to 10 milliamperes. Using Ohm's law, you can figure the voltage (E_{coil}) across the meter coil (and the shunt) at full-scale deflection, as follows:

$$\begin{aligned} E_{coil} &= I \times R \\ &= 0.001 \text{ ampere} \times 50 \text{ ohms} \\ &= 50 \text{ millivolts} \end{aligned}$$

The current that flows through the shunt (I_{shunt}) is the difference between the line current and the meter current, as figured below:

$$\begin{aligned} I_{shunt} &= I_{total} - I_{meter} \\ &= 10 \text{ mA} - 1 \text{ mA} \\ &= 9 \text{ mA or } 0.009 \text{ ampere} \end{aligned}$$

The shunt resistance (R_{shunt}) may then be figured, as follows:

$$\begin{aligned} R_{shunt} &= \frac{E}{I} \\ &= \frac{0.05 \text{ volt}}{0.009 \text{ ampere}} \\ &= 5.55 \text{ ohms} \end{aligned}$$

Notice that, in this case, the exact value of shunt resistance has been used rather than an approximation.

The formula for determining the resistance of the shunt is given by $R_s = I_m / I_s$ times R_m, where R_s is the shunt resistance in ohms; I_m is the meter current at full-scale deflection; I_s is the shunt current at full-scale deflection; and R_m is the resistance of the meter coil. If the values given in the previous example are used in this equation, it will yield 5.55 ohms, the value previously calculated.

SWITCHING SHUNT VALUES.—Various values of shunt resistance can be used, by means of a suitable switching arrangement, to increase the number of current ranges that can be covered by the meter. Two switching arrangements are shown in figure 3-5. View A is the simpler of the two arrangements when a number of shunts are used to calculate the values of the shunt resistors. However, it has two disadvantages:

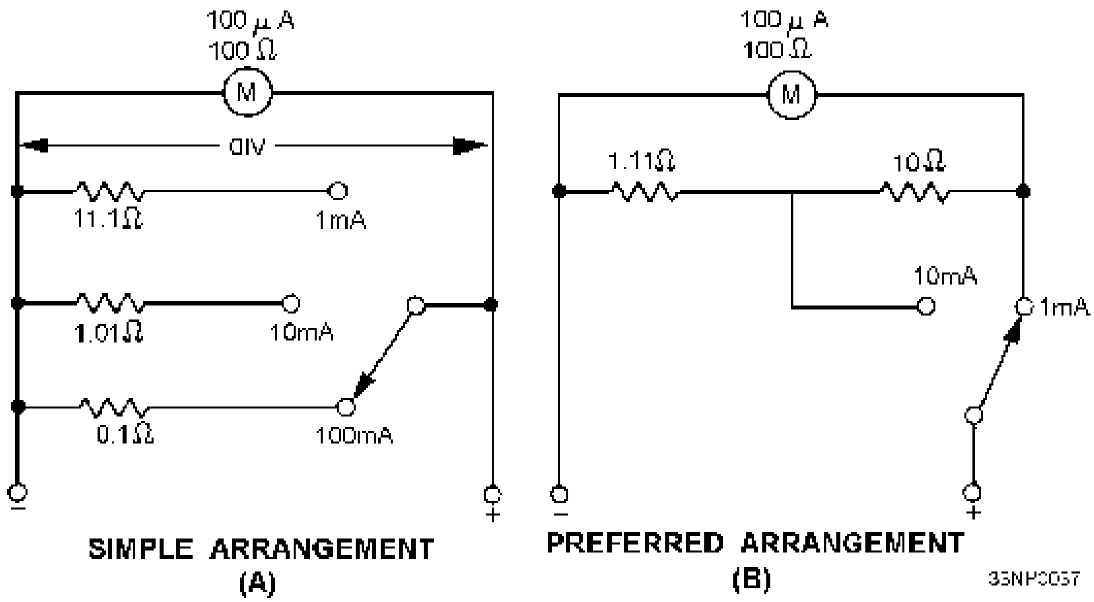

Figure 3-5.—Ways of connecting internal meter shunts.

1. When the switch is moved from one shunt resistor to another, the shunt is momentarily removed from the meter. The line current then flows through the meter coil. Even a momentary surge of current could easily damage the coil.

2. The contact resistance (resistance between the blades of the switch when they are in contact) is in series with the shunt, but not with the meter coil. In shunts that must pass high currents, this contact resistance becomes an appreciable part of the total shunt resistance. Because the contact resistance is of a variable nature, the ammeter indication may not be accurate.

The generally preferred method of range switching is shown in (figure 3-5, view B). Although only two ranges are shown, as many ranges as needed can be used. In this type of circuit, the contact resistance of the range-selector switch is external to the shunt and meter in each range position. The contact resistance in this case has no effect on the accuracy of the current measurement.

Ammeter Connections

When you are using ammeters, a primary rule of safety is that such current-measuring instruments must always be connected **in series** with a circuit, never in parallel with it. When an ammeter is connected across a constant-potential source of appreciable voltage, the low internal resistance of the meter bypasses the circuit resistance. This results in the application of the source voltage (or a good portion of it) directly to the meter terminals. The resulting excessive current burns up the meter coil and renders the meter useless until repaired.

Q-11. In what manner are current-measuring instruments connected to a circuit?

If you do not know the approximate value of current in the circuit, you should take a reading at the highest range of the ammeter; then you should switch progressively to lower ranges until a suitable reading is obtained. Most ammeter scales indicate the current being measured in increasing values from left to right. If you connect the meter without observing proper polarity, the pointer may be deflected backwards (from right to left). This action often damages the meter movement. You should ensure that the ammeter is always connected so that the current will flow into the negative terminal and out the positive terminal. Figure 3-6 shows various circuit arrangements and the proper ammeter connection methods to measure current in various portions of the circuit.

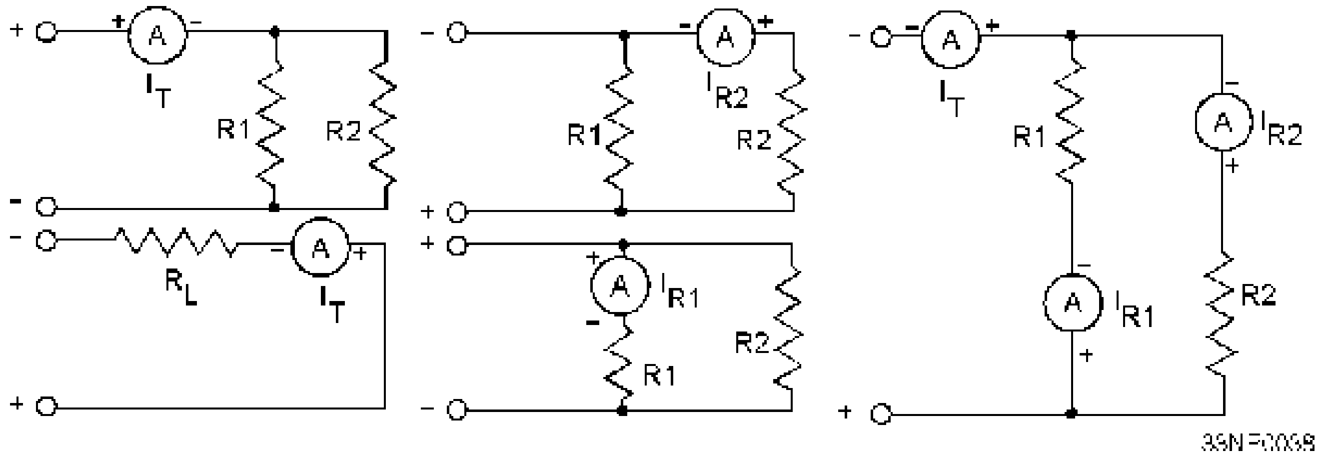

Figure 3-6.—Proper ammeter connection.

Q-12. An ammeter should always be connected so that current will flow into what terminal and out of what terminal?

Ammeter Sensitivity

Ammeter sensitivity is determined by the amount of current required by the meter coil to produce full-scale deflection of the pointer. The smaller the amount of current required to produce this deflection, the greater the sensitivity of the meter. A meter movement that requires only 100 microamperes for full-scale deflection has a greater sensitivity than a meter movement that requires 1 milliampere for the same deflection.

Q-13. (True or False) The larger the current required to produce full-scale deflection of the meter coil, the better the sensitivity of the meter.

Good sensitivity is especially important in ammeters to be used in circuits in which small currents flow. As the meter is connected in series with the load, the current flows through the meter. If the internal resistance of the meter is a large portion of the load resistance, an effect known as METER-LOADING will occur. Meter-loading is the condition that exists when the insertion of a meter into a circuit changes the operation of that circuit. This condition is not desirable. The purpose of inserting a meter into a circuit is to allow the measurement of circuit current in the normal operating condition. If the meter changes the circuit operation and changes the amount of current flow, the reading you obtain will be in error. An example of this is shown in figure 3-7.

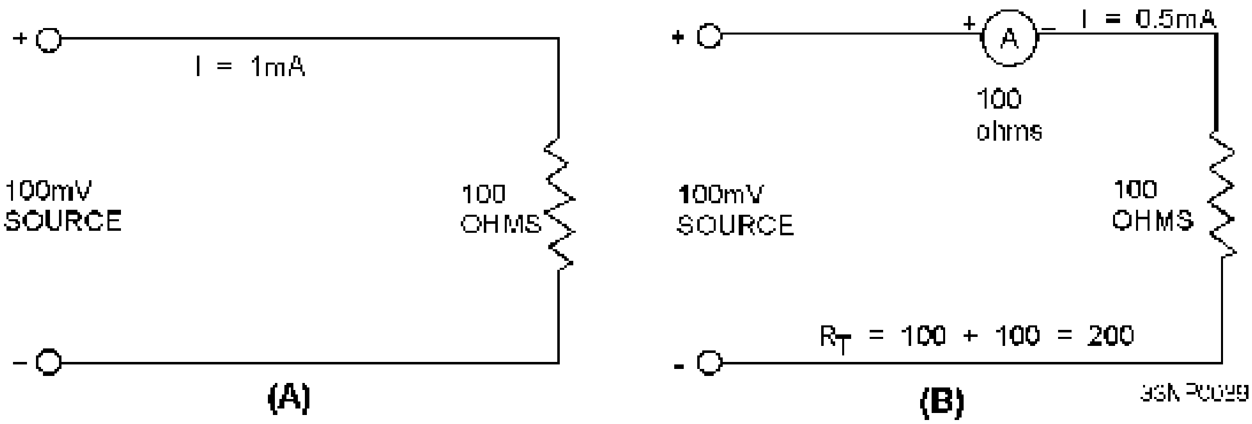

Figure 3-7.—Ammeter loading effect.

Q-14. What condition exists when the insertion of a meter into a circuit changes the operation of the circuit?

In view A of figure 3-7, the circuit to be tested has an applied voltage of 100 millivolts and a resistance of 100 ohms. The current normally flowing in this circuit is 1 milliampere. In view B, an ammeter that requires 1 milliampere for full-scale deflection and that has an internal resistance of 100 ohms has been inserted. Since 1 milliampere of current flow is shown in view A, you might naturally assume that with the meter inserted into the circuit, a full-scale deflection will occur. You might also assume that the 1 milliampere of circuit current will be measured. However, neither of these assumptions is correct. With the ammeter inserted into the circuit, as shown in view B, the total resistance of the circuit is 200 ohms. With an applied voltage of 100 millivolts, applying Ohm’s law shows the actual current ($I_{circuit}$) to be 0.5 milliampere.

$$I = \frac{E}{R}$$

$$I_{\text{circuit}} = \frac{100 \times 10^{-3}\,\text{volts}}{200\ \text{ohms}}$$

$$= 0.5 \times 10^{-3}\,\text{ampere}$$

$$= 0.0005\ \text{ampere or } 0.5\ \text{milliampere}$$

Since the meter reads 0.5 milliampere instead of the normal value of current, the meter reveals that a definite loading effect has taken place. In cases such as this, the use of ammeters, which have a lower internal resistance and a better current sensitivity, is desirable.

DC VOLTMETER

Up to this point, we have been discussing the 100-microampere D’Arsonval movement and its use as an ammeter. However, it can also be used to measure voltage if a MULTIPLIER (high resistance) is placed in series with the moving coil of the meter. For low-voltage instruments, this resistance is physically mounted inside the meter case with the D’Arsonval movement. The series resistance is constructed of a wire-wound resistance that has a low temperature coefficient wound on either a spool or card frame. For high-voltage ranges, the series resistance can be connected externally. A simplified diagram of a voltmeter is shown in figure 3-8.

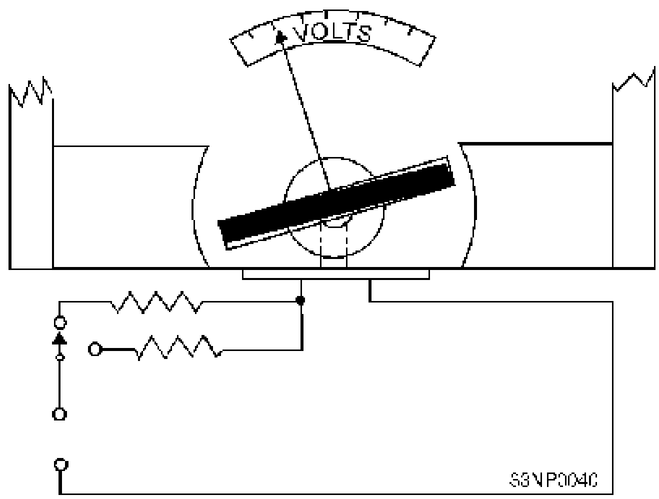

Figure 3-8.—Internal construction and circuit of a simplified voltmeter.

Q-15. What modification is made to the D’Arsonval meter movement to enable the meter to measure voltage?

Keep in mind that the D’Arsonval meter movement uses current flow to produce a magnetic field that is proportional to the current. The meter movement is, therefore, an indicator of current flow rather than voltage. The addition of the series resistance is what allows the meter to be calibrated in terms of voltage; that is, the meter movement of a voltmeter operates because of the current flow through the meter, but the scale is marked in volts. For example, the meter movement shown in figure 3-9 has an internal resistance of 100 ohms, requires 100 microamperes for full-scale deflection, and has a voltage drop of 10 millivolts when full-scale deflection is reached. If you were to place this meter directly across a 10-volt source, an excessive current (in milliamperes) would flow. The meter would be destroyed because of the excessive current flowing through the meter movement. This can be seen in the following Ohm’s law application:

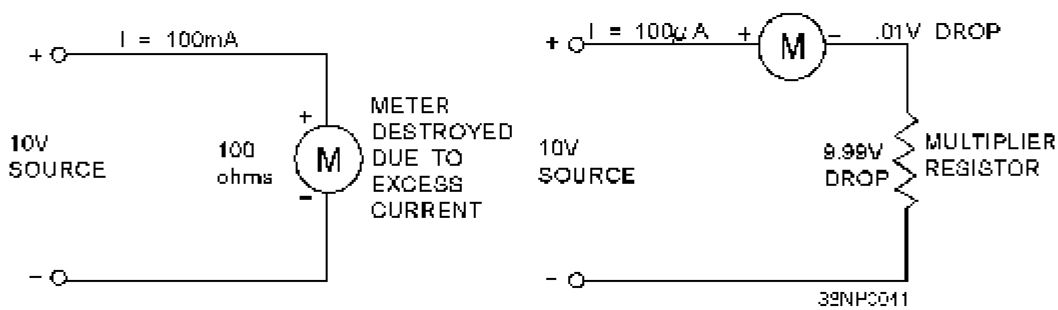

Figure 3-9.—Use of multiplier resistors with D'Arsonval meter movement.

Using this equation, you can see that a current through the meter of 100 milliamperes is excessive and will cause damage.

$$
\begin{aligned}
I &= \frac{E}{R} \\
&= \frac{10 \text{ volts}}{100 \text{ ohms}} \\
&= 100 \text{ milliamperes}
\end{aligned}
$$

Since the normal voltage drop for the meter is 10 millivolts at full-scale deflection, some means must be supplied to drop the extra 9.99 volts without applying it directly to the meter. This is done by the addition of a multiplier resistor, as shown in figure 3-9.

Extending Voltmeter Ranges

The value of series resistance is determined by the current required for full-scale deflection and by the range of the voltages to be measured. Since the current through the meter circuit is directly proportional to the applied voltage, the meter scale can be calibrated directly in volts for a fixed value of series resistance. For example, let's assume that the basic meter is to be made into a voltmeter with a full-scale deflection of 1 volt. The coil resistance of the basic meter is 100 ohms, and 100 microamperes of current causes full-scale deflection. The resistance (R_{meter}) required to limit the total current in the circuit to 100 microamperes can be found as follows:

$$
\begin{aligned}
R_{meter} &= \frac{E}{I} \\
&= \frac{1 \text{ volts}}{100 \text{ microamperes}} \\
&= 10 \text{ kilohms}
\end{aligned}
$$

Because the meter coil already measures 100 ohms, the series resistance required is equal to 10 kilohms minus 100 ohms, or 9.9 kilohms.

Q-16. What factors determine the value of the multiplier resistor?

Multirange voltmeters use one meter movement. The required resistances are connected in series with the meter by a switching arrangement. A schematic diagram of a multirange voltmeter with three ranges is shown in figure 3-10. The total meter resistance (R_{meter}) for each of the three ranges, beginning with the 1-volt range, is figured by the application of Ohm's law, as follows:

1 – volt range

$$R_{meter} = \frac{1}{.0001} = 10 \text{ kilohms}$$

100 – volt range

$$R_{meter} = \frac{100}{.0001} = 10 \text{ megohm}$$

1,000 – volt range

$$R_{meter} = \frac{1000}{.0001} = 10 \text{ megohms}$$

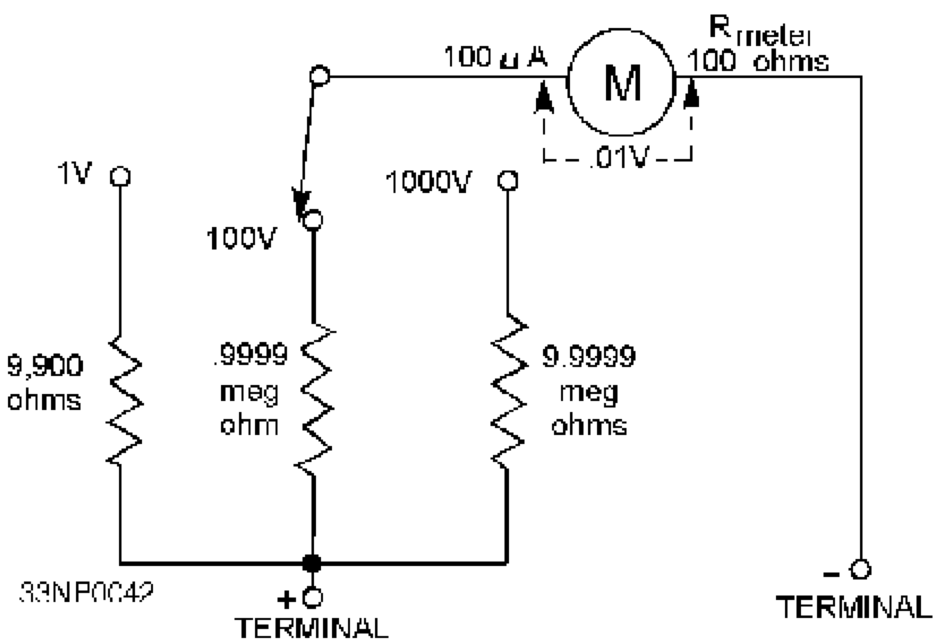

Figure 3-10.—Multirange voltmeter.

The actual value of the multiplying series resistor (R_{series}) for each of these circuits is 100 ohms less than the total resistance. This allows for the resistance of the meter coil (R_{coil}).

Voltmeter Circuit Connections

When voltmeters are used, a primary rule of safety is that such voltage-measuring instruments must always be connected in **parallel** with (across) a circuit. If you are unsure of the level of the voltage to be measured, take a reading at the highest range of the voltmeter and progressively (step by step) lower the range until a suitable reading is obtained. In many cases, the voltmeter you will be using will not be a center-zero- (0 reading is in the center) indicating instrument. Observing the correct polarity is important when connecting the instrument to the circuit. Voltmeter polarity is the same as for the dc ammeter; that is, current flows from negative to positive.

Q-17. In what manner are voltage-measuring instruments connected to the circuit to be measured?

Influence of a Voltmeter in a Circuit

The purpose of a voltmeter is to indicate the potential difference between two points in a circuit. When a voltmeter is connected across a circuit, it shunts the circuit. If the voltmeter has a low resistance, it will draw a substantial amount of current. This action lowers the effective resistance of the circuit and changes the voltage reading. When you are making voltage measurements in high-resistance circuits, use a HIGH-RESISTANCE VOLTMETER to prevent the shunting action of the voltmeter. The effect is less noticeable in low-resistance circuits because the shunting effect is less. The problem of voltmeter shunting (sometimes called circuit loading) is illustrated in figure 3-11.

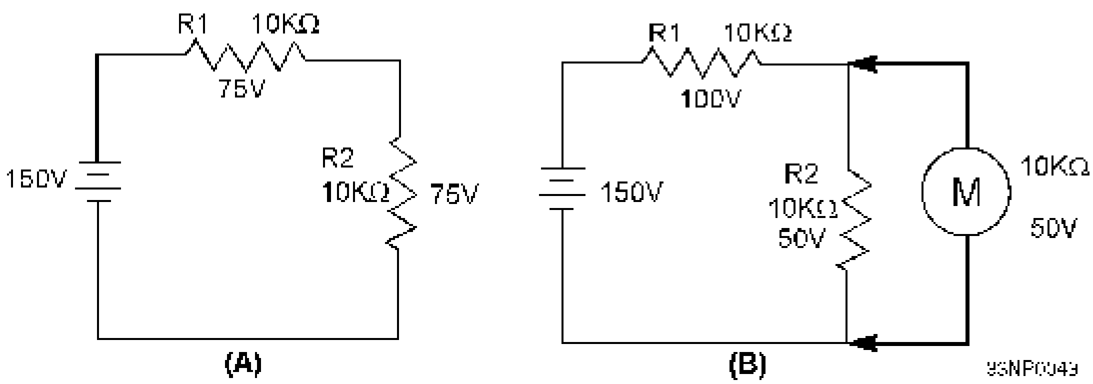

Figure 3-11.—Shunting action caused by a voltmeter.

Q-18. When making voltage measurements in a high-resistance circuit, you should always use a voltmeter with what relative value of resistance?

In view A of figure 3-11, a source of 150 volts is applied to a series circuit consisting of two 10-kilohm resistors. View A shows the voltage drop across each resistor to be 75 volts. In the 150-volt range, the voltmeter to be used has a total internal resistance of 10 kilohms. View B shows the voltmeter connected across the circuit. The parallel combination of R2 and the meter now present a total resistance of 5 kilohms. Because of the addition of the voltmeter, the voltage drops change to 100 volts across R1 and 50 volts across R2. Notice that this is not the normal voltage drop across R2. Actual circuit conditions have been altered because of the voltmeter.

Voltmeter Sensitivity

The sensitivity of a voltmeter is given in ohms per volt. It is determined by dividing the sum of the resistance of the meter (R_{meter}), plus the series resistance (R_{series}), by the full-scale reading in volts. In equation form, sensitivity is expressed as follows:

$$\text{sensitivity} = \frac{R_m + R_S}{E}$$

This is the same as saying the sensitivity is equal to the reciprocal of the full-scale deflection current. In equation form, this is expressed as follows:

$$\text{sensitivity} = \frac{\text{ohms}}{\text{volt}} = \frac{1}{\text{volt}/\text{ohms}} = \frac{1}{\text{ampere}}$$

Therefore, the sensitivity of a 100-microampere movement is the reciprocal of 0.0001 ampere, or 10,000 ohms per volt.

$$\text{sensitivity} = \frac{1}{\text{ampere}} = \frac{1}{.0001} = 10{,}000 \text{ ohms per volt}$$

Q-19. What term is used to express the sensitivity of a voltmeter?

METERS USED FOR MEASURING RESISTANCE

The two instruments you will use most often to check continuity, or to measure the resistance of a circuit or circuit component, are the OHMMETER and the MEGGER (MEGOHMMETER). The ohmmeter is widely used to measure resistance and to check the continuity of electrical circuits and devices. Its range usually extends to only a few megohms. The megger is widely used for measuring insulation resistance, such as that between a wire and the outer surface of its insulation, and the insulation resistance of cables and insulators. The range of a megger can be extended to more than 1,000 megohms.

Q-20. What instrument is used for measuring the insulation resistance of cables?

The Ohmmeter

A simple ohmmeter circuit is shown in figure 3-12. The ohmmeter consists of the dc milliammeter, discussed earlier in this chapter, and the added features shown below:

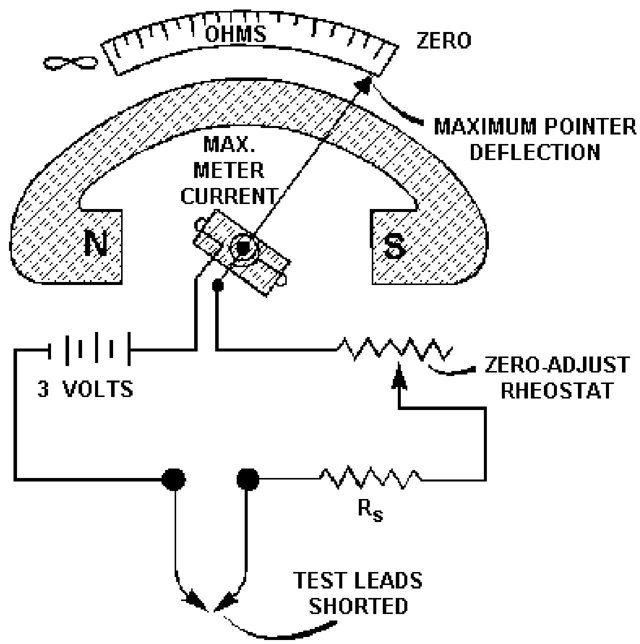

Figure 3-12.—Simple ohmmeter circuit.

- A source of dc potential; and
- One or more resistors (one of which is variable).

Q-21. What added features enable a dc milliammeter to function as an ohmmeter?

The deflection of the pointer of an ohmmeter is controlled by the amount of battery current passing through the moving coil. Before you can measure the resistance of an unknown resistor or electrical circuit, you must calibrate the ohmmeter to be used. If the value of resistance to be measured can be estimated within reasonable limits, select a range on the ohmmeter that will give approximately half-scale deflection when the resistance is inserted between the probes. If you cannot estimate the resistance to be measured, then set the range switch on the highest scale. Whatever range you select, the meter must be calibrated to read zero before the unknown resistance is measured.

To calibrate the meter, you first short the test leads together, as shown in figure 3-12. With the test leads shorted, a complete series circuit exists. The complete series circuit consists of the 3-volt source, the resistance of the meter coil (R_{meter}), the resistance of the zero-adjust rheostat, and the series multiplying resistor (R_{series}). The shorted test leads cause current to flow and the meter pointer to deflect.

Notice that the zero point on the ohmmeter scale (as opposed to the zero points for voltage and current) is located at the extreme right side of the scale. With the test leads shorted, the zero-adjust potentiometer is set so that the pointer rests on the zero mark. Therefore, a full-scale deflection indicates zero resistance between the leads.

Q-22. A full-scale deflection on an ohmmeter scale indicates what resistance between the leads?

If you change the range on the meter, you must "zero" (calibrate) the meter again to obtain an accurate reading. When you separate the test leads, the pointer of the meter will return to the left side of the scale. This action, as explained earlier, is caused by the restoring force of the spring tension acting on the movable coil assembly. The reading at the left side of the scale indicates an infinite resistance.

After you have adjusted the ohmmeter for zero reading, it is ready to be connected to a circuit to measure resistance. A typical circuit and ohmmeter arrangement is shown in figure 3-13. You must ensure that the power switch of the circuit to be measured is in the de-energized (OFF) position. This prevents the source voltage of the circuit from being applied to the meter, a condition that could cause severe damage to the meter movement.

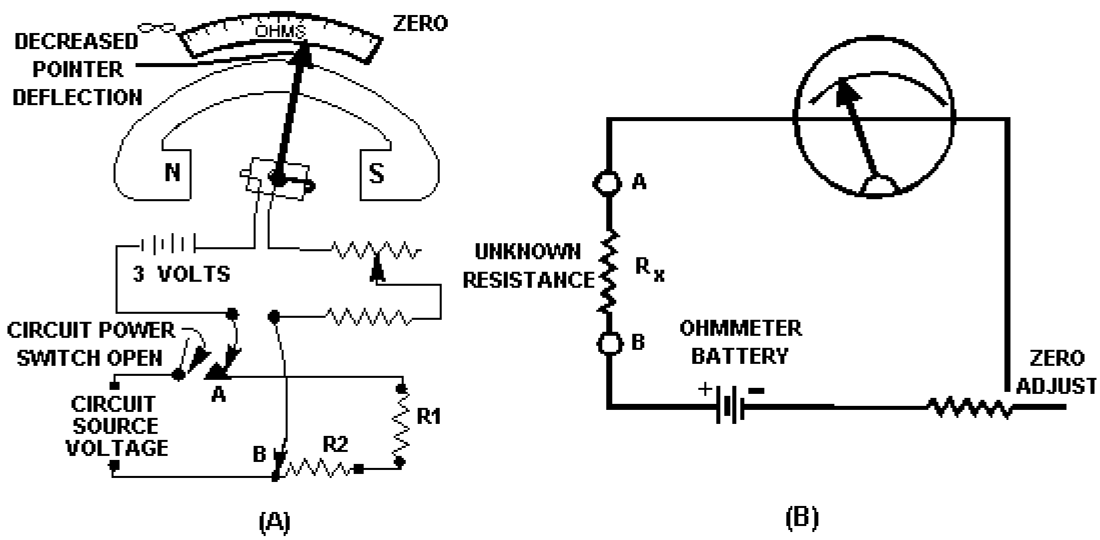

Figure 3-13.—Measuring circuit resistance with an ohmmeter.

Remember that the ohmmeter is an open circuit when the test leads are separated. To take a resistance reading with a meter, you must provide a path for current flow produced by the meter's battery. In view A of figure 3-13, the meter is connected at points **A** and **B** to produce this path. Connecting these test leads places resistors R1 and R2 in series with the resistance of the meter coil, the zero-adjust potentiometer, and the series multiplying resistor. Since you previously calibrated the meter, the amount of coil movement now depends only on the resistances of R1 and R2.

The addition of R1 and R2 into the meter circuit raises the total series resistance and decreases the current. This decreases the amount of pointer deflection. The pointer comes to rest at a scale reading that indicates the combined resistance of R1 and R2. If you were to replace either R1 or R2, or both, with a resistor having a larger ohmic value, the current flow in the moving coil of the meter would be decreased even more. This would further decrease the pointer deflection, and the scale indication would read a still higher circuit resistance. View B is a simplified version of the circuitry in view A.

From our ohmmeter discussion, two facts should be apparent: (1) Movement of the moving coil is proportional to the amount of current flow, and (2) the scale reading of the ohmmeter is inversely proportional to current flow in the moving coil.

The amount of circuit resistance to be measured may vary over a wide range. In some cases, it may only be a few ohms; in other cases, it may be as great as 1 megohm. Scale multiplication features are built into most ohmmeters so that they will indicate any ohmic value being measured and offer the least amount of error. Most ohmmeters are equipped with a selector switch for selecting the multiplication scale desired. For example, view A of figure 3-14 shows a typical meter that has a six-position switch. The positions are marked on the meter in multiples of 10, from R × 1 through R × 100K.

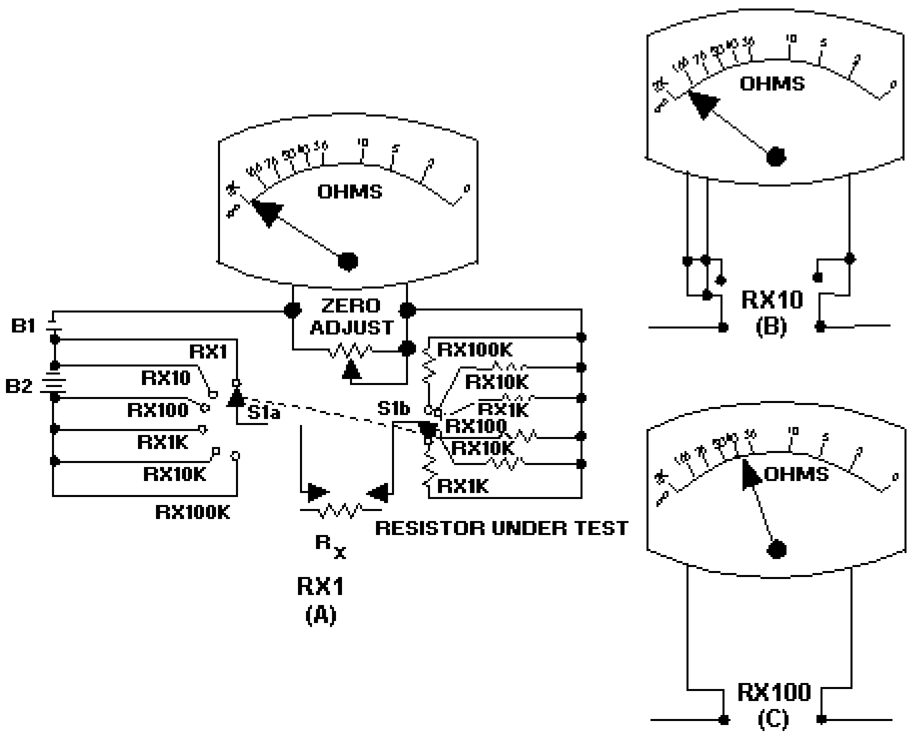

Figure 3-14.—Ohmmeter with multiplication switch.

The range used to measure any particular unknown resistance (R_x in view A of figure 3-14) depends on the approximate ohmic value of the unknown resistance. For instance, the ohmmeter scale of the figure is calibrated in divisions from 0 to infinity. Note that the divisions are easier to read on the right-hand portion of the scale than on the left. For this reason, if R_x is greater than 1,000 ohms and if you are using the R × 1 range, you will be unable to accurately read the indicated resistance. This happens because the combined series resistance of resistors R_x is too large for range R × 1 to allow enough battery current to flow to deflect the pointer away from infinity. You need to turn the range switch to the R × 10 position to obtain the 1,000-ohm reading.

Let's assume that you have changed the range switch to the R × 10 position and the pointer now deflects to a reading of 375 ohms, as shown in view B of figure 3-14. This would indicate to you that unknown resistance R_x has 3,750 (375 times 10) ohms of resistance. The change of range caused the deflection because resistor R × 10 has only 1/10 the resistance of resistor R × 1. Therefore, selecting the smaller series resistance allowed a battery current of sufficient value to cause a readable pointer deflection. If the R × 100 range were used to measure the same 3,750 ohm resistor, the pointer would deflect still further to the 37.5-ohm position, as shown in view C. This increased deflection would occur because resistor R × 100 has only 1/10 the resistance of resistor R × 10.

Q-23. The R × 100 resistance selection on an ohmmeter has what amount of resistance compared to the R × 10 selection?

The circuit arrangement in view A of figure 3-14 allows the same amount of current to flow through the moving meter coil. The same amount is allowed to flow whether the meter measures 10,000 ohms on the R × 1 scale, 100,000 ohms on the R × 10 scale, or 1,000,000 ohms on the R × 100 scale.

The same amount of current must always be used to deflect the pointer to a certain position on the scale (midscale position, for example), regardless of the multiplication factor being used. Since the multiplier resistors are of different values, you must always "zero" the meter for each multiplication scale selected. When selecting a range on the ohmmeter, select the one that will result in the pointer coming to rest as close to the midpoint of the scale as possible. This will enable you to read the resistance more accurately because scale readings are more easily interpreted at or near midpoint.

The Megohmmeter

An ordinary ohmmeter cannot be used for measuring multimillion ohm values of resistances, such as those in conductor insulation. To test for such insulation breakdown, you need to use a much higher potential than that supplied by the battery of an ohmmeter. This potential is placed between the conductor and the outside of the insulation. A megger (megohmmeter) is used for these tests. The megger, shown in figure 3-15, is a portable instrument consisting of two main elements: (1) a hand-driven dc generator, which supplies the necessary voltage for making the measurement, and (2) the instrument portion, which indicates the value of the resistance you are measuring. The instrument portion is of the opposed-coil type, as shown in view A. Coils **a** and **b** are mounted on movable member **c**. A fixed angular relationship exists between coils, and they are free to turn as a unit in a magnetic field. Coil **b** tends to move the pointer counterclockwise, and coil **a** tends to move it clockwise.

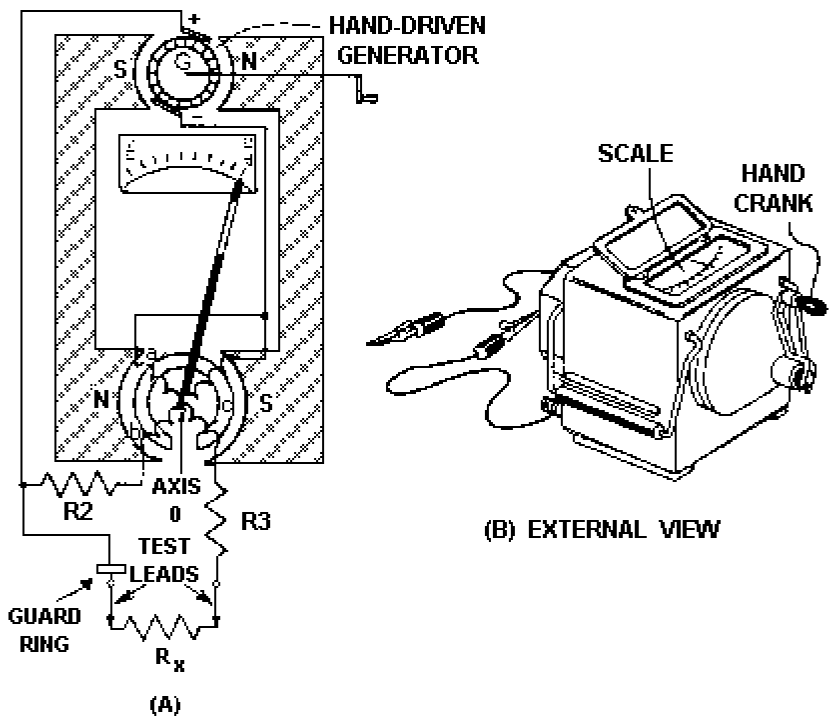

Figure 3-15.—Megger internal circuit and external view.

Coil **a** is connected in series with R3 and unknown resistance R_x. The combination of coil **a**, R3, and R_x forms a direct series path between the + and – brushes of the dc generator. Coil **b** is connected in series with R2, and this combination is also connected across the generator. Notice that the movable member (pointer) of the instrument portion of the megger has no restoring springs. Therefore, when the generator is not being operated, the pointer will float freely and may come to rest at any position on the scale.

The guard ring, shown in view A of figure 3-15, shunts any leakage currents to the negative side of the generator. This prevents such current from flowing through coil **a** and affecting the meter reading.

Q-24. What is the purpose of the guard ring in a megohmmeter?

If the test leads are open, no current will flow in coil **a**. However, current will flow internally through coil **b** and deflect the pointer to infinity. This reading indicates a resistance too large to measure. When a resistance, such as R_x, is connected between the test leads, current also flows in coil **a**; the pointer tends to move clockwise. At the same time, coil **b** still tends to move the pointer counterclockwise. Therefore, the moving element, composed of both coils and the pointer, comes to rest at a position in which the two forces are balanced. This position depends upon the value of R_x, which controls the amount of the current in coil **a**. Because changes in voltage affect both coils in the same proportion, the position of the moving element is independent of the voltage. If you short the test leads together, the pointer will come to rest at zero because the current in coil **a** is relatively large. Since R3 limits the current, the instrument will not be damaged under these circumstances. The external appearance of one type of megger is shown in view B of figure 3-15.

Most meggers you will use are rated at 500 volts; however, there are other types. Meggers are usually equipped with friction clutches, which are designed to slip if the generator is cranked faster than its rated speed. This prevents the generator speed and output voltage from exceeding rated values. A 1,000-volt generator is available for extended ranges. When an extremely high resistance, such as 10,000 megohms or more, is to be measured, a high voltage is needed to cause enough current flow to actuate the meter movement.

CAUTION

When using a megger, you can easily be injured or damage equipment if you do not observe the following MINIMUM safety precautions:

- Use meggers on high-resistance measurements only (such as insulation measurements or to check two separate conductors on a cable).
- Never touch the test leads while the handle is being cranked.
- De-energize and discharge the circuit completely before connecting a megger.
- Whenever possible, disconnect the component being checked from other circuitry before using a megger

Q-25. Most meggers you will use are rated at what voltage?

Q-26. The development of excessive test voltages is avoided by the use of meggers equipped with what device?

ELECTRODYNAMOMETER-TYPE METERS

The electrodynamometer-type meter differs from the galvanometer types we have just studied in that two fixed coils are used to produce the magnetic field instead of a permanent magnet. Two movable coils are also used in the electrodynamometer meter. The electrodynamometer meter is most commonly found in various types of power meters.

Q-27. What components in an electrodynamometer-type meter movement produce the magnetic field?

As shown in figure 3-16, the fixed coils are connected in series and positioned coaxially (in line) with a space between them. The two movable coils are also positioned coaxially and are connected in series. The two pairs of coils (fixed pair and movable pair) are also connected in series with each other. The movable coil is pivot-mounted between the fixed coils. The main shaft on which the movable coils are mounted is restrained by spiral springs that restore the pointer to zero when no current is flowing through the coil. These springs also act as conductors for delivering current to the movable coils. Since these conducting springs are very small, the meter cannot carry a high value of current.

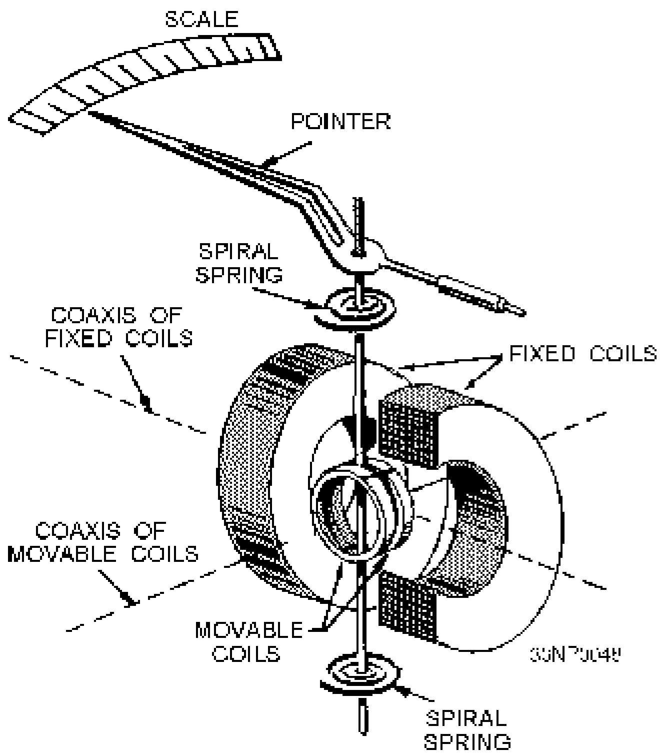

Figure 3-16.—Internal construction of an electrodynamometer.

Q-28. What is the limiting factor as to the amount of current an electrodynamometer meter movement can handle?

METER ACCURACY

The meter is mechanically damped by means of aluminum vanes that move in enclosed air chambers. Although very accurate, electrodynamometer-type meters do not have the sensitivity of the D'Arsonval-type meter movement. For this reason, you will not find them used outside of the laboratory environment to a large extent.

METER MOVEMENT

The primary advantage of the electrodynamometer-type meter movement is that it can be used to measure alternating as well as direct current. If you apply alternating current to the standard galvanometer-type meter, it will not produce a usable reading. Instead, the meter will vibrate at or near the zero reading. On one-half cycle of the ac, the meter is deflected to the left and on the other half cycle to the right. Since the frequencies you will be measuring are 60 hertz or greater, the meter is incapable of mechanically responding at this speed. The result is simply a vibration near the zero point; in addition, no useful reading of voltage or current is obtained. This problem does not exist with the electrodynamometer-type movement. Current flow through the stationary (fixed) coils sets up a magnetic field. Current flow through the moving coils sets up an opposing magnetic field. With two magnetic fields opposing, the pointer deflects to the right. If the current reverses direction, the magnetic fields of *both* sets of coils will be reversed. With both fields reversed, the coils still oppose each other, and the pointer still deflects to the right. Therefore, no rectifying devices are required to enable the electrodynamometer meter movement to read both ac and dc. Rectifying devices are required for the D'Arsonval-type meter movement to enable it to be used for measuring ac voltages and currents.

Q-29. What is the primary advantage of the electrodynamometer-type meter over the D'Arsonval-type meter?

VOLTMETER

When an electrodynamometer is used as a voltmeter, no problems in construction are encountered because the current required is not more than 0.1 ampere. This amount of current can be handled easily by the spiral springs. When the electrodynamometer is used as a voltmeter, its internal connections and construction are as shown in view A of figure 3-17. Fixed coils **a** and **b** are wound of fine wire since the current flow through them will not exceed 0.1 ampere. They are connected directly in series with movable coil **c** and the series current-limiting resistor.

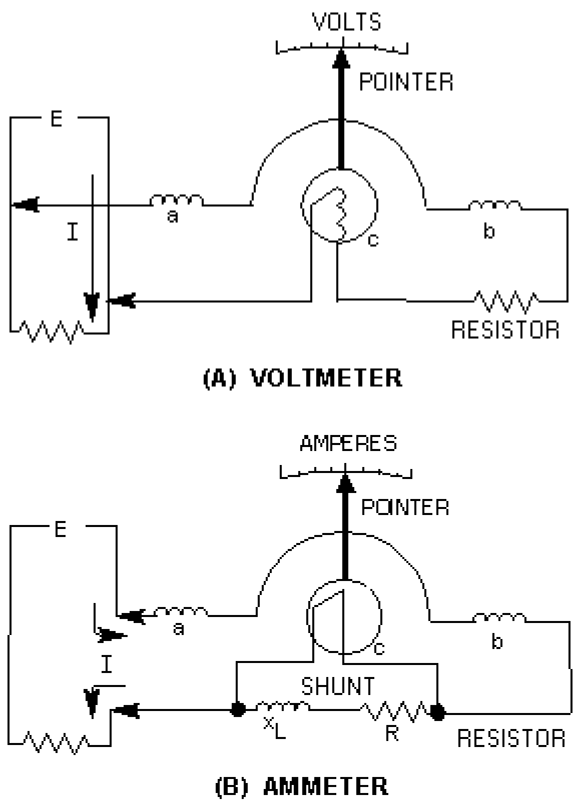

Figure 3-17.—Circuit arrangement of electrodynamometer for use as a voltmeter and an ammeter.

AMMETER

When the electrodynamometer is used as an ammeter, a special type of construction must be used. This is because the large currents that flow through the meter cannot be carried through the moving coils. In the ammeter in view B of figure 3-17, stationary coils a and b are wound of heavier wire to carry up to 5.0 amperes. An inductive shunt (X_L) is wired in parallel with the moving coils and permits only a small part of the total current to flow through the moving coil. The current flowing through the moving coil is directly proportional to the total current flowing through the instrument. The shunt has the same ratio of reactance to resistance as the moving coil does. Therefore, the instrument will be reasonably correct at frequencies at which it is used if ac currents are to be measured.

WATTMETER

Electric power is measured by means of a wattmeter. This instrument is of the electrodynamometer type. As shown in figure 3-18, it consists of a pair of fixed coils, known as current coils, and a moving coil, called the voltage (potential) coil. The fixed current coils are wound with a few turns of a relatively large conductor. The voltage coil is wound with many turns of fine wire. It is mounted on a shaft that is supported in jeweled bearings so that it can turn inside the stationary coils. The movable coil carries a needle (pointer) that moves over a suitably graduated scale. Coil springs hold the needle at the zero position in the absence of a signal.

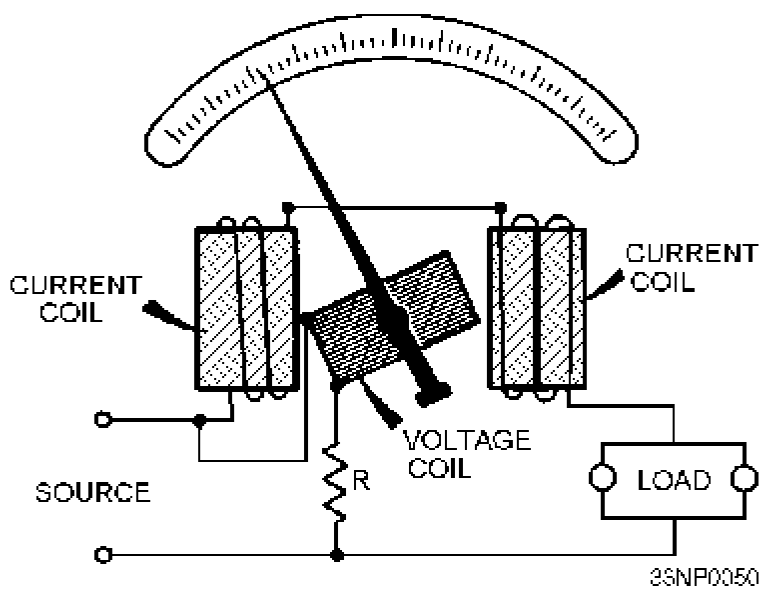

Figure 3-18.—Simplified electrodynamometer wattmeter circuit.

Wattmeter Connection

The current coil of the wattmeter is connected in series with the circuit (load), and the voltage coil is connected across the line. When line current flows through the current coil of a wattmeter, a field is set up around the coil. The strength of this field is in phase with and proportional to the line current. The voltage coil of the wattmeter generally has a high-resistance resistor connected in series with it. The purpose for this connection is to make the voltage-coil circuit of the meter as purely resistive as possible. As a result, current in the voltage circuit is practically in phase with line voltage. Therefore, when voltage is impressed on the voltage circuit, current is proportional to and in phase with the line voltage. Figure 3-19 shows the proper way to connect a wattmeter into a circuit.

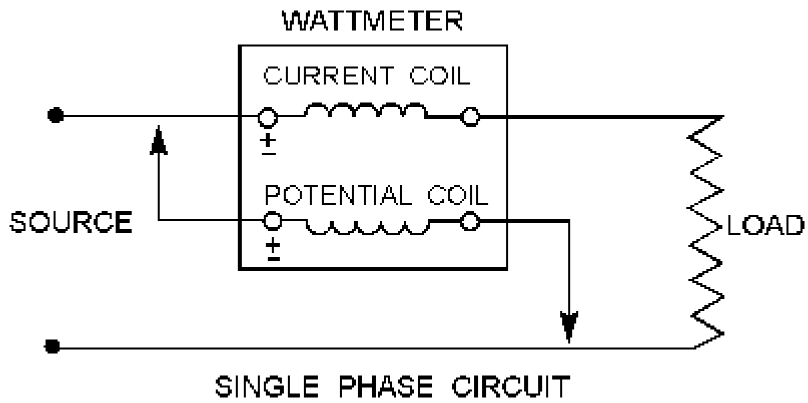

Figure 3-19.—Wattmeter connection.

Wattmeter Errors

Electrodynamic wattmeters are subject to errors arising from such factors as temperature and frequency. For example, heat through the coils eventually causes the small springs attached to the pointer to lengthen and lose tension, which produces deflection errors. Large currents through the wattmeter also produce a noticeable deflection error. These errors are caused by the heat (I^2R) loss through coils from the application of high currents. Because of this, the maximum current range of electrodynamic wattmeters is normally restricted to approximately 20 amperes. The voltage range of wattmeters is usually limited to several hundred volts because of heat dissipation within the voltage circuit. However, the voltage range can be extended by the use of voltage multipliers.

Good-quality, portable wattmeters usually have an accuracy of 0.2 to 0.25 percent. You must remember, though, that electrodynamic wattmeter errors increase with frequency. For the higher frequency and power ranges, special types of wattmeters are made specifically for those ranges. We will discuss two such wattmeters in chapter 5 of this module.

Wattmeter Overloads

The wattmeter consists of two circuits, either of which will be damaged if too much current passes through them. You should be especially aware of this fact because the reading on the instrument will not tell you whether or not the coils are being overheated. If an ammeter or voltmeter is overloaded, the pointer will indicate beyond the upper limit of its scale. In the wattmeter, both the current and potential circuit may carry such an overload that their insulations burn; yet the pointer may be only part of the way up the scale. This is because the position of the pointer depends upon the power factor of the circuit as well as upon the voltage and current. Therefore, a low power-factor circuit will provide a very low reading on the wattmeter. The reading will be low, even when the current and voltage circuits are loaded to the maximum safe limit. The safe rating for each wattmeter is always distinctly rated, not in watts, but in volts and amperes.

TECHNIQUES FOR METER USE

We have considered the more common meters; now let's consider some of the techniques employed in their use. The techniques suggested here are not all-inclusive. You will find, as you develop your technical skills, other variations and techniques in use. Consider the techniques for measuring current in a circuit. You can accomplish this by placing an ammeter in series with the circuit or by measuring the voltage across a resistor of known value and using Ohm's law to figure current. This last technique has the advantage of eliminating the necessity of opening the circuit to connect the ammeter.

CONTINUITY TESTS

Open circuits are those in which the flow of current is interrupted by a broken wire, defective switch, or any means by which the current cannot flow. The test used to detect open circuits (or to see if the circuit is complete or continuous) is continuity testing.

An ohmmeter (which contains its own batteries) is excellent for use in a continuity test. Normally, continuity tests are performed in circuits where the resistance is very low, such as the resistance of a copper conductor. An open is indicated in these circuits by a very high or infinite resistance between two continuously connected points.

Figure 3-20 shows a continuity test of a cable that connects two electronic units. Notice that both plugs are disconnected and the ohmmeter is in series with conductor **D** under test. The power should be off. When checking conductors **A**, **B**, and **C** (connection of ohmmeter to conductors not shown), the current from the ohmmeter flows through plug **2** (female) through conductor **A**, **B**, or **C** to plug **1** (female). From plug **1**, current passes through the jumper to the chassis, which is "grounded" to the ship's structure. The metal structure serves as the return path to the chassis of unit **2** and completes the circuit through the series-connected ohmmeter. The ohmmeter indicates a low resistance because no break exists in conductors **A**, **B**, or **C**. However, checking conductor **D** reveals an open. The ohmmeter is shown indicating maximum resistance because current cannot flow in an open circuit. With an open circuit, the ohmmeter needle is all the way to the left since it is a series-type ohmmeter (reads right to left).

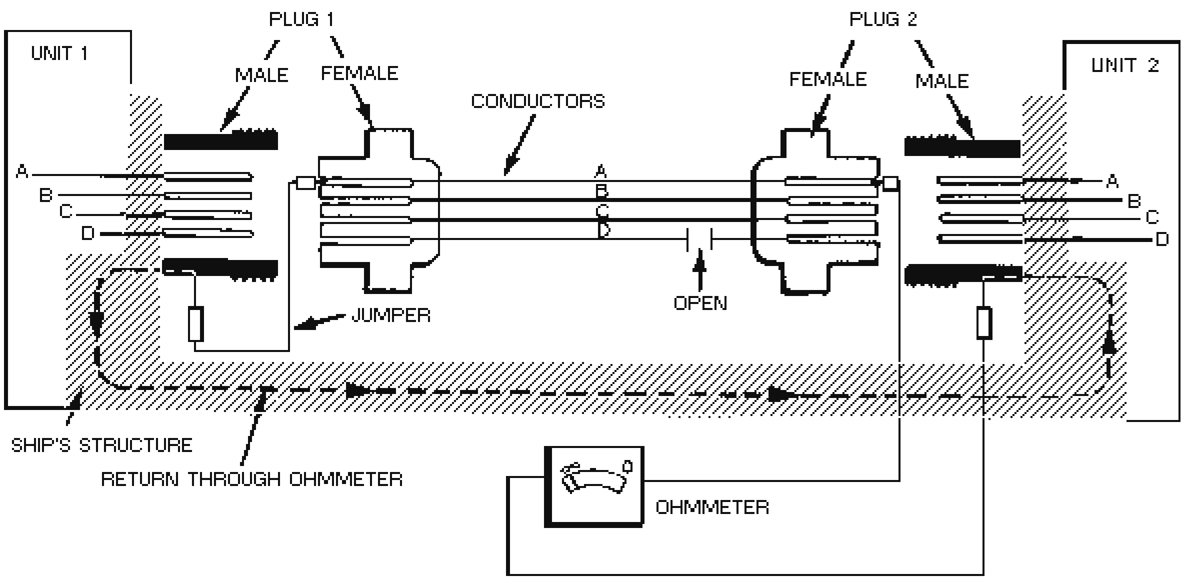

Figure 3-20.—Continuity test.

Where conditions are such that the ship's structure cannot be used as the return path, one of the other conductors (known to be good) may be used. For example, to check **D**, you can connect a jumper from pin **D** to pin **A** of plug **1** (female) and the ohmmeter leads to pins **D** and **A** of plug **2** (female). This technique will also reveal the open in the circuit.

TESTING FOR GROUNDS

Grounded circuits are caused by some conducting part of the circuit making contact either directly or indirectly with the metallic structure of the ship. Grounds can have many causes. The two most common are the fraying of insulation from a wire and moisture-soaked insulation. The fraying of insulation from a wire allows bare wire to come into contact with the metal ground. Moisture-soaked insulation causes reduced insulation resistance (also classified as a ground).

Grounds are usually indicated by blown fuses or tripped circuit breakers. Blown fuses or tripped circuit breakers, however, can also result from a short circuit other than a ground. A high-resistance ground can also occur when current is increased significantly but not enough to rupture the fuse or trip the circuit breaker.

CAUTION

Before testing any circuit, ensure the circuit under test has been de-energized and checked with a safety shorting probe.

In testing for grounds, you may use a megger or an ohmmeter. Measuring the resistance to ground from points in a circuit determines if the point is grounded. Referring again to figure 3-20, you can see one possible means of testing a cable for grounds. If the jumper is removed from pin **D** of plug **1** (female), a test for ground can be made for each conductor in the cable. You can do this by connecting one meter lead to ground and the other to each of the pins of either of the plugs. A low resistance indicates that some part of that conductor or one of the plug assemblies is grounded. Both plugs must be removed from their units; if only one plug is removed, a false indication is possible because a conductor may be grounded through the unit.

TESTING FOR SHORTS

A short circuit, other than a grounded one, is one where two conductors touch each other directly or through another conducting element. Two conductors with frayed insulation may touch and cause a short. Too much solder on the pin of a connector may short to the adjacent pin. In a short circuit, enough current may or may not flow to blow a fuse or open a circuit breaker. A short may occur between two cables carrying signals but might not be indicated by a blown fuse.

Shorts occur in many components, such as transformers, motor windings, and capacitors. The major test method used to detect shorts in such components is to measure resistance. The indicated resistance is then compared with the resistance given on schematics or in the equipment technical manuals to determine whether the measured value is within specifications.

An ohmmeter is the device used to check for shorts. You can use the ohmmeter to detect a short between two conductors by measuring the resistance between them (be sure electrical power has been disconnected). A low resistance reading indicates a short. You can test the circuit in figure 3-20 for a short by first removing the jumper and disconnecting both plugs; you then measure the resistance between the two suspended conductors.

WARNING

The following section discusses voltage measurements on live circuits. BE SURE YOU ALWAYS FOLLOW PRESCRIBED SAFETY RULES WHEN MEASURING VOLTAGES.

VOLTAGE TESTS

Voltage tests must be made with the power applied; therefore, the prescribed safety precautions must be followed to prevent injury to personnel and damage to the equipment. You will find in your maintenance work that the voltage test is of utmost importance. It is used not only in isolating casualties to major components but also in the maintenance of subassemblies, units, and circuits. Before checking a circuit voltage, you should check the voltage of the power source to be sure that the normal voltage is being applied to the circuit.

The voltmeter is used for voltage tests. In using the voltmeter, make certain that the meter used is designed for the type of current (ac or dc) to be tested and has a scale with a suitable range. Since defective parts in a circuit can cause higher than normal voltages to be present at the point of test, the highest voltmeter range available should be used first. Once you have obtained a reading, determine if a lower scale can be used that will cause no damage to the meter movement. If so, use the lower scale. This provides a more accurate reading.

Another consideration in the circuit voltage test is the resistance and current in the circuit. A low resistance in a high-current circuit could result in considerable voltage drop, whereas the same resistance in a low-current circuit may be minimal. Abnormal resistance in part of a circuit can be checked with either an ohmmeter or a voltmeter. Where practical, an ohmmeter should be used because the test is then carried out with a "dead" circuit.

The majority of the electronic circuits you will encounter in equipment will be low-current circuits, and most voltage readings will be direct current. Also, many of the schematics will indicate the voltages at various test points. Therefore, if you suspect that a certain stage is defective, you can check the voltage by connecting a voltmeter from the test point to ground. If the suspected stage is not defective, the voltmeter readings should match the voltages given on the schematic.

Some technical manuals also contain voltage charts on which all the voltage measurements are tabulated. These charts usually indicate the sensitivity of the meter (for example, 20,000 ohms/volt) used to obtain the voltage readings for the chart. To obtain comparable results, you must use a voltmeter of the same sensitivity (or greater) as that specified. Make certain that the voltmeter is not "loading" the circuit while taking a measurement. If the meter resistance is not considerably higher than the circuit resistance, the reading will be markedly lower than the true circuit voltage because of the voltmeter's loading effect. (To calculate meter resistance, multiply the rated ohms-per-volt sensitivity value of the meter by the scale in use. For example, a 1,000-ohms-per-volt meter set to the 300-volt scale will have a resistance of 300,000 ohms.)

RESISTANCE TESTS

Before checking the resistance of a circuit or of a part, make certain that the power has been turned off. Also make sure capacitors in the associated circuit are fully discharged. To check continuity, always use the lowest ohmmeter range. If the highest range is used, the meter may indicate zero, even though appreciable resistance is present in the circuit. Conversely, to check a high resistance, use the highest scale since the lower range scale may indicate infinity, even though the resistance is less than a megohm. In making resistance tests, you must remember that even though the external ohmmeter leads are connected in parallel with the circuit to be measured, the internal meter circuitry is electrically connected in series.

In making resistance tests, take into account that other circuits containing resistances and capacitances may be in parallel with the circuit to be measured. Erroneous conclusions may be drawn from readings obtained in such cases. Remember, a capacitor blocks the dc flow from the ohmmeter. To obtain an accurate reading when other parts are connected across the suspected circuit, disconnect one end of the circuit to be measured from the equipment. For example, many of the resistors in major components and subassemblies are connected across transformer windings. To obtain a valid resistance measurement, you must isolate the resistors to be measured from the shunt resistances of the coils of the transformers.

Resistance tests are also used to check a component for grounds. In these tests, the component to be tested should be disconnected from the rest of the circuit so that no normal circuit ground will exist. Dismounting the component to be checked is not necessary. The ohmmeter is set for a high-resistance range. Then the ohmmeter is connected between ground and each electrically separate circuit of the component being tested. Any resistance reading less than infinity indicates at least a partial ground. You can also check capacitors suspected of being short-circuited by measuring the resistance. To check a capacitor suspected of being open, temporarily shunt a known good capacitor then recheck the performance of the circuit.

CAUTION

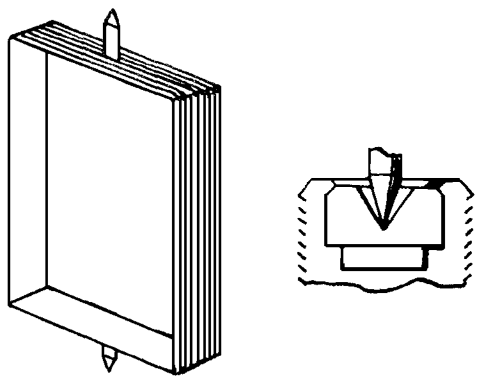
To avoid possible damage to equipment during resistance tests, observe the following precautions:

- Always connect an ammeter in series—*never* in parallel.
- Connect a voltmeter in parallel.
- *Never* connect an ohmmeter to a live circuit.
- Observe polarity when using a dc ammeter or a dc voltmeter.
- View meters directly from the front. When viewed from an angle off to the side, an incorrect reading will result because of OPTICAL PARALLAX. (Parallax was covered in NEETS, Module 3, *Introduction to Circuit Protection, Control, and Measurement.)*
- Always choose an instrument suitable for the measurement desired.
- Select the highest range first and then switch to the proper range.
- In using a meter, choose a scale that will result in an indication as near midscale as possible.
- Do not mount or use instruments in the presence of a strong magnetic field.
- Remember, a low internal resistance voltmeter (low sensitivity) may shunt the circuit being measured and result in incorrect readings.

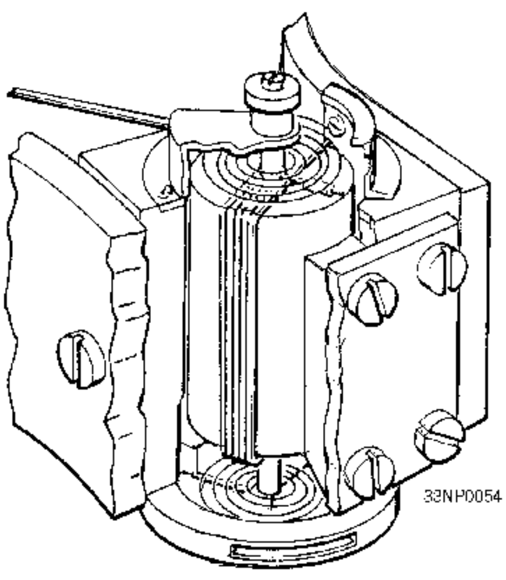
SUMMARY

The important points of this chapter are summarized in the following paragraphs. You should be familiar with these points before continuing with your study of test equipment.

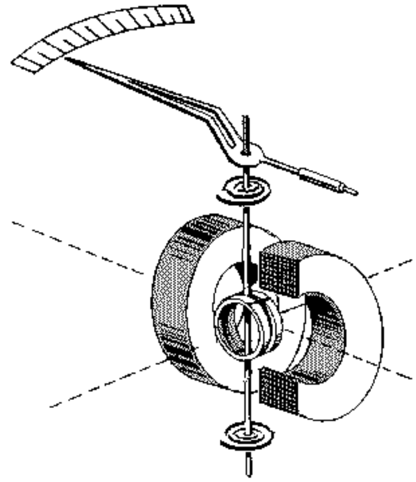
A permanent-magnet, moving-coil meter movement (**D'ARSONVAL** movement) uses the interaction of magnetic fields to produce movement.



DAMPING is used to smooth out the vibration and to help prevent overshooting of the meter pointer.



ELECTRODYNAMOMETER movements are usually used in wattmeters. They operate much like the D'Arsonval meter movement, except field coils are used instead of a permanent magnet. Electrodynamometer movements measure either ac or dc without the use of a rectifier.

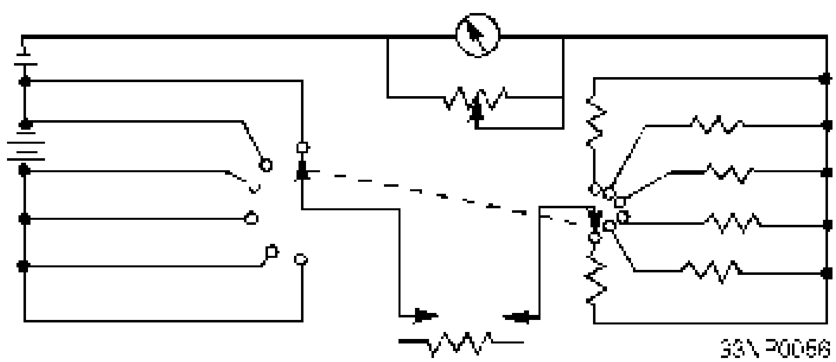


A **SHUNT** is a physically large, low-resistance conductor connected in parallel with the meter terminals. It carries the majority of the load current so that only a small portion of the total current will flow through the meter coil.

An **AMMETER** measures current and is always connected in series with the circuit being measured. An ammeter should have a low resistance so that the effect of the ammeter on the circuit will be kept to a minimum.

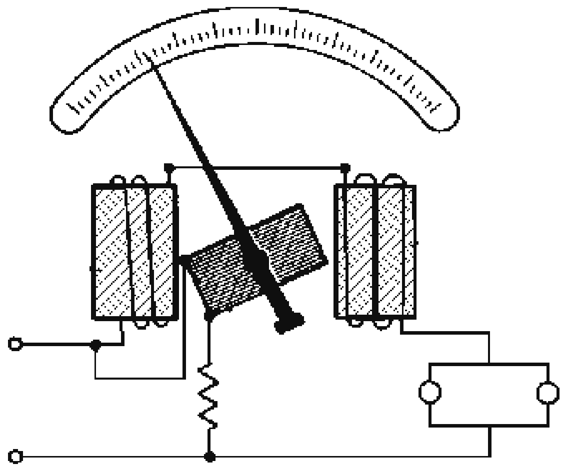
VOLTMETERS are used to measure voltage and are always connected in parallel with the circuit being measured. A voltmeter should have a high resistance compared to the circuit being measured to minimize the loading effect. Voltmeter sensitivity is expressed in ohms per volt.

OHMMETERS are used to measure resistance and to check continuity. An ohmmeter is electrically connected in series with the resistance being measured. The ohmmeter range, which allows a midscale deflection, should be used.



A **MEGOHMMETER (MEGGER)** is used to measure very high resistance, such as the insulation of wiring.

A **WATTMETER** is usually an electrodynamometer and is used to measure power.



A **CONTINUITY TEST** is accomplished with an ohmmeter. This test is used to check for opens (or to see if the circuit is complete or continuous).

GROUNDED CIRCUITS are caused by some conducting part of the circuit making contact either directly or indirectly with the metallic structure of the ship or chassis. In testing for grounds, you may use either an ohmmeter or a megger.

A **SHORT CIRCUIT**, other than a grounded one, is where two conductors touch each other directly or through another conducting element. An ohmmeter is used to test for shorts.

A-29. The electrodynamometer-type meter can be used to measure both ac and dc currents.

CHAPTER 4

COMMON TEST EQUIPMENT

LEARNING OBJECTIVES

Upon completing this chapter, you should be able to:

1. Describe the proper operating procedures for using the multimeter.
2. Describe the proper operating procedures for using the digital multimeter.
3. Describe the proper operating procedures for using the differential voltmeter.
4. Describe the proper operation of the transistor tester.
5. Describe the proper procedure for using the RCL bridge to measure resistance, capacitance, and inductance.

INTRODUCTION

In the previous chapters, you have learned how to use some basic and miscellaneous measuring instruments to perform required maintenance and upkeep of electronic systems and components. You were also introduced to the construction and operation of basic meter movements in test equipment. This chapter will introduce you to some of the testing instruments commonly used in the Navy today.

MULTIMETERS

During troubleshooting, you will often be required to measure voltage, current, and resistance. Rather than using three or more separate meters for these measurements, you can use the MULTIMETER. The multimeter contains circuitry that allows it to be used as a voltmeter, an ammeter, or an ohmmeter. A multimeter is often called a VOLT-OHM-MILLIAMMETER (VOM).

One of the greatest advantages of a VOM is that no external power source is required for its operation; therefore, no warm-up is necessary. Other advantages are its portability, versatility, and freedom from calibration errors caused by aging tubes, line voltage variations, and so forth.

Q-1. What is one of the greatest advantages of a VOM?

Two disadvantages are that (1) the VOM tends to "load" the circuit under test, and (2) the meter movement is easily damaged as a result of improper testing procedures.

CAUTION

Never press down on or place any object on the glass face of any multimeter. This can disable the meter movement from operating properly or cause damage.

MEASURING RESISTANCE, VOLTAGE, AND CURRENT WITH A VOM

In the discussion that follows, you will become familiar with the operation and use of the multimeter in measuring resistance, voltage, and current.

The meter selected for this discussion is the Simpson 260 multimeter, as shown in figure 4-1. The Simpson 260 is a typical VOM used in the Navy today.

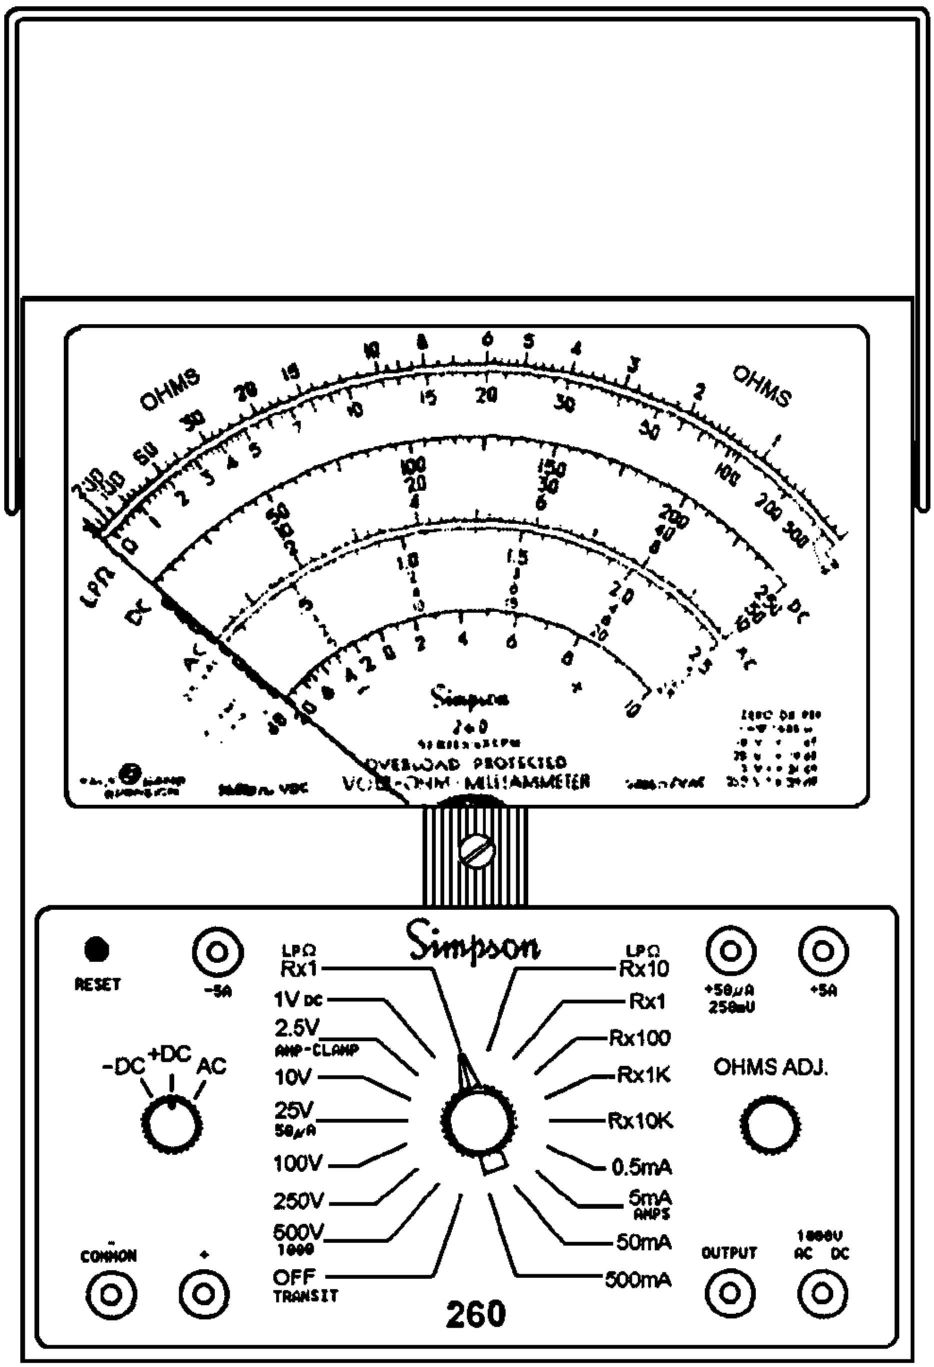

Figure 4-1.—Simpson 260 Series 6XLP Volt-Ohm-Milliammeter (VOM).

The multimeter has two selector switches. The switch on the lower left is the function switch, and the one in the lower center is the range switch. The function switch selects the type of current you will be measuring (+dc, –dc, or ac). The range switch is a 12-position switch that selects the range of ohmmeter, voltmeter, or milliammeter measurements you will make.

The multimeter is equipped with a pair of test leads; red is the positive lead and black is the negative, or common, lead. Eight jacks are located on the lower part of the front panel. To prepare the meter for use, simply insert the test leads into the proper jacks to obtain the circuit and range desired for each application. In most applications, the black lead will be inserted into the jack marked at the lower left with a negative sign (–) or with the word COMMON.

Measuring Resistance

Before proceeding, you should be aware of the following important safety precaution that must be observed when using the ohmmeter function of a VOM:

CAUTION

Never connect an ohmmeter to a "hot" (energized) circuit. Be sure that no power is applied and that all capacitors are discharged.

Q-2. Before you connect a VOM in a circuit for an ohmmeter reading, in what condition must the circuit be?

The internal components of the multimeter use very little current and are protected from damage by an overload protection circuit (fuse or circuit breaker). However, damage may still occur if you neglect the safety precaution in the CAUTION instructions above.

Because no external power is applied to the component being tested in a resistance check, a logical question you may ask is, Where does the power for deflection of the ohmmeter come from? The multimeter contains its own two-battery power supply inside the case. The resistive components inside the multimeter are of such values that when the leads are connected together (no resistance), the meter indicates a full-scale deflection. Because there is no resistance between the shorted leads, full-scale deflection represents zero resistance.

Before making a measurement, you must zero the ohmmeter to ensure accurate readings. This is accomplished by shorting the leads together and adjusting the OHMS ADJ control so that the pointer is pointing directly at the zero mark on the OHMS scale. The ZERO OHMS control is continuously variable and is used to adjust the meter circuit sensitivity to compensate for battery aging in the ohmmeter circuits.

An important point to remember when you are making an accurate resistance measurement is to "zero" the meter each time you select a new range. If this is not done, the readings you obtain will probably be incorrect.

When making a resistance measurement on a resistor, you must give the following considerations to the resistor being tested:

- The resistor must be electrically isolated. In some instances, a soldered connection will have to be disconnected to isolate the resistor. Generally, isolating one side of the resistor is satisfactory for you to make an accurate reading.

- The meter leads must make good electrical contact with the resistor leads. Points of contact should be checked for dirt, grease, varnish, paint or any other material that may affect current flow.

- Touch only the insulated portions of the test leads. Your body has a certain amount of resistance, which the ohmmeter will measure if you touch the uninsulated portions of the leads.

Figure 4-2 is a functional block diagram of the ohmmeter circuit in a VOM. The proper method of checking a resistor is to connect the red lead to one end of the resistor and the black lead to the other end of the resistor.

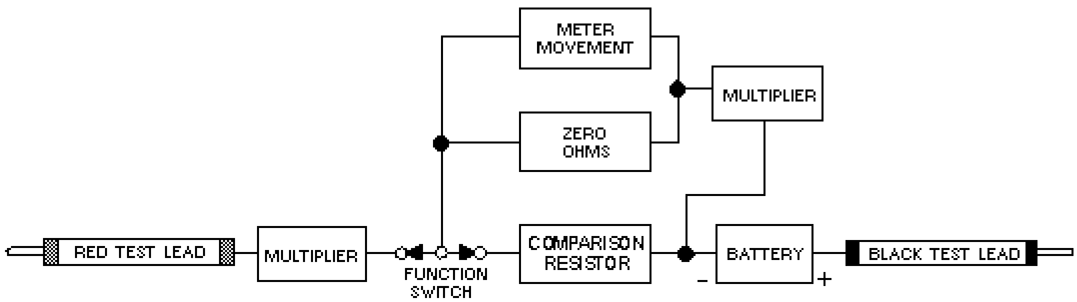

Figure 4-2.—Functional block diagram of an ohmmeter circuit.

Because zero resistance causes full-scale deflection, you should realize that the deflection of the meter is inversely proportional to the resistance being tested; that is, for a small resistance value, the deflection will be nearly full scale; and for a large resistance value, the deflection will be considerably less. This means that the left portion of the OHMS scale represents high resistance; the right side of the scale represents low resistance. Zero resistance (a short circuit) is indicated on the extreme right side of the scale; infinite resistance (an open circuit) is located on the extreme left side of the scale.

Notice that you read the OHMS scale on the multimeter from RIGHT to LEFT. For example, the pointer of the multimeter in figure 4-3 indicates 8.0 ohms. To determine the actual value of a resistor, multiply the reading on the meter scale by the range switch setting ($R \times 1$, $R \times 100$, or $R \times 10,000$).

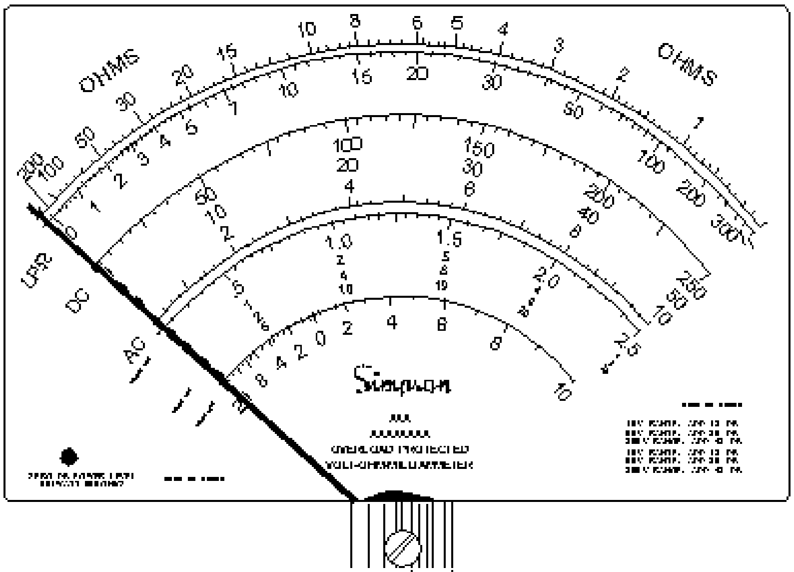

Figure 4-3.—Ohmmeter scale.

Notice that the scale marks are crowded on the left side of the OHMS scale, which makes them difficult to read. Therefore, the best range to select is one in which the pointer will fall in the space from midscale to slightly to the right side of midscale. The divisions in this area of the scale are evenly spaced and provide for easier reading and greater accuracy.

Q-3. When taking resistance readings with a VOM, you will obtain the most accurate readings at or near what part of the scale?

To explain the relationship between the meter readings and the range switch setting, let's use an example. Suppose you have a 2,400-ohm resistor, which you have identified by the resistor color code. With the range switch in the R × 1 position, you connect the meter across the resistor. The meter point then deflects between 200 and the point labeled with the infinity symbol (∞) on the extreme left side of the scale. Because the R × 1 range is selected, you multiply the reading by 1. Obviously, the scale reading is not accurate enough. Therefore, you move the range selector switch to the next higher scale position (R × 100) to obtain a more easily read value.

In the R × 100 position, you again zero the meter. This time, the pointer moves to the 24 mark on the scale. Because the R × 100 scale is selected, the reading is multiplied by 100. This gives a more accurate reading of 2,400 ohms (24 times 100).

If you position the range switch to the R × 10,000 scale, accuracy decreases. The most accurate readings are obtained at or near midscale. Other VOM instruments have ranges with other settings, such as R × 10, R × 100, or R × 1,000, to make it easier to make such readings.

Another thing to remember when you are measuring resistance is the tolerance of the resistor. If the tolerance of the resistor in the preceding example is 10 percent, we would expect a reading between approximately 2,160 and 2,640 ohms. If the reading is not within these limits, the resistor has probably changed value and should be discarded.

An open resistor will indicate no deflection on the meter. A shorted resistor causes full-scale deflection to the right on the lowest range scale, such as if the leads were shorted together.

Measuring dc Voltages

You set the multimeter to operate as a dc voltmeter by placing the function switch in either of two positions: +DC or –DC. The meter leads, as in the case of the ohmmeter function, must be connected to the proper meter jacks. When you measure dc voltages, be sure the red lead is the positive lead and the black lead is the negative, or common, lead. View A of figure 4-4 is a functional block diagram of dc voltage circuits in a multimeter. View B shows the jacks and switch positions for measuring dc voltages.

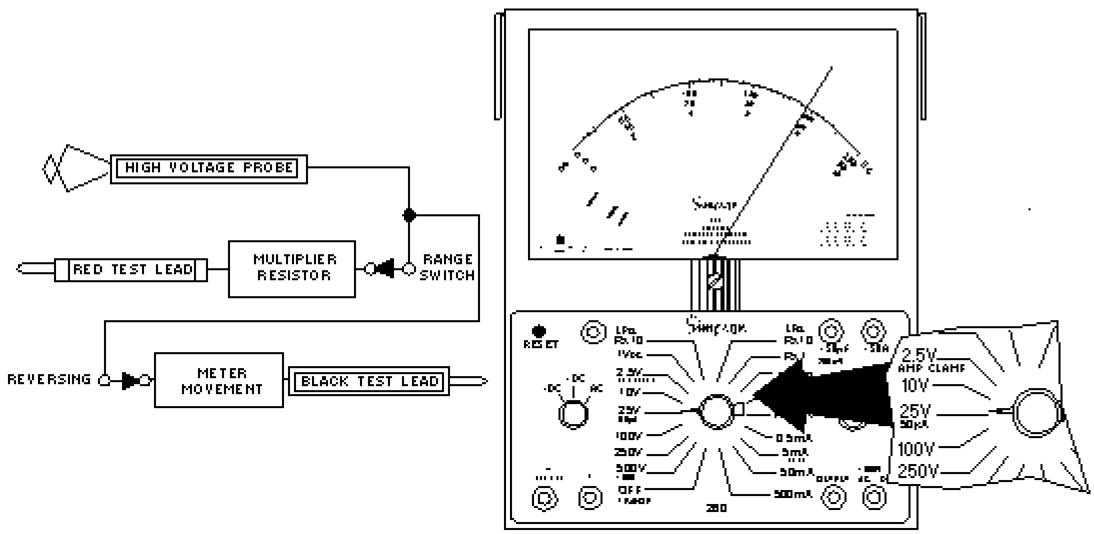

Figure 4-4.—Functional block diagram of dc voltage circuits.

When the meter is connected in a circuit, it becomes a circuit component. Because all meters have some resistance, they alter the circuit by changing the current. The resistance presented by the voltmeter depends on the amount of voltage being measured and the position of the function switch.

Some multimeters use a 20,000 ohms-per-volt meter sensitivity for measuring dc voltage and a 5,000 ohms-per-volt sensitivity for measuring ac voltage. The higher the meter resistance, the less it will load the circuit. The idea is to keep circuit loading to an absolute minimum so that the circuit under test is unaffected by the meter. In this way, you can get a clearer picture of what the circuit malfunction is, not the effect of the meter on the circuit.

Again, refer to figure 4-4. With the function switch set to either +DC or –DC, let's consider the effect of the range switch on the meter scale to be used. When measuring dc voltages, you have eight voltage ranges available: .25V, 2.5V, 10V, 50V, 250V, and 500V (1- and 1,000-volt special application plug-ins are also available). The setting of the range switch determines the maximum value represented on the meter. When measuring dc voltages, use the scale marked DC (figure 4-3). The last number at the extreme right side of the DC scale indicates the maximum value of the range being used. When the range switch is in the 2.5V position, the scale represents a maximum of 2.5 volts.

To simplify the relationship between the digits on the meter scale and the setting of the range switch, always use the multiple of the full-scale-deflection digits on the meter face that correspond to the numbers of the range switch. For example, use the 250 scale for the 250MV jack, 2.5V, and 250V ranges; the 50 on the scale for 50V and 500V ranges; and the 10 on the scale for the 10V and 1,000V ranges.

For explanation purposes, let's assume you wish to measure 30 volts dc. In this case, select the next higher range position, 50V. When you place the range switch to the 50V position (as shown in view B of figure 4-4), the meter pointer should rise from a little more than midscale to 30, which represents 30 volts dc.

When measuring a *known* dc voltage, position the range switch to a setting that will cause approximately midscale deflection. Readings taken near the center of the scale are the most accurate. When measuring an *unknown* dc voltage, always begin on the highest voltage range. Using the range switch, work down to an appropriate range. If the meter pointer moves to the left, you should reverse the polarity of the function switch.

CAUTION

Always check the polarity before connecting the meter.

Q-4. Besides setting up the meter for expected voltage ranges, what must be strictly observed when taking dc voltage readings?

Now let's discuss how you take a voltage measurement on a component within a circuit. As an example, let's measure the voltage drop across the resistor shown in figure 4-5.

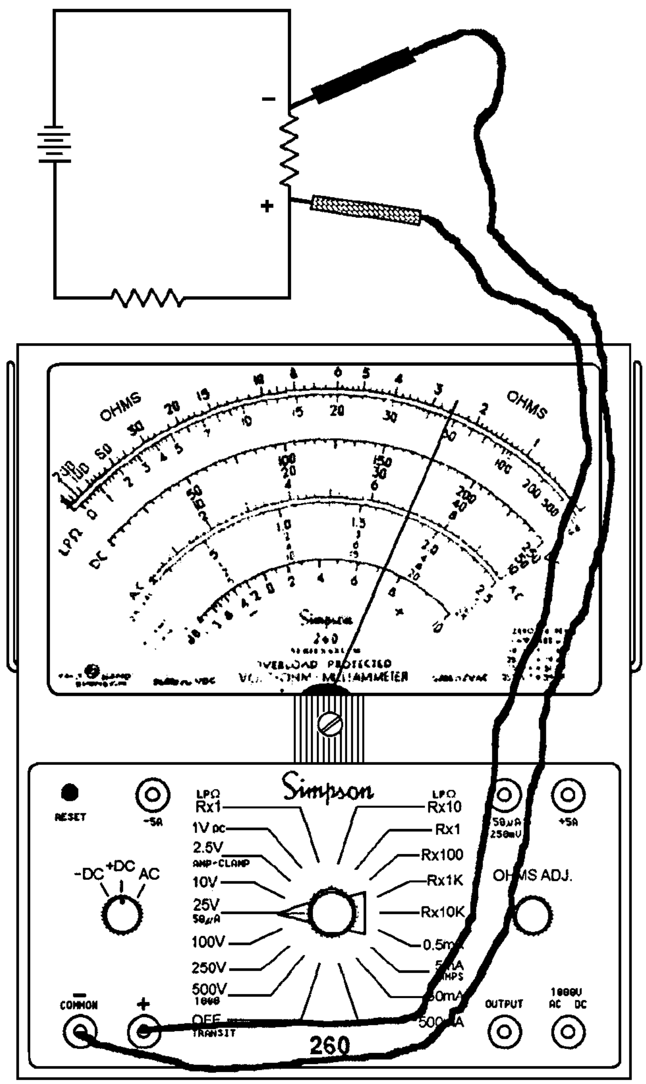

Figure 4-5.—Measuring the voltage drop of a resistor.

When measuring a dc voltage drop across a component in a circuit, you must connect the voltmeter in parallel with the component. As you can see in figure 4-5, the positive (red) lead is connected to the positive side of the resistor, and the negative (black) lead is connected to the negative side. A voltage reading is obtained on the meter when current flows through the resistor.

Some voltmeter readings will require the use of a ground as a reference point. Under these conditions, one voltmeter lead is connected to the equipment ground, and the other lead is connected to the test point where voltage is to be measured. Be sure to observe polarity.

Measuring ac Voltages

To measure ac voltages, you must set the function switch to the AC position. The same procedure used to measure dc voltages applies, except that in reading the voltage, you use the AC volts scale (the polarity of the test leads is not important). When measuring very low or high frequencies of ac voltages, you should be aware that the multimeter has a tendency to be inaccurate. View A of figure 4-6 is a functional block diagram of the ac and output voltage circuits in the multimeter. View B shows the jacks and switch positions used to measure ac voltages.

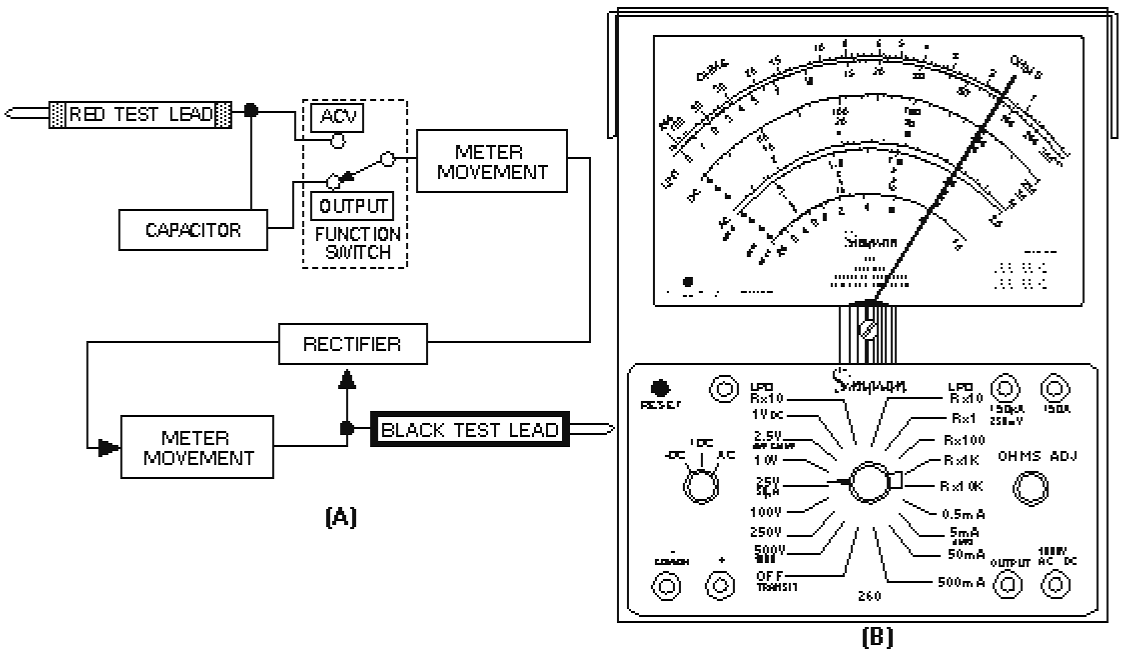

Figure 4-6.—Functional block diagram of ac and output voltage circuits.

Measuring Output Voltages

You will often measure the ac component of an output voltage where both ac and dc voltage levels exist. This occurs primarily in amplifier circuits.

The multimeter has a 0.1-microfarad, 400-volt blocking capacitor in series with the OUTPUT jack. The capacitor blocks the dc component of the current in the circuit under test, but allows the ac component to pass on to the indicating circuits.

CAUTION

When using OUTPUT, do not attempt to use the meter in a circuit in which the dc voltage component exceeds the 400-volt rating of the blocking capacitor.

To use the multimeter to measure output voltage, you must follow these steps:

1. Set the function switch to AC.
2. Plug the black test lead into the COMMON jack and the red test lead into the OUTPUT jack.
3. Set the range switch at the appropriate range position, marked as 2.5V, 10V, 50V, or 250V.
4. Connect the test leads to the component being measured with the black test lead to the negative side of the component.

5. Turn on the power in the test circuit. Read the output voltage on the appropriate ac voltage scale. For the 2.5V range, read the value directly on the scale marked 2.5. For the 10V, 50V, or 250V range, use the red scale marked AC and read the black figures immediately above the scale.

Measuring Current

The multimeter can function as an ammeter to measure current flow.

CAUTION

When using the multimeter as a current-indicating instrument, *NEVER* connect the test leads directly across a voltage. ALWAYS connect the instrument in series with the load.

To use the multimeter as an ammeter, you must take the following steps:

1. Set the function switch at +DC (assuming the current to be positive).
2. Plug the black test lead in the COMMON jack and the red test lead into the + jack.
3. Set the range switch at one of the five ampere-range positions.
4. Ensure the equipment is OFF and then physically open the circuit in which the current is being measured.
5. Connect the VOM in series with the circuit, ensuring that proper polarity is observed when making this connection.
6. Turn the equipment ON and then read the current on the DC scale. (This is the same scale used to measure dc voltages.)

The setting of the range switch determines the maximum value represented by the DC scale. Always use the range scale that corresponds to the range switch setting.

CAUTION

Never attempt to measure currents greater than the setting of the range switch. Increase the range with a shunt, if necessary, but do not exceed the marked current.

When measuring unknown currents, follow the same procedures as when measuring voltages. Always start with the highest range available and work down. Use the range that gives approximately half-scale deflection. If this procedure isn't followed, the meter could be burned out.

Figure 4-7 is a functional block diagram of the dc current circuits in a multimeter.

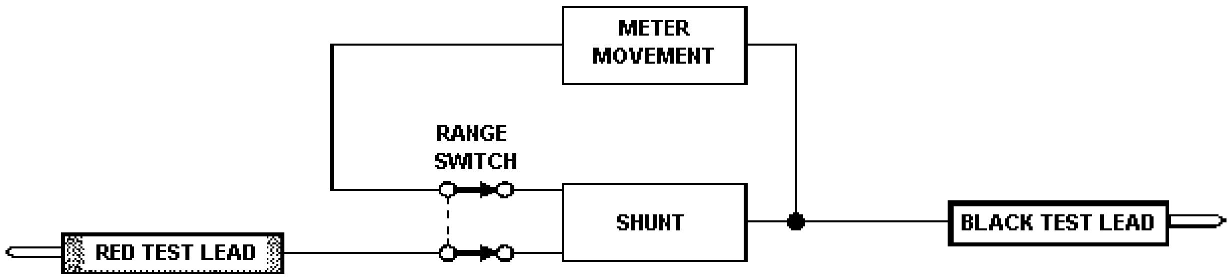

Figure 4-7.—Functional block diagram of dc current circuits.

Accessories

A dc high-voltage probe is available for use with the multimeter. The probe extends the range of the multimeter in a safe and convenient manner. It is primarily used to measure high-voltage, low-power, dc-current sources, such as the anode supplies in television receivers and other cathode-ray tube circuitry.

CAUTION

Do not use this probe on electrical equipment that can deliver high power under short-circuit conditions, such as from a large dc motor-generator set.

Also available is an ac high-voltage probe. The 10,000-volt ac probe is similar to the high-voltage dc probe with the following exceptions:

- The ac high-voltage probe is designed primarily to extend the range of a 5,000-ohms-per-volt VOM.
- The probe is used with the VOM in the 10V AC position.
- You take readings on the 0-10V AC scale and multiply by 1,000.

ELECTRONIC DIGITAL MULTIMETER

As you studied in chapter 3 (externally excited meters), placing a meter into a circuit causes energy to be taken from the circuit. The amount of energy taken depends on the sensitivity of the meter. In some cases, this energy loss cannot be tolerated. For example, in extremely sensitive circuits, such as oscillator grid circuits and automatic volume control circuits, degradation of normal circuit operation will occur. This often results in failure to obtain a usable indication of the fault. The use of electronic multimeters is practical in these sensitive electronic circuits. The higher the input impedance of a meter, the less the loading effect and the more accurate the measurements taken. Electronic multimeters have considerably greater input impedances than do nonelectronic multimeters.

One example of a typical electronic multimeter in use within the Navy is the electronic Model 8000A Digital Multimeter. Most electronic digital multimeters overcome the disadvantage of requiring a continuous external power source by combining an external ac source with an internal rechargeable battery. Another advantage of this meter is that it can be read directly and does not use a scale. Figure 4-8 shows the model 8000A multimeter.

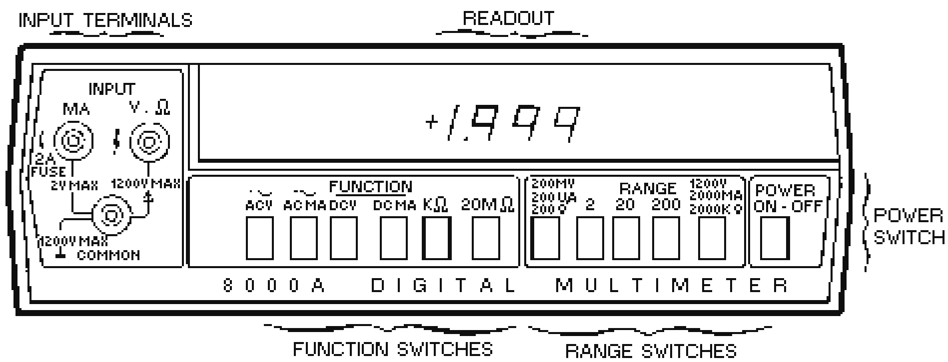

Figure 4-8.—Digital voltmeter 8000A operating features.

Operating Features

The locations of all controls, connectors, and indicators are shown in figure 4-8. The INPUT terminals, located on the left-hand side of the meter face, provide input connections for voltage or resistance (V-?) and milliampere current (MA) measurements with respect to the common terminal. The readout section, located across the upper half of the meter face, contains light-emitting diode (LED) indicators. They display the measured input and polarity signs for dc measurements. The POWER switch, located on the lower right-hand side of the meter face, is a push-button switch used to energize the instrument. The RANGE switches, located on the lower, middle, right-hand portion of the meter face, select the voltage (200 millivolts, 2, 20, 200, or 1,200 volts), current (200 microamperes, 2, 200, or 2,000 milliamperes), and resistance (200 ohms, 2, 20, 200, or 2,000 kilohms) ranges. The FUNCTION switches, located on the lower, middle, left-hand portion of the meter face, select the voltage, current, or resistance modes. The MA input terminal is also a fuse holder for the current protection fuse.

Internal Battery Models

Power is supplied by internal rechargeable batteries that allow the instrument to operate for at least 8 hours. Recharging the batteries is accomplished by switching the POWER switch to OFF and connecting the instrument to an ac power line. You can use the instrument when recharging the batteries on ac power, but the recharging time will be extended.

Q-5. Power for the electronic digital multimeter is normally supplied by what internal power source?

Overload Protection

An overload condition is indicated by the simultaneous flashing of the display readouts. The dc voltage function can withstand up to 1,200 volts dc or 1,200 volts root-mean-square (rms) on any range.

Q-6. How is an overload condition indicated by the electronic digital multimeter?

The ac voltage function can sustain up to 1,200 volts rms on the 20-, 200-, and 1,200-volt ranges and 500 volts rms on the 200-millivolt and 2-volt ranges. The current input fuse is protected above 2 amperes rms. Protection for the resistance function is to 130 volts rms in the 200-ohm and 2-kilohm ranges, and 250 volts rms in the 20-kilohm through 20-megohm ranges.

Basic Digital Multimeter Measurement

Table 4-1 lists the proper function push buttons, range push buttons, and input terminal connections for performing specific measurements with the model 8000A.

Table 4-1.—Basic Measurement Instructions

MEASUREMENT	FUNCTION	RANGE	INPUT CONNECTION	MAXIMUM OVERLOAD	REMARKS
DC Volts	DCV	200MV, 2, 20, 200, or 1200V	V—Ω and COMMON	1200V dc or 1200V rms (sinusoidal)	Auto-polarity
DC Milliamperes	DC MA	200µA, 2, 20, 200, or 2000MA	MA and COMMON	2A (fuse protected)	
AC Volts	ACV	200MV, 2, 20, 200, or 1200V	V—Ω and COMMON	1200V rms (sinusoidal), not to exceed 107 V-Hz on 20, 200, 1200V ranges. 500V rms (sinusoidal) on 200mV and 2V ranges.	
AC Milliamperes	AC MA	200µA, 2, 20, 200, or 2000MA	MA and COMMON	2A (fuse protected)	
Kilohms	KΩ	200Ω, 2, 20, 200, or 2000KΩ	V—Ω and COMMON	130V rms, 200Ωand 2KΩ ranges. 250V rms, 20kΩ thru 2000kΩ ranges.	
Megohms	20MΩ	Any	V—Ω and COMMON	250V rms	Ranges switches non-functional

Block Diagram Analysis

Figure 4-9 is a block diagram of an electronic digital multimeter. Note that the block diagram divides the instrument into three major sections: the SIGNAL CONDITIONING section, the ANALOG-TO-DIGITAL CONVERTER section, and the DISPLAY section.

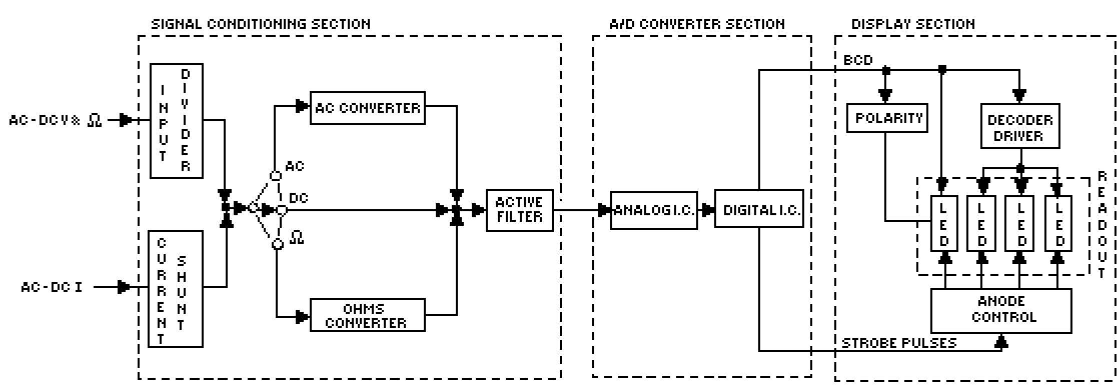

Figure 4-9.—Model 8000A block diagram.

The signal conditioning section provides a dc analog voltage, characteristic of the applied input, to the analog-to-digital converter section. This task is accomplished by the input voltage divider, current shunts, ac converter, active filter, and associated switching.

The analog-to-digital (a/d) converter section changes the dc output voltage from the signal conditioning section to digital information. The a/d converter uses a voltage-to-frequency conversion technique. A dc voltage at the input of the a/d converter is changed to a frequency by the analog integrated circuit (ic). This frequency is characteristic of the magnitude and polarity of the dc input voltage. Counting of the output frequency from the analog ic is accomplished by the digital ic. The resulting count is transferred in binary format to the display section. (Binary number systems are covered in NEETS, Module 13, *Introduction to Number Systems, Boolean Algebra, and Logic Circuits*.)

The display section takes the digital (binary) information from the a/d converter section, decodes it, and visually displays it. The decoded digital information is displayed on numerical LED readouts.

Q-7. In an electronic digital multimeter, the digital information is displayed by what type of numerical readouts?

Accessories

Several accessories are available for use with the electronic digital multimeter. One accessory is the test lead kit, shown in figure 4-10. The kit contains two color-coded test leads with threaded adapters. These adapters attach to banana plugs, pin tips, test prod tips, alligator clips, and binding post lugs.

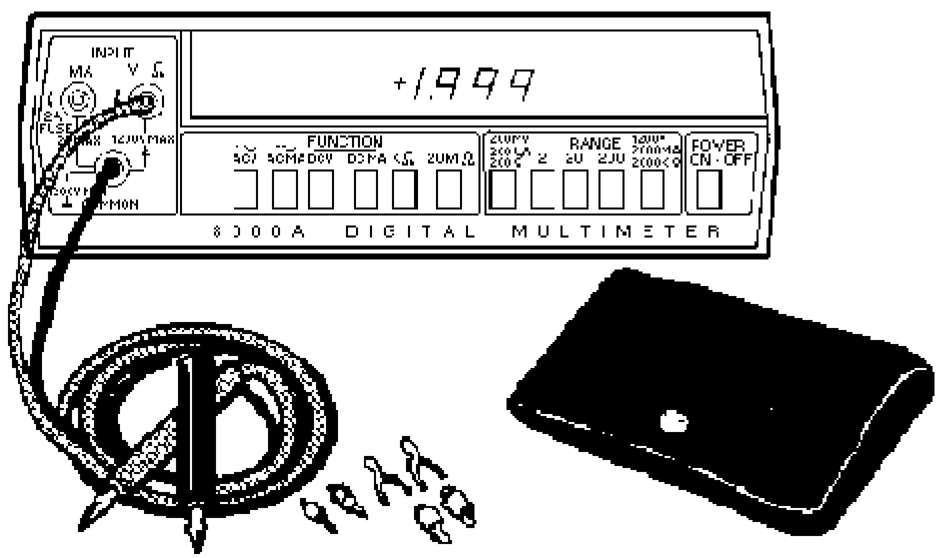

Figure 4-10.—Test lead kit.

Figure 4-11 shows a high-current probe. This probe extends the ac current measurement capability from 2 to 600 amperes at frequencies up to 400 hertz.

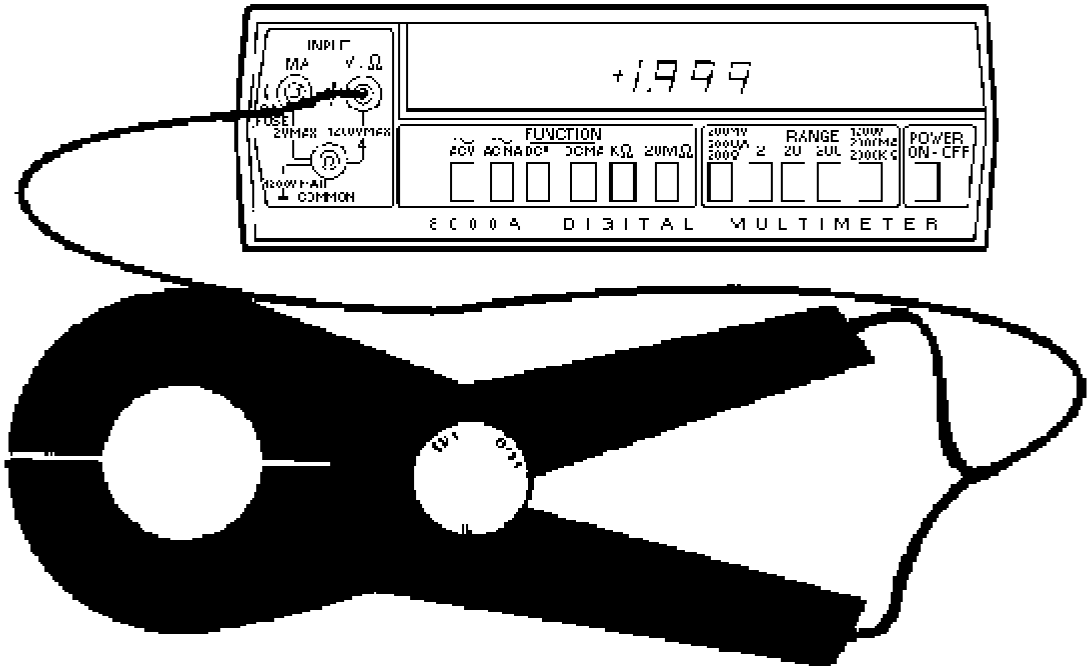

Figure 4-11.—Ac high-current probe.

Figure 4-12 shows a high-voltage probe. The probe extends the dc voltage range to 30 kilovolts.

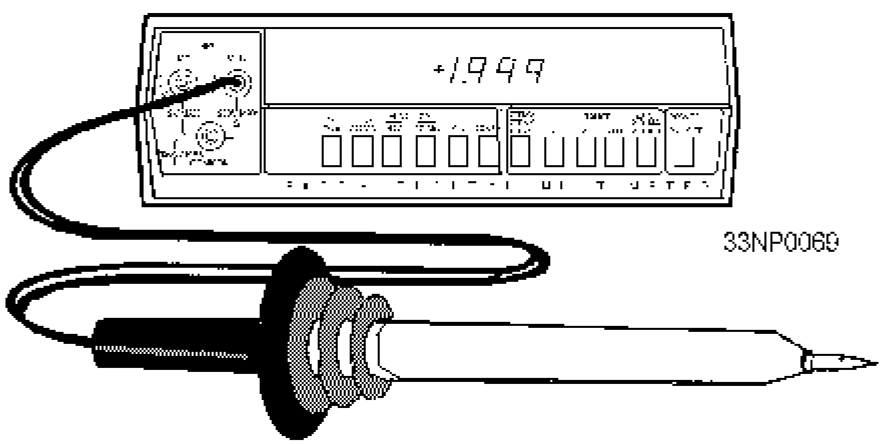

Figure 4-12.—High-voltage probe.

Figure 4-13 shows a high-frequency probe, which allows measurements over a frequency range of 10 kilohertz to 500 megahertz.

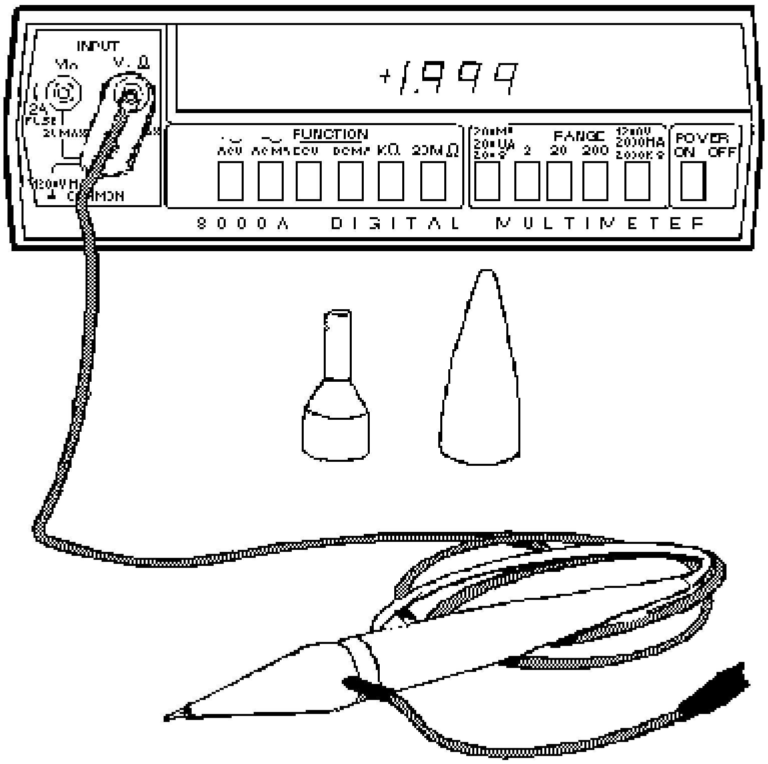

Figure 4-13.—High-frequency probe.

AC/DC DIFFERENTIAL VOLTMETER

The DIFFERENTIAL VOLTMETER provides extremely accurate voltage measurements and is a highly reliable piece of precision test equipment. Its general function is to compare an unknown voltage with a known internal reference voltage and to indicate the difference in their values. The differential voltmeter in common use in the Navy today is the model 893A (figure 4-14).

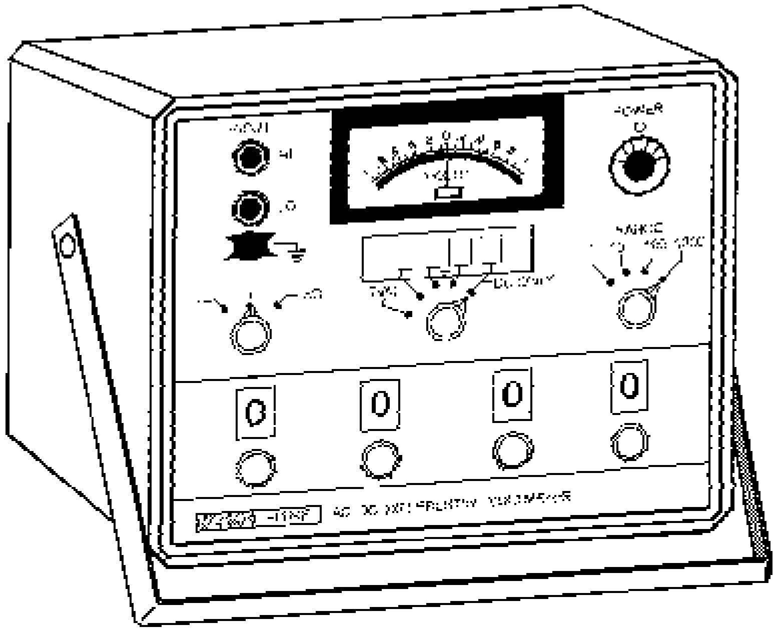

Figure 4-14.—Ac/dc differential voltmeter.

Q-8. What is the general function of the differential voltmeter?

The differential voltmeter can be used as a conventional TRANSISTORIZED ELECTRONIC VOLTMETER (TVM) and a DIFFERENTIAL NULL VOLTMETER. It can also be used to measure variations of a voltage near some known value (NULL DETECTOR), high resistance values (MEGGOMETER), and for dBm measurements.

METER DESIGN CHARACTERISTICS

The differential voltmeter is a solid-state instrument that provides the capability of making dc voltage measurements from +/− 10 microvolts to +/− 1,100 volts. Ac voltages from 0.001 to 1,100 volts can be measured over a frequency range from 5 hertz to 100 kilohertz. Both of these measurements can be made without concern for loading the circuit. The differential voltmeter has four voltage readout dials that vary the resistance of the divider assembly as described above.

The differential voltmeter uses a built-in NULL DETECTOR to measure an unknown voltage. The meter circuitry compares the unknown voltage to a known, adjustable reference voltage supplied by the meter. The reference voltage is provided by a high-voltage dc power supply and decade resistor divider assembly strings that are set by voltage readout dials. In this way, the output from the high-voltage power supply can be precisely divided into increments as small as 10 microvolts. The readout dials are used to adjust the meter pointer to 0 and the unknown voltage is then read from the voltage dials.

A primary feature of the differential voltmeter is that it does not draw current from the unknown source for dc measurements when the measurement is obtained. Therefore, the determination of the unknown dc potential is independent of its source.

FRONT PANEL CONTROLS

The front panel of a typical differential voltmeter is shown in figure 4-15. With a few differences, the controls and terminals are similar to those used on other differential voltmeters. The NULL SENSE switch selects the conventional TVM mode of operation and the various full-scale null detector sensitivity ranges when the instrument is operated in the differential mode of operation. The RANGE switch allows selection of the desired input voltage range, positions the readout dial decimal point, and selects the various ranges of the NULL SENSE switch. The readout dials provide a digital readout of the measured voltage when the instrument is in the differential mode.

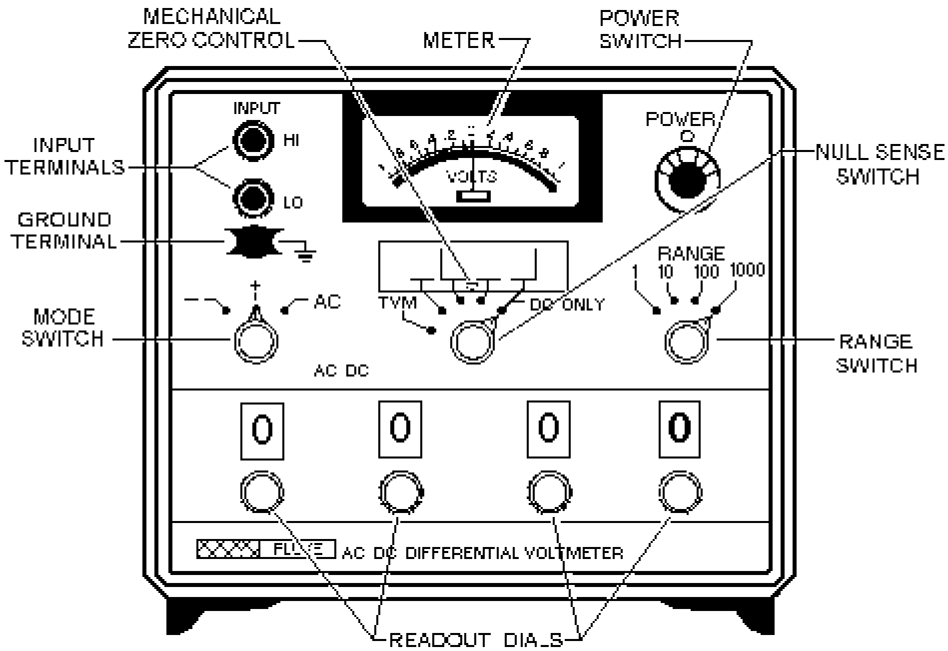

Figure 4-15.—Controls, terminals, and indicators.

MODES OF OPERATION

There are two primary modes of operation: the conventional transistorized voltmeter mode and the differential null mode. These modes are described in the next paragraphs.

Conventional Transistorized Voltmeter (TVM) Mode

When the instrument is used as a conventional transistorized dc voltmeter, the circuitry is connected as shown in figure 4-16. The null detector drives the front panel meter and provides a full-scale meter deflection for any full-scale input. Positive or negative voltage measurements are made by reversing the meter terminals through the contacts of the MODE switch.

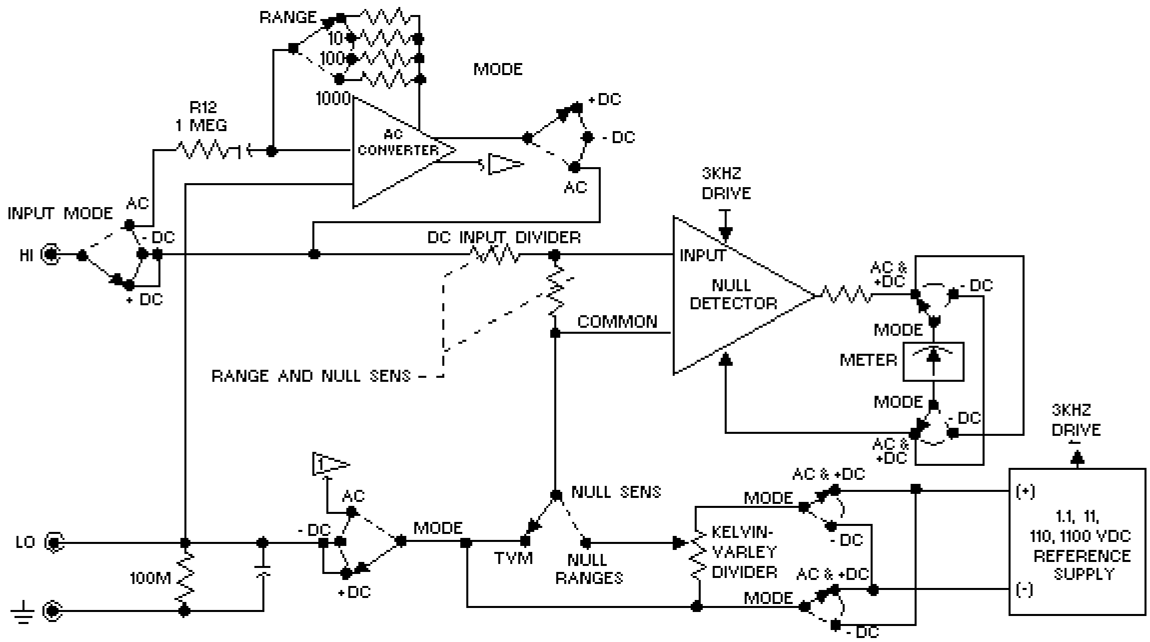

Figure 4-16.—Ac/dc differential voltmeter block diagram.

FUNCTIONAL BLOCK DIAGRAM

Figure 4-16 is a functional block diagram of a differential voltmeter. The circuitry is made up of a reference supply, a resistive divider, a dc input divider, an ac converter, a null detector, and a meter. The circuitry is interconnected by various switching arrangements when you perform the desired ac or dc conventional or differential voltage measurements.

Placing the MODE switch in figure 4-16 to the AC position connects the instrument circuitry as a conventional transistorized ac voltmeter. A full-scale input voltage at the input terminals of the instrument results in a voltage being applied to the input of the null detector. The null detector drives the front panel meter that indicates the value of the measured ac voltage.

Differential Null Mode

When the instrument is used as a dc differential voltmeter, the MODE and NULL SENS switches in figure 4-16 are placed to their respective +/– dc and desired full-scale meter sensitivity positions. In this mode of operation, the NULL SENS switch selects a suitable resistance value to determine the full-scale sensitivity of the meter. The dc input voltage applied to the instrument is then compared with the null detector, and any resulting difference is used to drive the meter. The meter terminals can be reversed through the contacts of the MODE switch for +/– dc voltage measurements.

TRANSISTOR TESTERS

Laboratory transistor test sets are used in experimental work to test characteristics of transistors. For maintenance and repair, however, checking all transistor parameters is not necessary. A check of two or three performance characteristics is usually sufficient to determine whether a transistor needs to be replaced.

Two of the most important parameters used for transistor testing are the transistor CURRENT GAIN (BETA) and the COLLECTOR LEAKAGE or REVERSE CURRENT (ICO). Two other tests that can be accomplished include the electrode resistance and diode measurements. You may want to review NEETS, Module 7, *Introduction to Solid-State Devices and Power Supplies*, for a review of transistors before continuing this section.

The Semiconductor Test Set AN/USM-206A (figure 4-17) is a rugged, field-type tester designed to test transistors and semiconductor diodes. The set will measure the beta of a transistor, the resistance appearing at the electrodes, and the reverse current of a transistor or semiconductor diode. It will also measure a shorted or open condition of a diode, the forward transconductance of a field-effect transistor, and the condition of its own batteries.

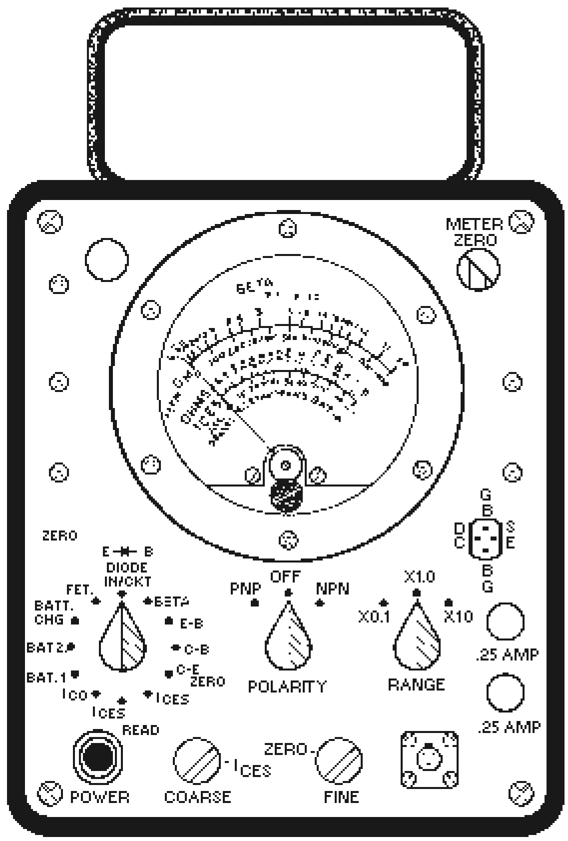

Figure 4-17.—Semiconductor test set.

To assure that accurate and useful information is gained from the transistor tester, you should make the following preliminary checks of the tester before testing any transistors:

1. With the POLARITY switch in the OFF position, the meter pointer should indicate exactly zero. (When required, rotate the meter ZERO ADJUST KNOB on the front of the meter to fulfill this requirement.) To prevent battery drain, be sure to leave the POLARITY switch in the OFF position when measurements are not actually being made.

2. Always check the condition of the test set batteries. To make this check, disconnect the test set power cord, place the polarity switch in the PNP position, and place the function switch first to BAT. 1and then to BAT. 2. In both BAT positions, the meter pointer should move so as to indicate within the red BAT box.

BETA MEASUREMENTS

If the transistor is to be tested out of the circuit, plug it into the test jack located on the right-hand side below the meter. If the transistor is to be tested in the circuit, at least 300 ohms must exist between E-B (emitter to base), C-B (collector to base), and C-E (collector to emitter) for accurate measurement. Initial setting of the test set controls is performed as follows:

1. Set the function switch to BETA.
2. Set the POLARITY switch to PNP or NPN (depending on the type of transistor under test).
3. Set the RANGE switch to X10.
4. Adjust METER ZERO for zero meter indication (transistor disconnected).
5. The POLARITY switch should remain OFF while the transistor is connected to or disconnected from the test set; it should then be set to PNP or NPN, as in step 2 above.

If the beta reading is less than 10, perform the following steps:

1. Reset the RANGE switch to X1 and reset the meter to zero.
2. After connecting the yellow test lead to the emitter, the green test lead to the base, and the blue test lead to the collector, plug the test probe (not shown) into the jack located at the lower right-hand corner of the test set.
3. When testing grounded equipment, unplug the 115-volt line cord and use battery operation. A beta reading is attained by multiplying the meter reading times the RANGE switch setting. Refer to the transistor characteristics book provided with the tester to determine if the reading is normal for the type of transistor under test.

ICO MEASUREMENTS

Adjust the METER ZERO control for a zero meter indication. Plug the transistor to be tested into the jack, or connect the test leads to the device. Set the PNP/NPN switch to correspond with the type of transistor under test. Set the function switch to ICO and the RANGE switch to X0.1, X1.0, or X10, as specified by the transistor data book for allowable leakage. Read leakage on the bottom scale and multiply by the range setting figure as required.

ELECTRODE RESISTANCE MEASUREMENTS

Connect the in-circuit probe test leads to the transistor with the yellow lead to the emitter, the green lead to the base, and the blue lead to the collector. Set the function switch to the OHMS E-B position and read the resistance between the emitter and base electrode on the center scale of the meter marked OHMS.

To read the resistance between the collector and base and the collector and emitter, set the function switch to OHMS C-B and OHMS C-E, respectively. These in-circuit electrode resistance measurements are used to correctly interpret the in-circuit beta measurements. The accuracy of beta times 1 and 10 range is ±15 percent only when the emitter-to-base load is equal to or greater than 300 ohms.

DIODE MEASUREMENTS

Diode in-circuit quality measurements are made by connecting the green test lead to the cathode and the yellow test lead to the anode. Set the function switch to DIODE IN/CKT and the RANGE switch to times 1 position. Ensure that the meter has been properly zeroed on this scale. If the meter reads down-scale, reverse the polarity switch. If the meter reads less than midscale, the diode under test is either open or shorted. The related circuit impedance of this test is less than 25 ohms.

RESISTANCE-CAPACITANCE-INDUCTANCE (RCL) BRIDGES

Resistance, capacitance, and inductance can be measured with precise accuracy by alternating-current bridges. These bridges are composed of capacitors, inductors, and resistors in a wide variety of combinations. These bridges operate on the principle of the Wheatstone bridge; that is, an unknown resistance is balanced against known resistances and, after the bridge has been balanced, the unknown resistance is calculated in terms of the known resistance.

The universal Impedance Bridge, Model 250DE (shown in figure 4-18) is used to measure resistance, capacitance, and inductance (RCL) values. It is also used to make other special tests, such as determining the turns ratio of transformers and capacitor quality tests. This instrument is self-contained, except for a source of line power, and has an approximate 500-hour battery life expectancy. It has its own source of 1,000-hertz bridge current with a sensitive bridge balance indicator and an adjustable source of direct current for electrolytic capacitor and resistance testing. The bridge also contains a meter with suitable ranges to test for current leakage on electrolytic capacitors.

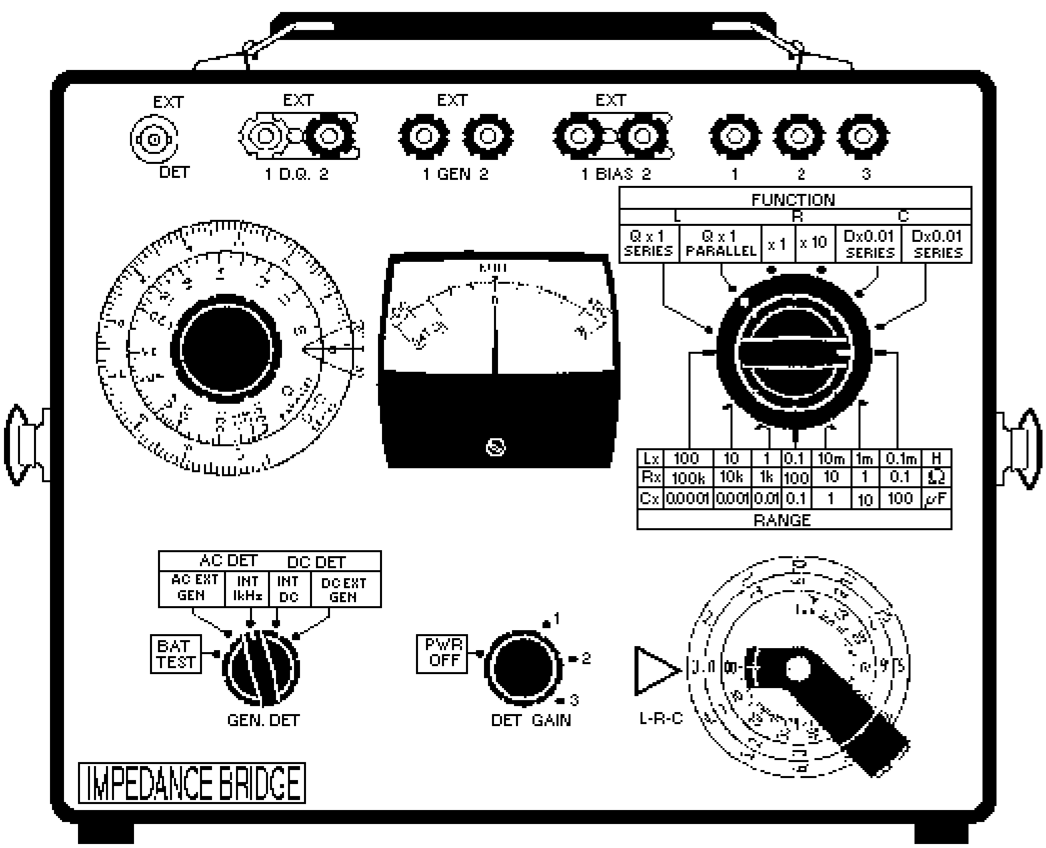

Figure 4-18.—Resistance-capacitance-inductance bridge.

CONTROLS

Figure 4-18 is a panel view of the model 250DE bridge switches, dials, controls, and connections. Refer to the figure as we briefly discuss some of the switches and dials below.

- The FUNCTION switch selects the type of bridge circuit that will measure resistance, capacitance, or inductance.
- The RANGE switch selects the multiplier for each function.
- L-R-C decade dials are a DEKASTAT decade resistor that is the main balancing element of the bridge. The setting of the dials after the bridge is balanced indicates the value of inductance, resistance, or capacitance.
- The D-Q dial is used to balance the phase of the capacitance or inductance of the bridge. The setting of the dial after the bridge is balanced indicates the value of dissipation factor (D) or storage factor (Q).
- The GEN-DET switch selects bridge generator and detector connections, ac or dc, internal or external generator. The switch also connects the internal batteries to the battery test circuit.
- The DET GAIN control adjusts the sensitivity of the ac-dc detector and turns on power to the generator.

CONNECTIONS

L, R, and C terminals 1, 2, and 3 are used to connect unknown resistors, inductors, and capacitors to the bridge. Resistors and inductors are connected between terminals 1 and 2, and capacitors are connected between terminals 2 and 3. **EXT BIAS** terminals are normally connected with a shorting lug. They allow insertion of a dc voltage or current to bias capacitors or inductors. **EXT DET** connector is a BNC coaxial socket that allows an external detector to be used with the instrument. It is connected to the bridge at **ALL TIMES**.

EXT D-Q terminals are normally connected with a shorting lug. They allow an external rheostat to extend the range of the D-Q dial. **EXT GEN** terminals provide a connection to the bridge for an external generator. When the GEN-DET switch is in the AC EXT GEN position, the terminals connect an isolation transformer so that a grounded external generator can be used. When the GEN-DET switch is in the DC EXT GEN position, the terminals are connected directly to the bridge.

BATTERY

The model 250DE bridge has a battery supply consisting of four 1.5 V dc batteries with an expected life of 500 hours. The battery power supply should be checked before each day's operation. Turn DET GAIN control to 1 and set GEN-DET switch to BATT. TEST (battery test). If the meter deflects beyond the BAT OK mark, the battery is good.

RESISTANCE MEASUREMENTS

Resistance is usually measured with direct current for maximum accuracy. The model 250DE bridge can be used to measure resistance with alternating current, but external reactance compensation is usually required. On high-resistance ranges, care should be taken to avoid leakage across a resistor under test. Insulation with a resistance of 109 ohms, which is adequate for most purposes, will cause a measurement error of 1 percent if it shunts a 10-megohm resistor. Using the following steps, you will be able to measure dc resistance ONLY:

1. Turn the DET GAIN control to 2.
2. Set the FUNCTION switch to R × 1 or R × 10.
3. Set L-R-C decade dials to 3.000.
4. Connect the unknown resistor to R-L terminals 1 and 2.
5. Set the GEN-DET switch to INT DC.
6. Adjust the RANGE switch for minimum detector deflection.
7. Adjust L-R-C decade dials for null, turning the DET GAIN control clockwise to increase sensitivity as necessary.
8. The measured resistance is the product of the L-R-C decade dial setting times the RANGE and FUNCTION switch settings.

CAPACITANCE MEASUREMENTS

Capacitance is measured in terms of a two-element equivalent circuit consisting of a capacitor in series with a resistor. The internal ac generator and detector of the model 250DE bridge are tuned to 1 kilohertz. Other frequencies can be used, but an external generator and detector are required. The D and Q ranges of the bridge can be extended by use of an external rheostat connected to the terminals provided. The measured capacitance is the product of the L-R-C dial setting times the setting of the RANGE switch. Using the following steps, you can make a standard capacitance measurement:

1. Turn the DET GAIN control to 1.
2. Set the FUNCTION switch to C, D × 0.1 or D × 0.01 SERIES.
3. Set L-R-C decade dials to 3.000 and D-Q dial to 0.
4. Connect the unknown capacitor to C terminals 2 and 3.
5. Set the GEN DET switch to INT 1 kHz.
6. Adjust the RANGE SWITCH for minimum detector deflection.
7. Adjust L-R-C decade dials and D-Q dial alternately for a minimum meter deflection, turning the DET GAIN control clockwise to increase sensitivity as necessary.
8. The measured capacitance is the product of the L-R-C decade dial settings.
9. The measured dissipation factor (D) is the product of the D-Q setting times the FUNCTION switch setting.

INDUCTANCE MEASUREMENTS

Inductance is measured in terms of a two-element equivalent circuit consisting of an inductance either in series or in parallel with a resistance. The internal ac generator and detector of the model 250DE bridge are tuned to 1 kHz. Other frequencies can be used, but like capacitance measurements, an external generator and detector are required. When inductance is being measured in ac or dc, it should be realized that iron-core inductors are sensitive to current variations. Quantitative measurements of dc effects can be made by supplying current to the unknown inductor through the EXT BIAS terminal. Use the following steps to make inductance measurements:

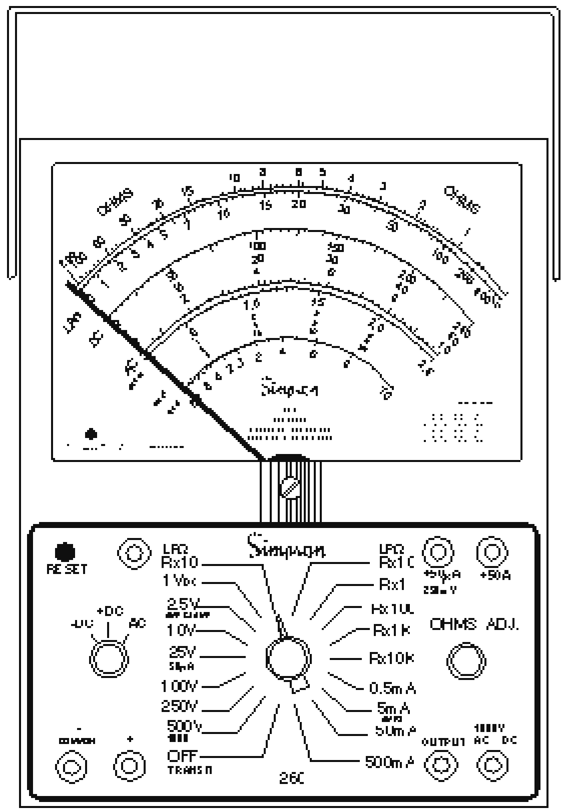
1. Turn the DET GAIN control to 1.
2. Set the FUNCTION switch to L PARALLEL if Q is greater than 10 to L SERIES if Q is less than 10.
3. Set L-R-C decade dials to 3.000 and D-Q dial to maximum.
4. Connect the unknown inductor to the R-L terminals 1 and 2
5. Set the GEN DET switch to INT 1 kHz.
6. Adjust the RANGE switch for minimum detector deflection.
7. Adjust the L-R-C decade dials and D-Q dial alternately for a minimum meter deflection, turning the DET GAIN control clockwise to increase sensitivity as necessary.
8. The measured inductance is the product of the L-R-C decade dial setting times the RANGE switch setting.
9. The measured storage factor (Q) is read directly from the D-Q dial, inner scale for parallel and outer scale for series inductance.

SUMMARY

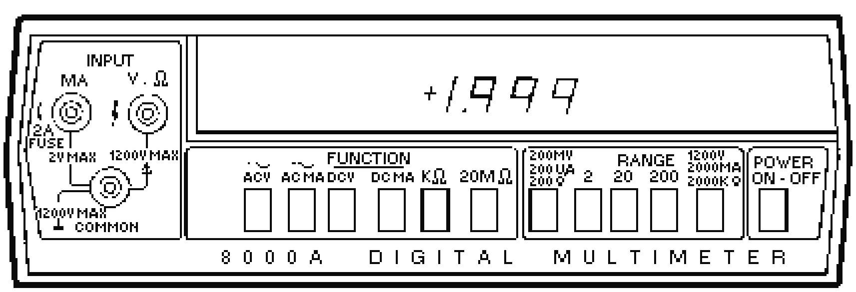
The important points of this chapter are summarized in the following paragraphs. You should be familiar with these points before continuing with your studies of test equipment.

A **MULTIMETER** is a single meter that combines the functions of a dc ammeter, a dc voltmeter, an ac ammeter, an ac voltmeter, and an ohmmeter. Observe the following safety precautions when using a multimeter:

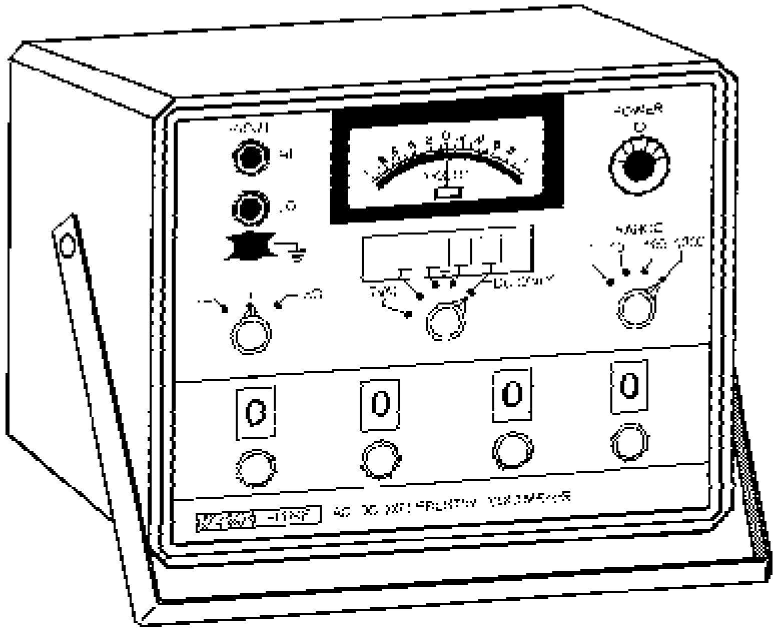
- De-energize and discharge the circuit completely before connecting a multimeter.
- Never apply power to the circuit while you are measuring resistance with an ohmmeter.
- Connect the ammeter **in series** for current measurements and **in parallel** for voltage measurements.
- Be certain the multimeter is switched to ac before attempting to measure ac circuits.
- Observe proper dc polarity when measuring dc circuits.
- Always start with the highest voltage or current range.
- Select a final range that allows a reading near the middle of the scale.
- Adjust the "0 ohms" reading after changing resistance ranges and before making a resistance measurement.



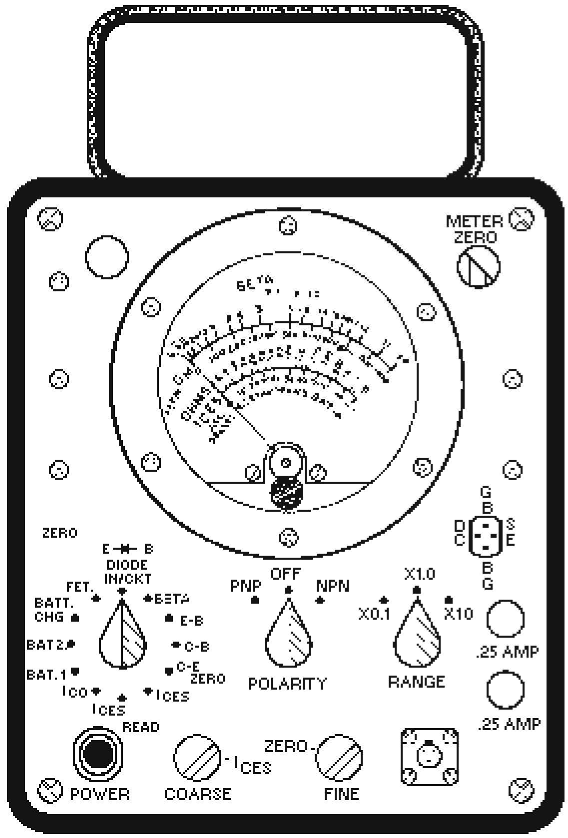
An **ELECTRONIC DIGITAL MULTIMETER** is used in sensitive electronic circuits where only extremely small amounts of energy can be extracted without disturbing the circuits under test, or causing them to be inoperative.



The **DIFFERENTIAL VOLTMETER** is a precision piece of test equipment used to compare an unknown voltage with an internal reference voltage and to indicate the difference in their values.



A **SEMICONDUCTOR TEST SET** is used to measure the beta of a transistor, the resistance appearing at the electrodes, and the reverse current of a transistor or semiconductor diode. It also measures a shorted or open condition of a diode, the forward transconductance of a field-effect transistor, and the condition of its own batteries.



Resistance, capacitance, and inductance are measured for precise accuracy by **RCL BRIDGES**. They are composed of capacitors, inductors, and resistors and operate on the principle of the Wheatstone bridge.

ANSWERS TO QUESTIONS Q1. THROUGH Q8.

A-1. No external power source is required.

A-2. De-energized.

A-3. Midscale.

A-4. Polarity.

A-5. Rechargeable batteries.

A-6. Simultaneous flashing of display readouts.

A-7. Light-emitting diodes.

A-8. To compare an unknown voltage with a known reference voltage and indicate the difference in their values.

CHAPTER 5

SPECIAL-APPLICATION TEST EQUIPMENT

LEARNING OBJECTIVES

Upon completing this chapter, you should be able to:

1. Explain the theory of operation of two types of power meters.
2. Describe the purpose of the controls and indicators found on power meters.
3. Describe the proper procedure for taking power measurements for incident and reflected energy.
4. Describe the uses and purposes of the controls and indicators found on the signal generator.
5. Explain the theory of operation of a typical frequency counter.
6. Describe the uses and purposes of the controls and indicators found on the frequency counter.
7. Explain the uses and purposes of the controls and indicators found on the Huntron Tracker 2000.
8. Describe the proper procedures for troubleshooting with a logic probe.
9. Describe the proper procedures for troubleshooting using the Huntron Tracker 2000.

INTRODUCTION

In chapters 3 and 4, you studied the more common pieces of test equipment. As a technician, you will routinely use this test equipment to troubleshoot and perform maintenance on electronic equipment. However, the equipments you will study in this chapter may or may not be found in your shop. This is because these equipments have specific or specialized uses. Unless your rating is involved with the equipment with which they are used, you may not have reason to use them. They are presented here so that you will be familiar with their overall function should the need arise. The equipments you will study in this chapter are power meters, signal generators, frequency counters, and integrated circuit-testing devices.

POWER METERS

As a technician, you will use a POWER METER to measure power. There are various types of power meters, some of which are called WATTMETERS. Figure 5-1 shows the AN/URM-120 wattmeter, which is one type of power meter commonly used in the Navy. This particular power meter measures power directly; that is, you connect it directly between the transmitter output (rf source) and the load, most likely an antenna.

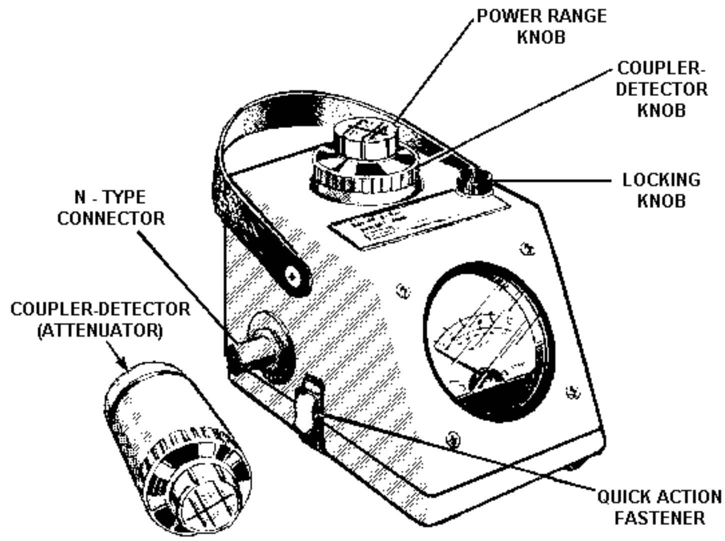


Figure 5-1.—Wattmeter (AN/URM-120).

Other types of power meters measure power indirectly; that is, they sample power in other ways—but not by being placed directly between the output of the transmitter and the load. Let's discuss the direct-measuring power meter first; then we'll talk about an indirect-measuring power meter.

DIRECT-MEASURING POWER METERS

The direct-measuring power meter is designed to measure incident (forward) and reflected (reverse) rf power from 50 to 1,000 watts at 2 MHz to 30 MHz and 10 to 500 watts at 30 MHz to 1,000 MHz. Three separate COUPLER-DETECTORS (sometimes called ATTENUATORS), each rated to cover a portion of the frequency and power ranges, are provided with the wattmeter. These devices couple the rf signal into the wattmeter and detect the signal. The coupler-detector knob projects through the top of the wattmeter case, as shown on the AN/URM-120 wattmeter in figure 5-1.

A nameplate on the top of the POWER RANGE knob indicates the power range. The POWER RANGE knob can be rotated 360º to the desired power range. The coupler-detector rotates 180º inside the metal case for either forward or reverse power measurements. Also located inside the metal case are the indicating meter and cable for interconnecting the meter to the coupler-detector. The LOCKING knob locks the coupler-detector and POWER RANGE knobs in place.

Two N-TYPE connectors (one male and one female) are located on either side of the wattmeter case to connect the instrument between the power source and the load. The upper and lower parts of the wattmeter are held together with quick-action fasteners, which permit easy access to the inside of the wattmeter.

Power measurements are made by inserting the proper coupler-detector and connecting the wattmeter in the transmission line between the load and the rf power source. To measure *incident power* with the wattmeter, rotate the arrow on the COUPLER-DETECTOR knob toward the load, and position the POWER RANGE knob for peak meter reading. To measure *reflected power*, position the arrow toward the rf power source.

In effect, rotating the coupler-detector causes the coupler to respond only to a wave traveling in a particular direction, either *to* (incident) or *from* (reflected) the load. It will be unaffected by a wave traveling in the opposite direction. A diode rectifier in the coupler rectifies the energy detected by the coupler. This detected rf energy is measured across a known impedance to obtain either incident or reflected power.

Operating the Wattmeter

Always de-energize and tag the rf power source before measuring *incident* power. Insert the proper coupler-detector for the rf power being measured into the wattmeter case. Remove the wire shunt (not shown in figure 5-1) from the meter terminals, then connect the wattmeter into the transmission line, either at the load or the rf source. Ensure that all connections are tight.

Position the POWER RANGE knob to a value higher than the rated power of the rf source.

CAUTION

If the rated power to be measured is not known, place the POWER RANGE knob in the highest power position before turning on the power source.

Rotate the coupler-detector so that the arrow indicating power flow points toward the load. Turn on the rf power source. Rotate the POWER RANGE knob to the proper range for measuring and observe the point at which the indicating meter peaks.

Q-1. To measure incident power, you must rotate the coupler-detector of the wattmeter so that the arrow indicating power flow points toward which end of the transmission line?

Reflected power is measured in the same manner as described for incident power, except that the coupler-detector is rotated so that the arrow points toward the rf source.

After completing power measurements, de-energize the rf source, disconnect the wattmeter from the transmission line, and place the wire shunt on the meter terminals.

Interpreting Power Measurements Made by the Wattmeter

The rf power measurements made by the wattmeter are used to determine the voltage standing wave ratio (VSWR) of the load and the power absorbed by the load. (VSWR is covered in NEETS, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas*.) The VSWR can be determined from a chart provided in the wattmeter technical manual, or it can be calculated (as shown in the following example for a UHF transmitter) by the formula below (Pi is the incident power, and Pr is the reflected power as measured by the wattmeter):

Where:

Pi = 30 watts

Pr = 0.5 watts

$$
\begin{aligned}
\text{VSWR} &= \frac{\sqrt{P_i}+\sqrt{P_r}}{\sqrt{P_i}-\sqrt{P_r}} \\
&= \frac{\sqrt{30}+\sqrt{0.5}}{\sqrt{30}-\sqrt{0.5}} \\
&= \frac{5.47+0.71}{5.47-0.71} \\
&= \frac{6.18}{4.76} \\
&= 1.30
\end{aligned}
$$

The example above results in a standing wave ratio expressed as 1.3 to 1. In a perfectly matched transmission line where there is no reflected power ($P_r = 0$), the standing wave ratio would be 1 to 1. A standing wave ratio of 1.5 to 1 indicates a 5-percent reflection of energy (loss) and is considered to be the maximum allowable loss. So, our example is within allowable limits.

If the standing wave ratio is greater than 1.5 to 1, then the transmission line efficiency has decreased and troubleshooting is necessary. An excellent discussion of the reasons for standing wave ratio increases is presented in EIMB, *Test Methods and Practices*, NAVSEA 0967-LP-000-0130.

You can determine the rf power absorbed by the load simply by subtracting the reflected power reading from the incident power reading made by the wattmeter (30 watts - 0.5 watts = 29.5 watts).

The power meter just discussed is often described as an IN-LINE POWER METER because readings are taken while the power meter is connected in series with the transmission line. Another type of power meter used by the Navy measures power indirectly. An example of an indirect-measuring power meter is described in the next section.

INDIRECT-MEASURING POWER METERS

An example of an indirect-measuring power meter is the HP-431C, shown in figure 5-2. The controls, connectors, and indicators for the power meter are illustrated in figure 5-3. This power meter can be operated from either an ac or dc primary power source. The ac source can be either 115 or 230 volts at 50 to 400 hertz. The dc source is a 24-volt rechargeable battery. Overall circuit operation of the power meter is shown in the block diagram in figure 5-4.

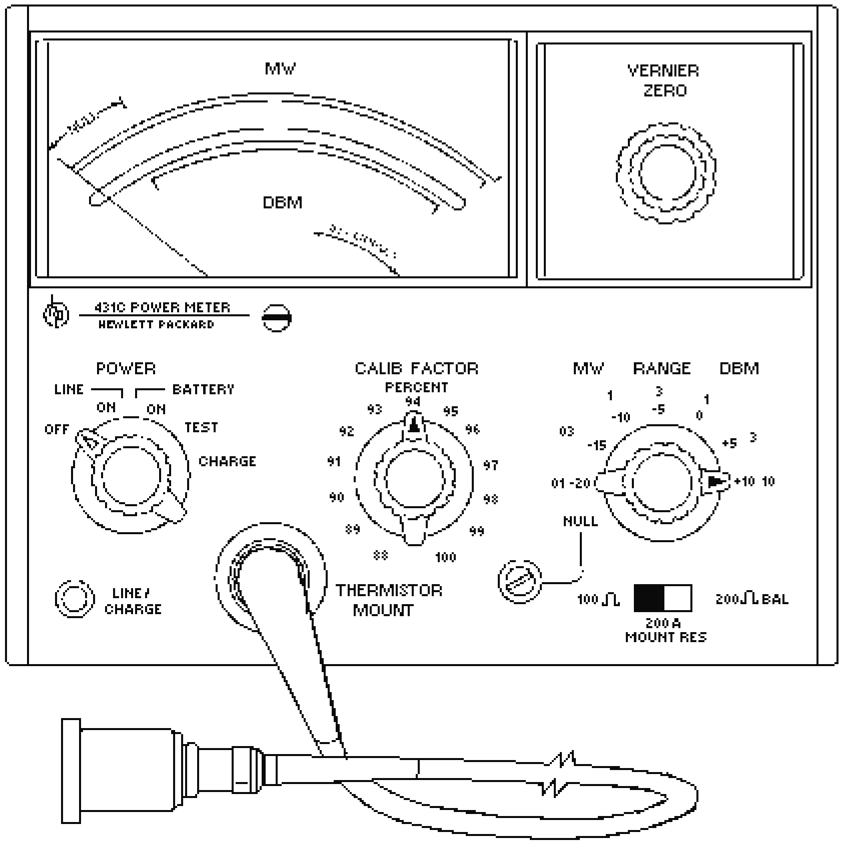

Figure 5-2.—Power meter (HP-431C).

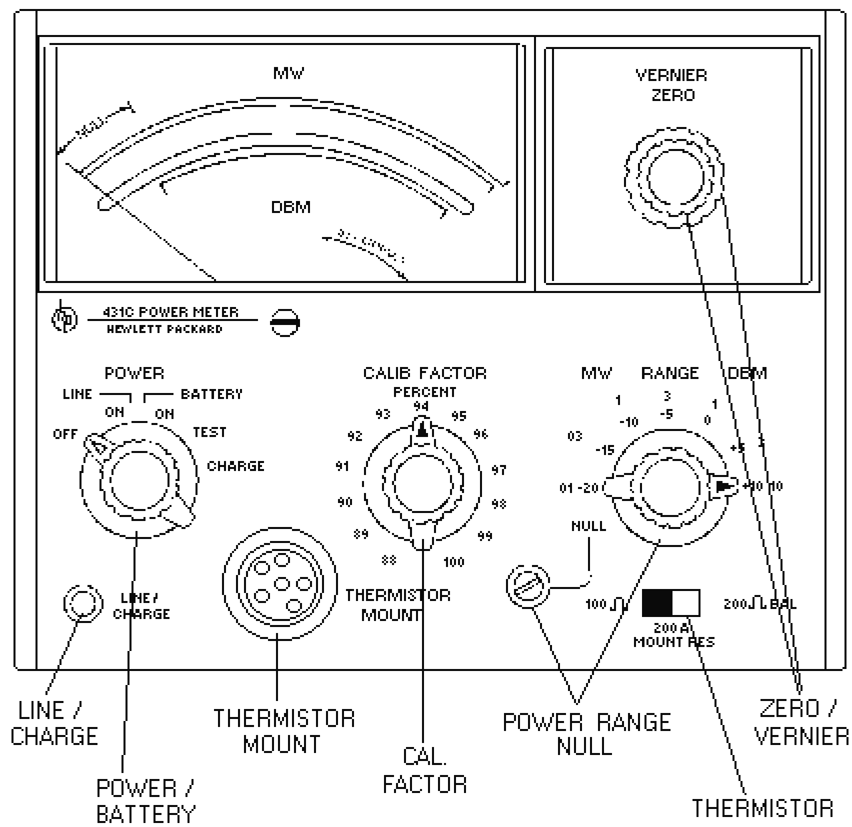

Figure 5-3.—Power meter controls, indicators, and connectors.

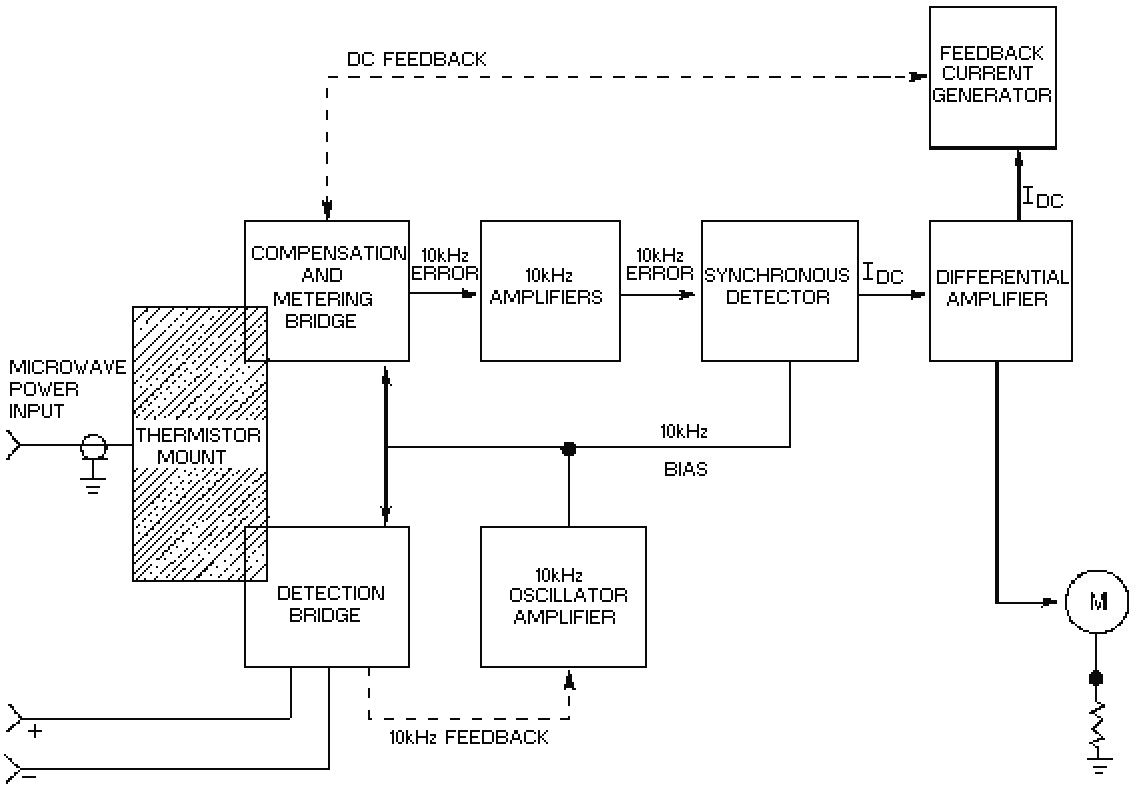

Figure 5-4.—Power meter block diagram.

The HP-431C power meter *indirectly* measures microwave frequency power by using two bridge circuits—the detection bridge and the compensation and metering bridge. The detection bridge incorporates a 10-kilohertz (kHz) oscillator in which the amplitude is determined by the amount of heating of the thermistors in that bridge caused by microwave power. (Thermistors were covered in chapter 2 of this module.) The compensation and metering bridge contains thermistors that are affected by the same microwave power heating as those of the detection bridge.

An unbalance in the metering bridge produces a 10-kHz error signal. This error signal, plus the 10-kHz bias that is taken directly from the 10-kHz OSCILLATOR-AMPLIFIER, is mixed in the SYNCHRONOUS DETECTOR. The synchronous detector produces a dc current (I_{dc}) that is proportional to the 10-kHz error signal. The I_{dc} error signal is fed back to the compensation and metering bridge, where it substitutes for the 10-kHz power in heating the thermistor and drives the bridge toward a state of balance. The dc output of the synchronous detector also operates the meter circuit for a visual indication of power.

Q-2. What condition produces the 10-kHz error signal generated by the metering bridge in the HP-431C power meter?

The HP-431C power meter measures rf power from 10 microwatts (–20 dBm) to 10 milliwatts (+10 dBm) full scale in the 10 MHz to 18 GHz for a 50-ohm coaxial system and 2.6 GHz to 40 GHz for a waveguide system.

SIGNAL GENERATORS

Standard sources of ac energy, both audio frequency (af) and radio frequency (rf), are often used in the maintenance of electronic equipment. These sources, called SIGNAL GENERATORS, are used to test and align all types of transmitters and receivers. They are also used to troubleshoot various electronic devices and to measure frequency.

The function of a signal generator is to produce alternating current (ac) of the desired frequencies and amplitudes with the necessary modulation for testing or measuring circuits. (Modulation was discussed in NEETS, Module 12, *Modulation Principles*.) It is important that the amplitude of the signal generated by the signal generator be correct. In many signal generators, output meters are included in the equipment to adjust and maintain the output at standard levels over wide ranges of frequencies.

When using the signal generator, you connect the output test signal into the circuit being tested. You can then trace the progress of the test signal through the equipment by using electronic voltmeters or oscilloscopes. In many signal generators, calibrated networks of resistors, called ATTENUATORS, are provided. You use attenuators in signal generators to regulate the voltage of the output signal. Only accurately calibrated attenuators can be used because the signal strength of the generators must be regulated to avoid overloading the circuit receiving the signal.

Q-3. In signal generators, what device is used to regulate the voltage of the output signal?

There are many types of signal generators. They are classified by use and the frequency range covered as AUDIO-FREQUENCY (AF) GENERATORS, VIDEO SIGNAL GENERATORS, RADIO-FREQUENCY (RF) GENERATORS, FREQUENCY-MODULATED RF GENERATORS, and other special types, which combine frequency ranges.

AUDIO AND VIDEO SIGNAL GENERATORS

AUDIO SIGNAL GENERATORS produce stable af signals used for testing audio equipment. VIDEO SIGNAL GENERATORS produce signals that include the audio range and extend into the rf range. These signal generators are used to test video amplifiers and other wideband circuits. In both audio and video signal generators (figure 5-5), major components include a POWER SUPPLY, an OSCILLATOR (or oscillators), one or more AMPLIFIERS, and an OUTPUT CONTROL.

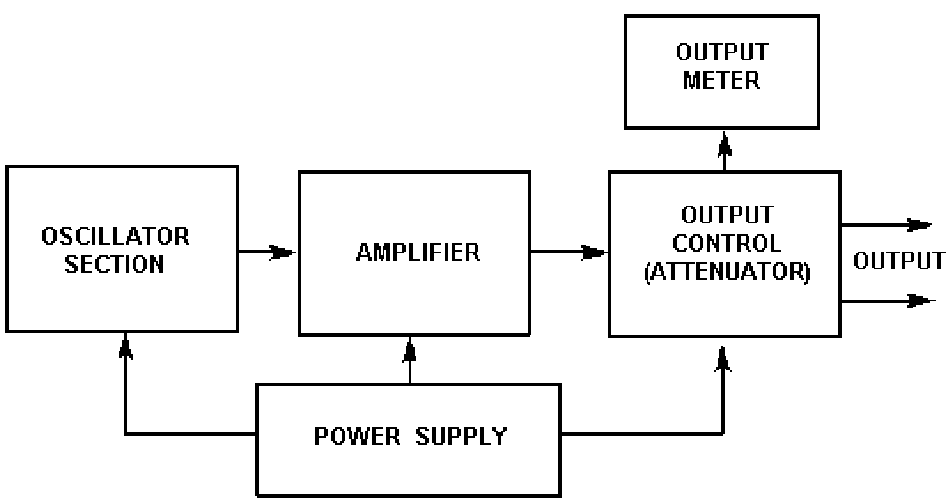

Figure 5-5.—Af and video signal generator block diagram.

In the audio and video generators that produce a beat-frequency, the output frequency is produced by mixing the signals of two separate rf oscillators. One is fixed in frequency, and the other is variable. The difference between the frequencies of the two oscillators is equal to the desired audio or video frequency.

Audio signal generators often include resistance-capacitance (rc) oscillators in which the af is directly produced. In these signal generators, a resistance-capacitance circuit is the frequency-determining part of the oscillator. The frequency varies when *either* the resistance or the capacitance is changed in value.

In other signal generators, however, the capacitance alone is often chosen as the *only* variable element. The change in frequency that can be produced by this method is limited, and it is usually necessary to cover the entire range of the generator in frequency steps. This is usually accomplished by providing several rc circuits, each corresponding to a specific portion of the entire range of frequency values. The circuits in the oscillator are switched one at a time to provide the desired portion of the af range.

The amplifier section of the block diagram (figure 5-5) usually consists of a voltage amplifier and one or two power amplifiers, which are coupled by means of rc networks. The output of the final power amplifier is often coupled to the output control (attenuator) by means of an output transformer.

The output control section regulates the amplitude of the signal. A commonly used af signal generator is the model SPN audio oscillator shown in figure 5-6. The model SPN is a programmable synthesized signal generator designed to provide a stable, low-distortion, wide-amplitude range signal over a 1-Hz to 1.3-MHz frequency range. Additionally, the equipment provides a square wave output and means for swept operation with an external signal and can be remotely controlled via an IEEE-488 bus. For the proper operation of any test equipment, you should always refer to the specific technical manual that describes its use.

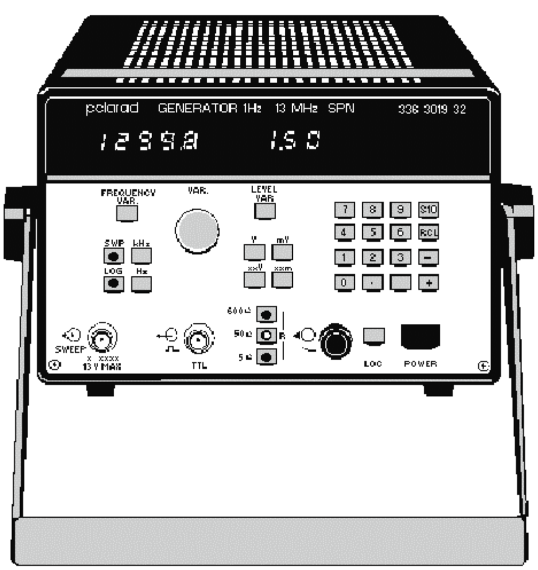

Figure 5-6.—Model SPN audio oscillator.

RADIO-FREQUENCY (RF) SIGNAL GENERATORS

In addition to the necessary power supply, a typical rf signal generator contains three other main sections: an OSCILLATOR CIRCUIT, a MODULATOR, and an OUTPUT CONTROL CIRCUIT. The modulator modulates the rf signal of the oscillator. In addition, most rf generators are provided with connections through which an external source of modulation of any desired waveform can be applied to the generated signal. Metal shielding surrounds the unit to prevent signals from the oscillator from affecting the circuit under test.

Q-4. Name the three main sections of a typical rf signal generator.

A block diagram of a representative rf signal generator is shown in figure 5-7. The function of the oscillator stage is to produce a signal that can be accurately set in frequency at any point within the range of the generator. The type of oscillator circuit used depends on the range of frequencies for which the generator is designed. In lower frequency rf signal generators, the oscillating circuit consists of one of a group of coils combined with a variable capacitor. One of the coils is selected by the position of a range selector switch that connects the coil to a capacitor to provide an inductance-capacitance circuit. The inductive-capacitance circuit then has the correct range of resonant frequencies.

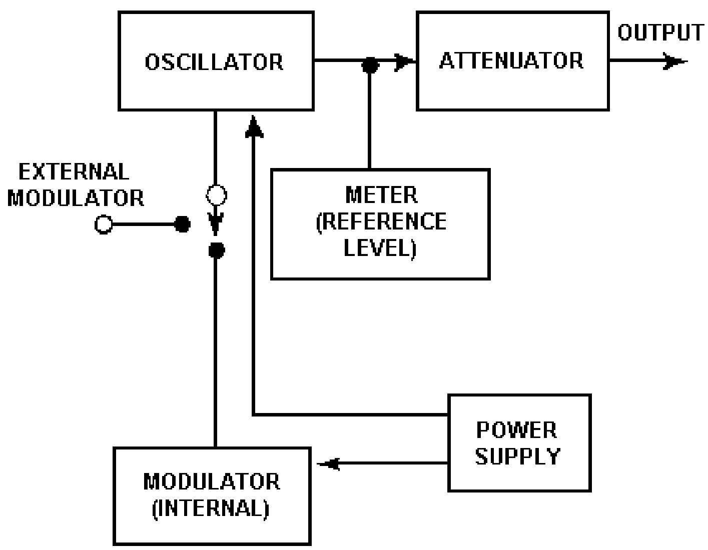

Figure 5-7.—Rf signal generator block diagram.

The function of the modulator is to produce an audio (or video) modulating signal that can be superimposed on the rf signal produced by the oscillator. The modulating signal may be provided by an audio oscillator within the generator. This is termed INTERNAL MODULATION. It may also be derived from an external source. This is termed EXTERNAL MODULATION. In some signal generators, either of these two methods of modulation can be employed. In addition, a means of disabling the modulator section is available so that the pure, unmodulated signal from the oscillator can be used when desired.

Q-5. What is the function of the modulating circuit?

The type of modulation selected depends on the application of the particular signal generator. The modulating signal may be a sine wave, a square wave, or pulses of varying duration. In some special generators, provision is made for pulses over a wide range of repetition rates and widths.

The output circuit of the rf signal generator usually contains a calibrated attenuator and an output level meter. The output level meter provides an indication and permits control of the output voltage of the generator. The attenuator allows you to select the amount of this output. The attenuator is made up of a group of resistors that form a voltage-dropping circuit.

It is controlled by a control calibrated in microvolts. When the control is adjusted so that the output meter reads unity (1.0), the reading on the attenuator control gives the exact value (no multiplication factor) of the output in microvolts. If an output voltage at a lower value is desired, the attenuator control is varied until the meter indicates some decimal value less than 1. This decimal is multiplied by the attenuator reading to give the actual output in microvolts.

An rf signal generator currently in wide use by the Navy is the HP 8640B (figure 5-8). The HP 8640B signal generator covers the frequency range of 500 kilohertz to 512 megahertz, and can be extended to 1,024 MHz by using adapters.

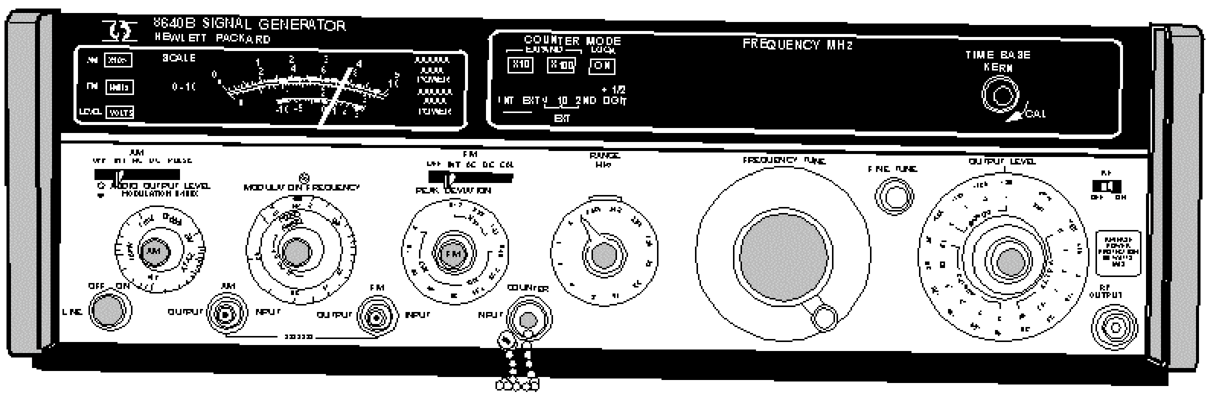

Figure 5-8.—Rf signal generator (HP-model 8640B).

This completes our discussion of signal generators. The following section deals with an instrument that *measures* frequency—the FREQUENCY COUNTER.

FREQUENCY COUNTERS

The signal generators you studied in the previous section *provide* signals for use in testing, aligning, and troubleshooting electronic equipment. Now, we will study the FREQUENCY COUNTER, an instrument that *measures* frequencies. Frequency counters are used to measure frequencies already in existence. An example of a typical frequency counter, the model 5328A, is shown in figure 5-9.

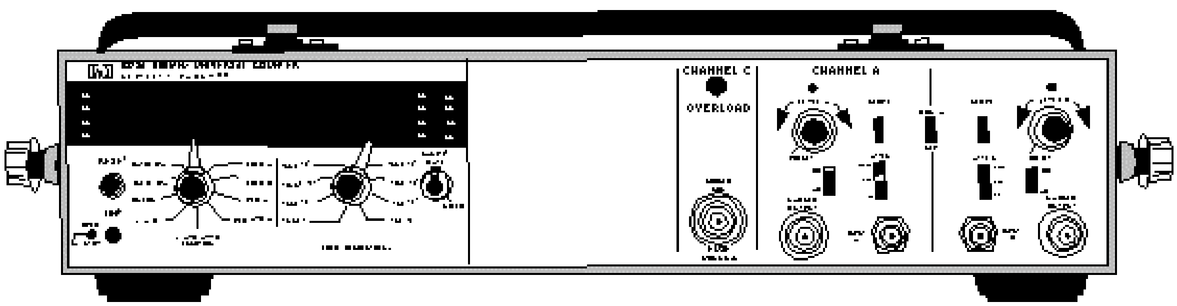

Figure 5-9.—Model 5328A 500 MHz universal frequency counter.

GENERAL DESCRIPTION OF THE FREQUENCY COUNTER

The following description is for the model 5328A counter only. Other counters use different techniques to derive the displayed frequency. The outputs available vary from counter to counter. For further information on other types of counters and their uses, refer to EIMB, *Test Equipment*, NAVSEA 0967-LP-000-0040.

The model 5328A is a portable, solid-state electronic frequency counter. It is used to precisely measure and display, using a nine-digit LED readout, frequency, period, period average, time interval, time interval average, and ratio of electronic frequency signals. This frequency counter can also provide a 1-MHz and 10-MHz output signal through the back-panel BNC.

Q-6. What frequencies are provided through the back-panel BNC?

The model 5328A frequency counter can be divided into four major internal subsections: the main counter section, input section, power supply, and interface bus section. Additionally, two separate (front panel) input channels provide for time interval measurements. Each channel has an attenuator, trigger slope selector, level control, ac or dc coupling, and an oscilloscope marker output. A third input channel is provided to allow the measurement of 30 MHz to 500 MHz with a maximum input of 5 volts rms with a fused-protected connection.

Front-panel controls are provided for you to do the function selection, frequency resolution, sample rate, and reset display. Also, a push-button control on the front panel allows the unit to be used in the operational or standby mode (power applied to the crystal oven to eliminate warm-up). Rear-panel connectors provide the gated output frequencies and an input for an external frequency standard. A detachable front cover is used to store accessory cables and connectors.

Controls and Indicators

Figures 5-10 and 5-11 show all the front- and rear-panel operating controls and indicators. Refer to tables 5-1 and 5-2 for a description of each of the numbered controls and connectors shown in figures 5-10 and 5-11, respectively.

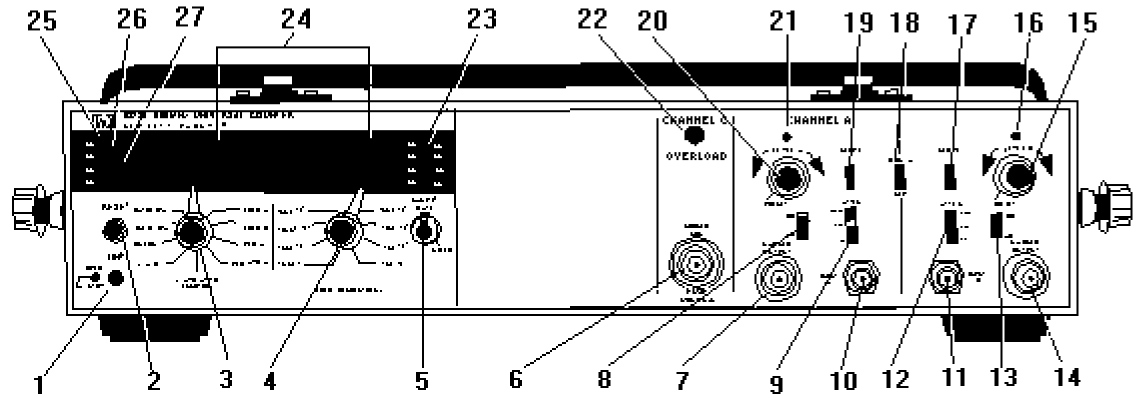

Figure 5-10.—Front-panel controls and indicators.

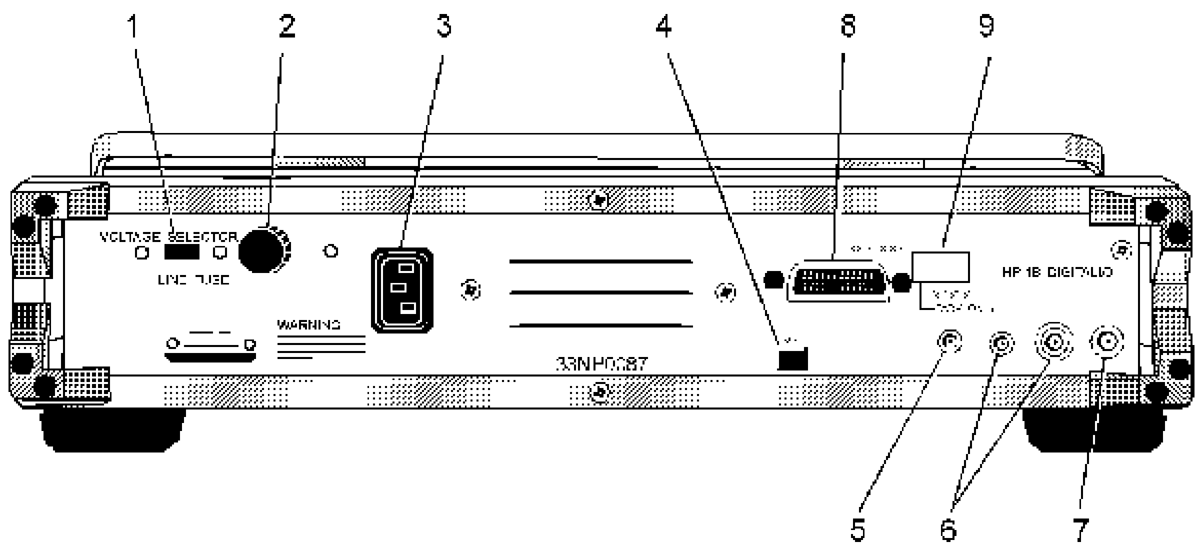

Figure 5-11.—Rear-panel controls and connectors.

Table 5-1.—Front Panel Controls and Connectors

NO.	NAME	DESCRIPTION
1	LINE switch	This is a two-position switch that can be selected for STBY or OPER. When in STBY, the power supply provides power to the oven of the high stability time base to maintain a constant temperature for the crystal. When in OPER, the power supplies normal power to the unit for operation.
2	RESET	This button, when pressed, resets the display and internal count to zero. When pressed continuously, this button lights all segments of the LED display and all annunciator LEDs for a LED test.
3	FUNCTION	This is a 10-position selector used to select the mode of operation.
	FREQ A	This position, when selected, allows the counter to measure frequency at channel A.
	FREQ C	This position, when selected, allows the counter to measure the frequency at channel C.
	PER A	This position, when selected, allows the counter to measure the period at channel A.
	PER AVG A	This position, when selected, allows the counter to make a period average measurement of the signal at channel A. The number of periods over which the average is made is determined by the RESOLUTION switch selection.
	T. I. AVG A→B	This position, when selected, allows the counter to make a time interval measurement of a signal applied to channel A. The number of time intervals over which the average will be made is determined by the RESOLUTION switch selection made.
	T. I. A→B	This position, when selected, allows the counter to make a time interval measurement. The start signal would be applied to channel A and the stop signal applied to channel B.
	CHECK	This position, when selected, applies a 10-MHz signal to the decade counting assemblies, verifying operation of the SAMPLE RATE control, RESOLUTION switch, and RESET.
3 Continued	RATIO C/A	This position, when selected, allows the counter to measure the ratio of the frequency at channel C to the frequency at channel A.
	RATIO B/A	This position, when selected, allows the counter to measure the ratio of the frequency at channel B to the frequency at channel A.
	Top	This position is blank and has no function.
4	FREQ RESOLUTION, N	This is an eight-position switch that is used to select the resolution in frequency measurements and N for totalizing and averaging measurements. This also determines how long the main gate is open for frequency measurements. N / GATE TIME (seconds) / RESOLUTION (Hz) 1 / 1×10^{-6} / 1 M 10 / 10×10^{-6} / 100 k 10^2 / 100×10^{-6} / 10 k 10^3 / 1×10^{-3} / 1 k 10^4 / .01 / 100 10^5 / .1 / 10 10^6 / 1 / 1 10^7 / 10 / .1
5	SAMPLE RATE control	This is used to vary the time between measurements continuously from approximately 2 milliseconds to an indefinite hold of the display.
6	500 MHz, 50 Ω	This is the channel C input connector.
7, 14	OUTPUT MARKER	These are the channel A and B Schmidt trigger outputs used to indicate when a channel is triggered by 0 to 300 mV levels with less than 20 nanoseconds delay.

Table 5-1.—Front Panel Controls and Connectors—Continued

8, 13	AC/DC	These control the selection of ac or dc coupling for the input signal. When the input amplifier control switch (No. 18) is in COM A, channel B coupling is determined by setting of channel A coupling switch.
9, 12	ATTEN switches	These select the attenuation of the input signal. The signal amplitude is reduced by 10 in ×10 and by 100 in ×100. When the input amplifier control switch (No. 18) is in COM A, the channel B attenuation is determined by the channel A attenuation switch.
10, 11	INPUT A and B	These are the input BNC connectors for channels A and B.
15, 20	LEVEL A/B	These controls are used in conjunction with the ATTEN (Nos. 9, 12) to select the voltage at which triggering will occur. With X1 attenuator selected, the level is variable at ±2.5 volts, and ×100 at ±250 volts.
16, 21	Channel A and B triggering lights	The light will blink for the associated channel when triggering is occurring. When the light is off, the input signal is below triggering level and on when the signal is above triggering level.
17, 19	Channel A and B SLOPE switch	These switches control the selection of triggering on either the positive or negative slope of the input signal.
18	COM A/SEP	This is the input amplifier control switch that selects independent operation of channels A and B in SEP (separate) position. When in COM A (common A) position, the signal at A is also applied to channel B; this disconnects the channel B input circuitry. Channel B coupling and attenuation are then determined by the channel A setting.
22	OVERLOAD	This indicator will flash on and off if more than 5 volts is applied to channel C input.
23	K, S, M, n, and Hz	These will light up to show the appropriate units multiplier of the measurement being taken.
24	LED display	This is a nine-digit LED display that shows the numerical measurement taken.
NO.	**NAME**	**DESCRIPTION**
25	OVFL	This indicates an overflow of one or more of the most significant digits (leftmost from the decimal point) are not displayed.
26	RMT	Lights when the unit is in remote operation.
27	GATE	Lights when the counter's main gate is open and a measurement is in progress.

Table 5-2.—Rear-Panel Controls and Connectors

NO.	NAME	FUNCTION
1	VOLTAGE SELECTOR	Used to select 115 or 230 volt operation.
2	LINE FUSE	This requires the insertion of a 2.0 amp fuse for 115 volt or 1.0 amp fuse for 230 volt operation.
3	Input ac connector	Used to connect the input ac to the unit.
4	ARM	When this switch is in the OFF position, the counter is armed by the signal that is selected for measurement. In the ON position, the measurement is armed by an input other than the input being measured.
5	EXT OSC	This input connector allows a separate outside signal to be used for the time base.
6	1 MHz OUT and 10 MHz OUT	These connectors allow an internal oscillator signal to be used externally when connected.
7	GATE/MARKER OUT	Applies a high to the output when the main gate is open.
8	HP-IB	This is an interface bus connector that allows the unit to receive programming instructions.

Frequency Measurement

As discussed previously, the model 5328A frequency counter is capable of measuring frequency, time period (inverse of frequency), ratio, and time interval. We will start with frequency. When the FUNCTION selector is in the FREQ A or FREQ C position, the counter measures the frequency, f, by accumulating the number of cycles, n, of the input signal that occurs over the time period, t. This is expressed by:

$$f = \frac{n}{t}$$

The basic counter elements necessary to perform this measurement are shown in figure 5-12. The INPUT AMPLIFIER/TRIGGER essentially conditions the input signal to a format that is compatible with the internal circuitry of the counter. As figure 5-12 indicates, the output of the amplifier/trigger corresponds directly to the input signal.

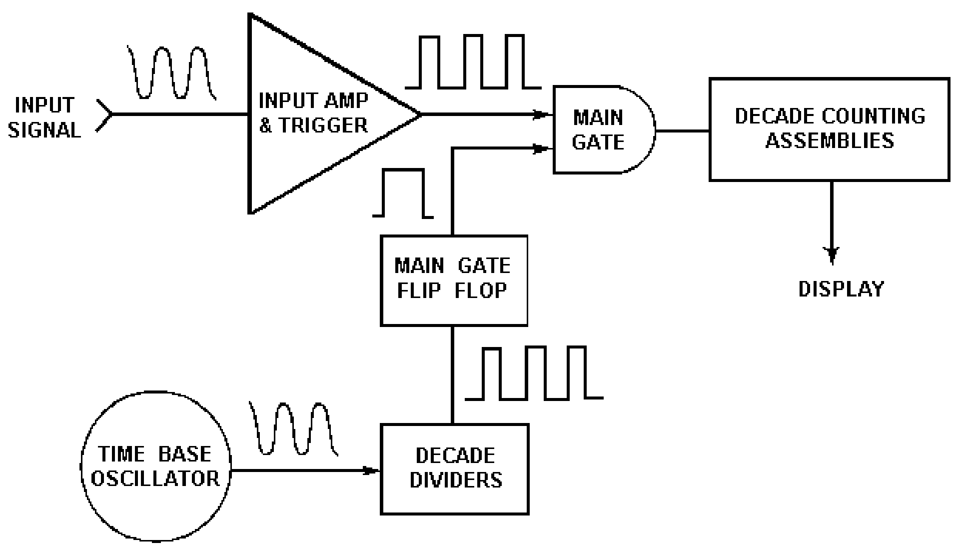

Figure 5-12.—Basic elements of the frequency counter.

The TIME BASE OSCILLATOR is a 10-MHz temperature-controlled (oven-regulated) precision, crystal oscillator used for the time base element from which time, t, is derived. DECADE DIVIDERS take the time base oscillator signal as the input and provide a pulse train, whose frequency is variable in decade steps. This frequency can be controlled by the FREQ RESOLUTION, N switch. The time, t, is determined by the period of this pulse train.

The heart of the counter is the MAIN GATE. When the gate is opened, pulses from the amplifier/trigger are allowed to pass through. The opening and closing of the main gate is controlled by the decade divider output to the main gate flip-flop. The output of the MAIN GATE is then sent to the DECADE COUNTING ASSEMBLIES (DCAs), where the pulses are combined and displayed after the gate is closed.

If the FREQUENCY RESOLUTION, N selection switch, is set for 10^6, the main gate is open for 1 second, and the decade counting assemblies display the frequency of the input signal in hertz (refer to figure 5-10, FREQUENCY RESOLUTION, N selection switch).

Period Measurement

Period, the inverse of frequency, can be measured with the counter by reversing the inputs to the main gate. With the FUNCTION selector switch in the PER A position, the input signal controls the duration over which the main gate is open and the decade divider output is counted by the DCAs (see figure 5-13). The duration of the count is one cycle or period of the input signal. When the FUNCTION selector is in the PER AVG A position, the unused decades in the decade divider chain are used to divide the amplifier/trigger output so that the gate remains open for decade steps of each input period rather than a single period. This is the basis for multiple period averaging. Period and period averaging techniques are used to increase measurement accuracy on low-frequency measurements.

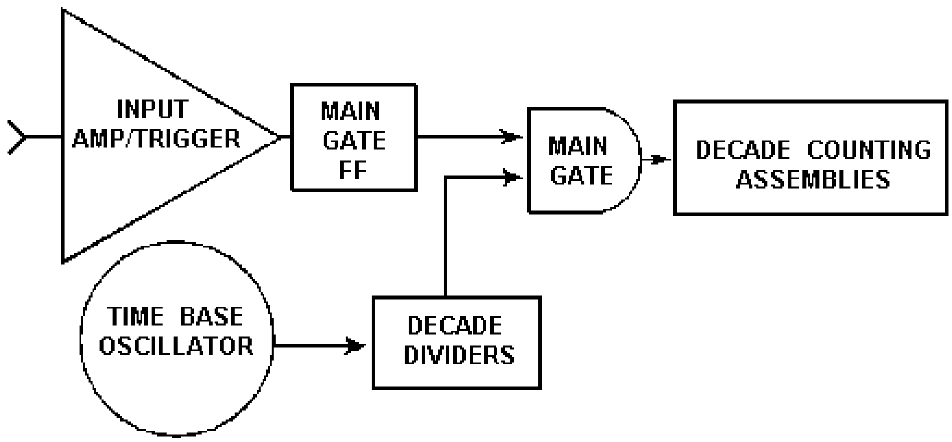

Figure 5-13.—Measuring period.

Ratio Measurement

Placing the FUNCTION selector switch to RATIO C/A OR B/A sets the counter to measure the ratio of the signal frequency at channel C or B to the signal frequency at channel A. Using the same configuration as in figure 5-13 and replacing the time base with a second input frequency, f_2, you can measure the ratio of f_2/f. The signal at frequency f can be divided into decade steps in the same manner as multiple period averaging for higher resolution.

Time Interval Measurement

Figure 5-14 illustrates the configuration for the measurement of time between two events or time interval. This is done by placing the FUNCTION selector in the T.I.AVG AB position. The START input opens the main gate, and the STOP input closes it. The START input is applied to channel A, and the STOP input is applied to channel B. The decade divider output (clock pulses) is counted, and the display shows the elapsed time between START and STOP signals, as shown in figure 5-15.

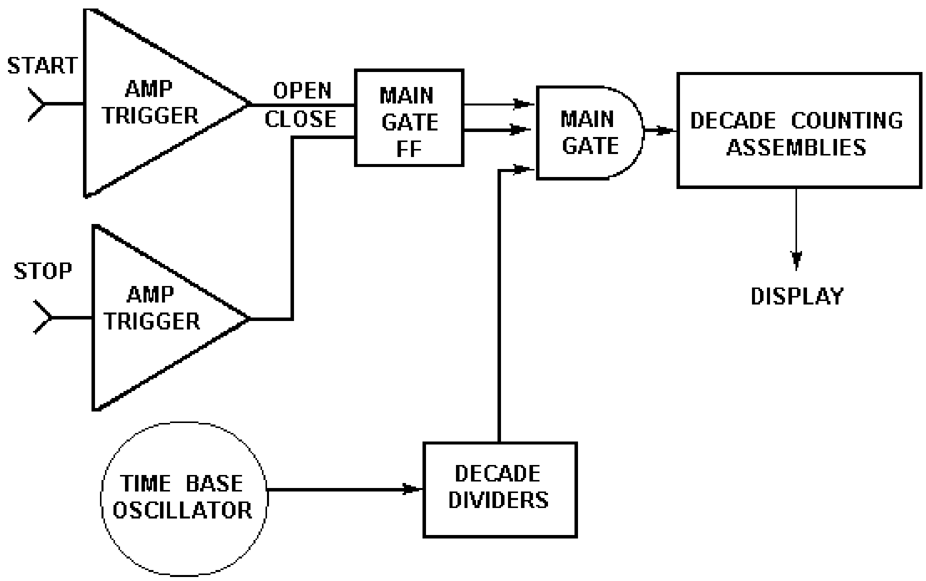

Figure 5-14.—Basic elements of a time interval counter.

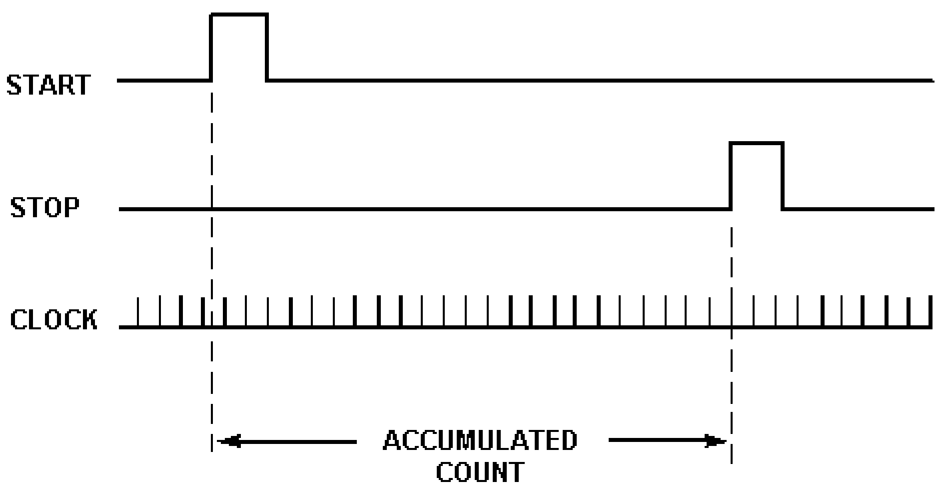

Figure 5-15.—Clock pulses.

Resolution

The resolution of the measurement is determined by the frequency of the counted clock (for example, a 10-MHz clock provides 100 ns resolution [see figure 5-10, FREQUENCY RESOLUTION, N selection switch]). The input amplifier, main gate, and DCAs (elements of the time interval counter) must operate at speeds consistent with the clock frequency; otherwise the instrument's resolution would be meaningless. Clock frequencies of 1, 10, and 100 MHz, and other 10n frequencies, are preferred, since the accumulated count, with the appropriate placement of the decimal point, gives a direct readout of the time interval. This explains why the conventional time interval counter is presently limited to 10 nanoseconds, a clock frequency of 100 MHz. One GHz is beyond reach, and a clock frequency of 200 MHz would require some arithmetic processing of the accumulated count in the DCAs to enable time to be displayed directly.

Time Interval Averaging

The time interval averaging technique is based on the fact that if the ±1 count error is truly random, it can be reduced by averaging a number of measurements. The words "truly random" are significant. For time interval averaging to work, the time interval must (1) be repetitive and (2) have a repetition frequency that is asynchronous to the instrument's clock. Under these conditions, the resolution of the measurement is:

$$\text{resolution} = \frac{\pm 1 \text{ count}}{\sqrt{N}}$$

$$\text{where } N = \text{number of time intervals averaged}$$

With averaging, resolution of a time interval measurement is limited only by the noise inherent in the instrument. The 5328A can obtain 10-picoseconds resolution. Most time interval averaging has one severe limitation: The clock period limits the minimum measurable time interval. With the FUNCTION selector switch in the T.I. AVG AB position, synchronizers are used to remove this limitation. These synchronizers enable the 5328A to measure intervals as short as 100 picoseconds.

Referring to figure 5-16, note that the input waveshape shows a repetitive time interval, which is asynchronous to the square wave clock. When these signals are applied to the main gate, with no synchronizers, an output similar to the third waveform results. Since the DCAs are designed to count at the clock frequency and are unable to accept pulses of shorter duration than the clock, the resulting counts accumulated in the DCAs will be in error, as shown in the fourth waveform. This problem is alleviated by the synchronizers, which are designed to detect leading edges of the clock pulses that occur while the gate is open. They detect and reconstruct the leading edges, making the pulses applied to the DCAs the same duration as the clock, as shown in the fifth waveform. Occasionally, when the input time interval repetition is synchronous with the internal clock, time interval averaging cannot be performed.

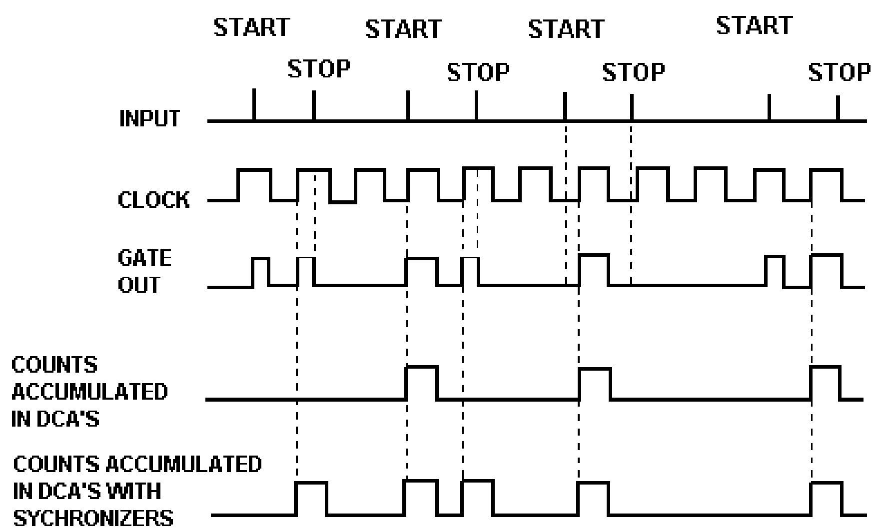

Figure 5-16.—Synchronizer operation with time interval averaging.

This ends our discussion on electronic frequency counters. Now, we'll study an area of electronics test equipment that is becoming more widespread and important each day—the testing of electronic logic components. A test instrument of value for any technician who works on digital equipment is the LOGIC PROBE, which is an integrated circuit-testing device.

INTEGRATED CIRCUIT-TESTING DEVICES

Digital integrated circuits are relatively easy to troubleshoot and test because of the limited numbers of input and output combinations involved in circuits. The two-state conditions in logic circuits are often referred to as (1) low or high, (2) on or off, or (3) one or zero (1 or 0).

Other terminology may also be used. Any particular integrated circuit (IC) can be tested by simply comparing it to a known good one. The LOGIC PROBE is a device that can be of great value in troubleshooting digital integrated logic circuits.

The ideal logic probe has the following characteristics:

- It will detect a steady logic level.
- It will detect a train of logic levels.
- It will detect an open circuit.
- It will detect a high-speed transient pulse.
- It will have over-voltage protection.
- It will be small, light, and easy to handle.

The use of a suitable logic probe can greatly simplify your troubleshooting of logic levels through digital integrated logic circuitry. It can immediately show you whether a specific point in the circuit is low, high, open, or pulsing. Some probes have a feature that detects and displays high-speed transient pulses as small as 10 nanoseconds wide. These probes are usually connected directly to the power supply of the device being tested, although a few have internal batteries.

Most IC failures show up in a circuit as a constant high or low level. Because of this, logic probes provide a quick, inexpensive way of locating the fault. They can also display the single, short-duration pulse that is hard to detect on an oscilloscope. Figure 5-17 shows a basic logic probe.

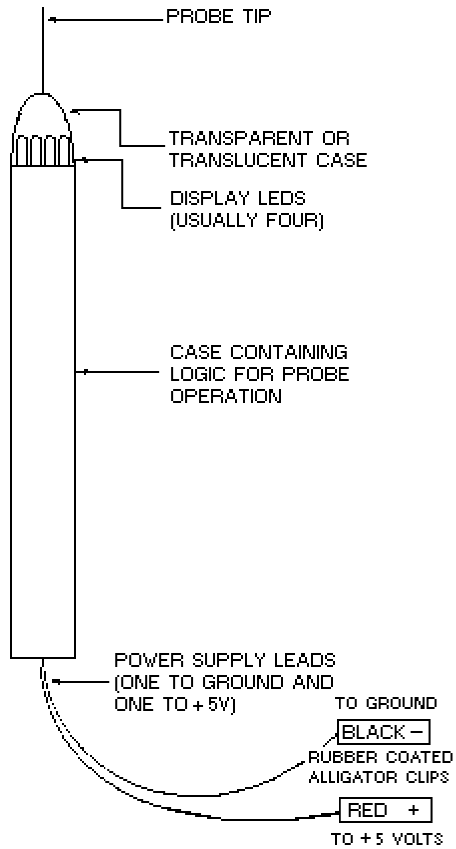

Figure 5-17.—Basic logic probe.

The logic probe can be powered from the supply of the circuit under test or from a regulated dc power supply. If a separate power supply is used, the ground points of the power supply and circuit under test should be connected together.

The display LED (light-emitting diode) near the probe tip provides an immediate indication of the logic state existing in the circuit under test. The LED will provide any of four indications: (1) off, (2) dim (about one-half brilliance), (3) bright (full brilliance), and (4) flashing on and off. The LED is normally in the dim state and must be driven to one of the other three states by voltage levels at the probe tip. The LED is usually bright for inputs above the logic "1" threshold and off for inputs below the logic "0" threshold. The LED is usually dim for voltages between the logic "1" and logic "0" thresholds and for open circuits.

Q-7. The LED lamps of a typical logic probe are normally in what state?

Another logic circuit analysis technique is useful with the logic probe. This technique is to run the circuit under test at its normal clock (timing) rate while monitoring for various control signals, such as RESET, START, STOP, SHIFT, TRANSFER, or CLOCK. Questions such as "Is the counter operating?" are quickly resolved by noting if the probe indicator is flashing on and off, indicating that pulse train activity is present.

This ends our discussion on logic probes. Now, we'll study another piece of electronics test equipment that is used in evaluating integrated circuits, the HUNTRON TRACKER 2000.

HUNTRON TRACKER 2000

The logic probe we just discussed is but one specialized tool used to isolate problems to the component level. Another device you can use is the Huntron Tracker 2000. It is a very versatile electronic troubleshooting tool that is used to evaluate suspect components and/or locate defective components on de-energized circuit cards quickly and safely without requiring the removal of component leads. The unit provides a built-in display that allows you to visually analyze the component under test conditions.

CAUTION

Before connecting the Huntron Tracker 2000, you must first secure all power, then discharge all high-voltage capacitors.

PHYSICAL FEATURES

Because the Tracker 2000 has so many controls and indicators, it would impractical to cover each within this chapter. We will therefore concentrate our discussion only to the externally accessible features. To find information on internal controls and indicators, you should review the most current technical manual with up-to-date changes entered for the unit being used.

Front Panel

The front-panel (figure 5-18) design allows you to easily select the desired function. All the push buttons are the momentary action type and have light-emitting diode (LED) indicators embedded in them to show the functions that are active, by lighting up when active. A detailed description of each item on the front panel is provided in table 5-3.

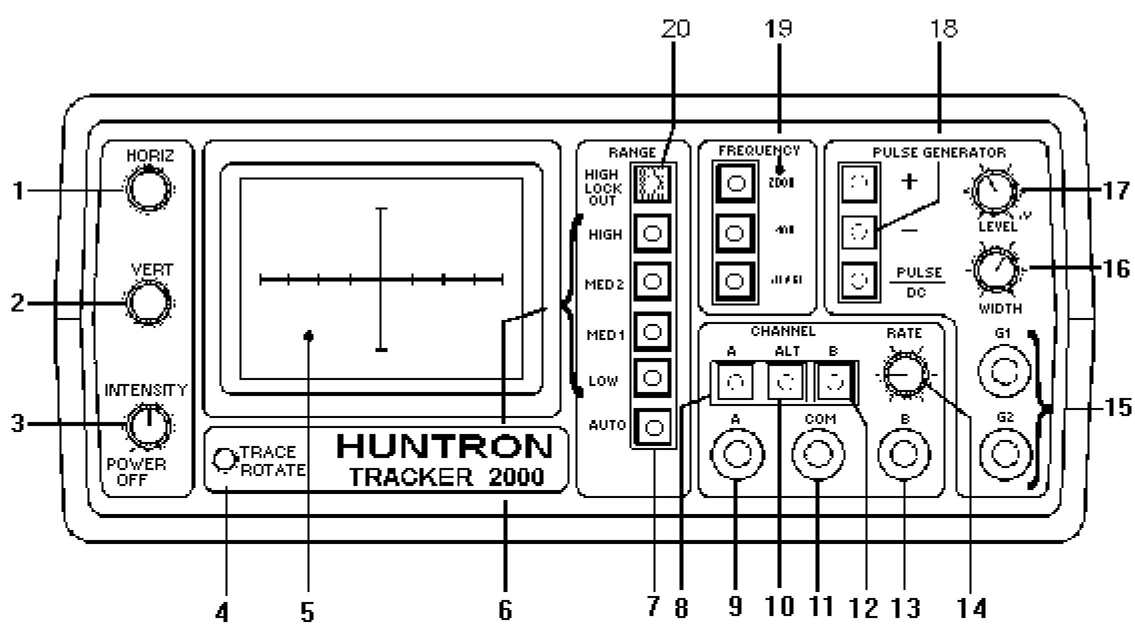

Figure 5-18.—Front Panel.

Table 5-3.—Front-Panel Controls and Connectors

NO.	NAME	DESCRIPTION
1	HORIZ control	When adjusted this controls the horizontal position of the CRT display.
2	VERT control	When adjusted, this controls the vertical position of the CRT display.
3	POWER on/off and INTENSITY control switch	When this is rotated clockwise, the power is turned on. Further adjustment of the switch controls the intensity of the CRT display. When it is rotated fully counterclockwise, the power is turned off.
4	TRACE ROTATE control	When adjusted, this controls the trace rotation of the CRT.
5	CRT display	This displays the signatures produced by the unit.
6	RANGE selectors	These are push buttons that are used to select one of four impedance ranges: LOW, MEDIUM 1, MEDIUM 2, and HIGH.
7	AUTO selector	This push button, when selected, initiates automatic scanning of the four ranges from low to high. The speed of the scanning is determined by the RATE control (item 14)
8	CHANNEL A selector	This push button, when selected, causes channel A to be displayed on the CRT.
9	CHANNEL A test plug	This is a fused test lead connector that is active when channel A is selected. All test lead connectors accept standard banana plugs.
10	ALT selector	When selected, this push button causes the unit to alternate between channel A and channel B. The speed of this is determined by the RATE control (item 14).
11	COM test plug	This test lead connector is the instrument common to and the common reference point for channel A and channel B.
12	CHANNEL B selector	This push button, when selected, causes channel B to be displayed on the CRT.
13	CHANNEL B test plug	This is a fused test lead connector that is active when channel B is selected.
14	RATE control	This controls the channel alteration and/or the range scanning.
15	G1 and G2 plugs	These are used for the pulse generator output test leads.
16	WIDTH control	This controls the duty cycle of the pulse generator.
17	LEVEL control	This controls the amplitude of the internal pulse generator.
18	PULSE GENERATOR selectors	These push buttons are used to select the output modes of the pulse generator: positive (+), negative (–) or PULSE/DC.
19	FREQUENCY selectors	These push buttons are used to select one of the three test signal frequencies: 50/60 Hz, 400 Hz, 2000 Hz.

Cathode-Ray Tube (CRT) Display

The CRT display (figure 5-19) is used to view the signature of the component under test. The display has a graticule consisting of a horizontal and vertical axes. The horizontal axis is used to represent voltage with the vertical axis being used to represent current. The axes divide the display into four quadrants. Each quadrant displays a different portion of the signature for the component under test.

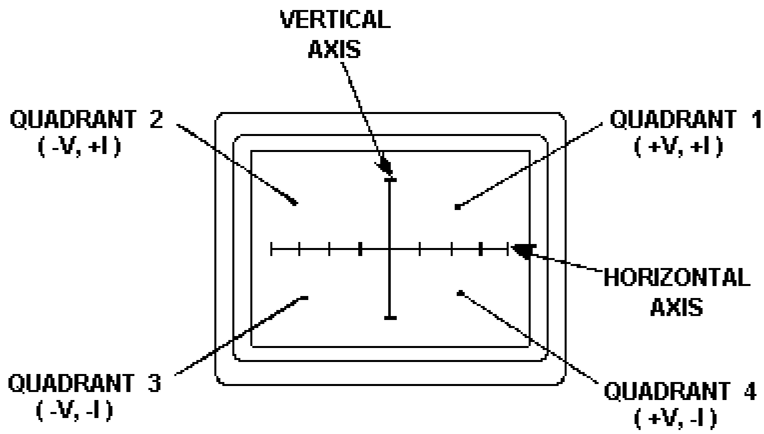

Figure 5-19.—CRT display.

- Quadrant 1 displays positive voltage and positive current.
- Quadrant 2 displays negative voltage and positive current.
- Quadrant 3 displays negative voltage and negative current.
- Quadrant 4 displays positive voltage and negative current.

Q-8. On the CRT display, what information is displayed in Quadrant 4?

The horizontal axis (see figure 5-19) is divided into eight equal divisions, allowing the technician to estimate the voltage at which changes occur in the signature for the component being tested. The associated approximate horizontal sensitivities for each range are:

- High = 15.0 Volts/Div.
- Medium 2 = 5.0 Volts/Div.
- Medium 1 = 3.75 Volts/Div.
- Low = 2.5 Volts/Div.

Back Panel

The back panel (figure 5-20) provides three additional controls and connectors. One is the accessory output connector (ACC), which provides a clock signal and power for the Huntron Switcher Model HSR410. Next, is the power cord connector used to provide the required ac line voltage used to power the unit. The last item found on the back panel is the FOCUS control; this controls the focus for the front-panel CRT display.

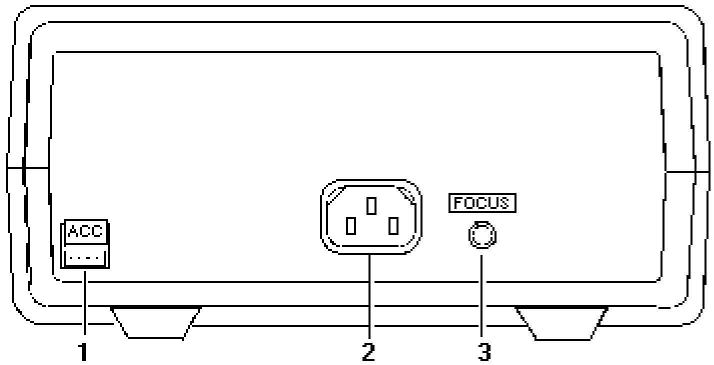

Figure 5-20.—Back panel.

OPERATION

The following sections explain how to use most of the front- and back-panel controls and connectors. Each control and connector has already been briefly described. To review this information, refer to figure 5-18 and table 5-3.

Initial Setup

First, turn the POWER/INTENSITY knob located on the front panel to the clockwise, on, position. Under normal conditions, the unit will come on with the following LEDs illuminated: power, channel A, 50/60 Hz, low range, and pulse/DC.

Focusing the CRT is very critical for the technician to be able to properly analyze the signature being displayed. This is done by first turning the INTENSITY control to a level comfortable for the eye, and then adjusting the FOCUS control (back panel) for the narrowest possible trace.

Aligning the trace will help determine, during troubleshooting, which quadrant the portion of the signature is in during a change. With a short circuit applied to channel A (connect a cable between jack A and COM), adjust the TRACE ROTATE control until the trace is as close to parallel as possible to the vertical axis. Then, adjust the HORIZ (horizontal) control until the vertical trace is as close to even with the vertical axis as possible.

Q-9. When aligning the trace with a short applied to channel A, which control should be adjusted to bring the trace parallel to the vertical axis?

With an Open applied to channel A (nothing connected to A and COM test plug), adjust the VERT (vertical) control until the horizontal trace is as close to even with the horizontal axis as possible. Once set, these adjustments should not need readjusting during the unit's operation. However, remember that each time the unit is used, this process will need to be repeated.

Range Selection

Four impedance ranges (LOW, MED 1, MED 2, and HIGH) can be selected on the Tracker 2000. These ranges will become active when the appropriate front-panel button is pressed. To obtain the most useful signature display when troubleshooting a component, you should always start by selecting one of the two medium ranges (medium 1 or medium 2). If the display appears to be an open (horizontal trace), then the next higher range should be selected to get a more accurate signature for analysis. If the display appears to be a short (vertical trace), then the next lower range should be selected.

The AUTO feature, when selected, will allow the unit to automatically scan through the four ranges at a speed set by the technician using the RATE control knob. This allows the user to keep his or her hands free to hold test leads while still being able to observe the component under test signature for analysis. The HIGH LOCKOUT, when selected by the technician, prevents the unit from functioning in the HIGH range in either the manual or AUTO mode.

Channel Selection

You can select two channels by pressing the channel A (test probes connected to A jack and COM) or channel B (test probes connected to B and COM jacks) push button on the front panel. When using a single channel, you should plug the red probe into the corresponding channel test jack, and plug the black test lead into the common test jack. When testing a component, you should connect the red probe to the positive terminal and the black probe to the negative terminal of the component under test. Following this procedure every time will ensure that the signature for the component under test will be displayed in the correct quadrants of the CRT display.

The ALT (alternate) mode provides automatic switching back and forth between channel A and channel B. This allows you to easily compare two components or the same test points on two circuit boards. You select the ALT mode by pressing the ALT push button on the front panel. The rate of switching between channels A and B can be varied by adjusting the RATE control knob on the front panel. You will find that the ALT mode feature is very useful for comparing a known good component with the same type of component that is of unknown quality.

Figure 5-21 shows a typical way of connecting the unit to a known good circuit board and a board under test. This test mode uses the supplied common test leads to connect two equivalent points on the boards to the common test jack. Note that the black probe is now being used in the channel B jack rather than the COM jack. When the technician uses the ALT and AUTO features together, each channel is displayed before the range selection will change. Figure 5-22 shows the sequence of these changes.

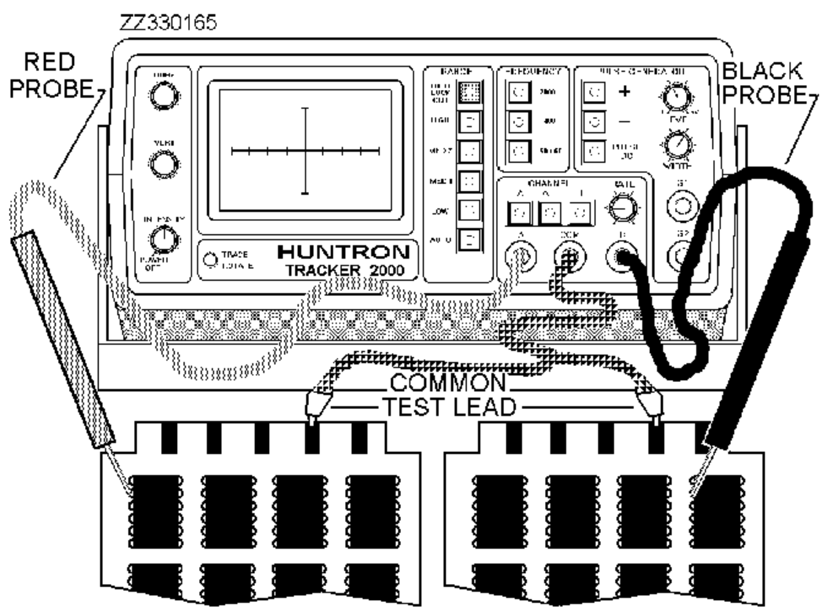

Figure 5-21.—ALT (alternate) mode setup.

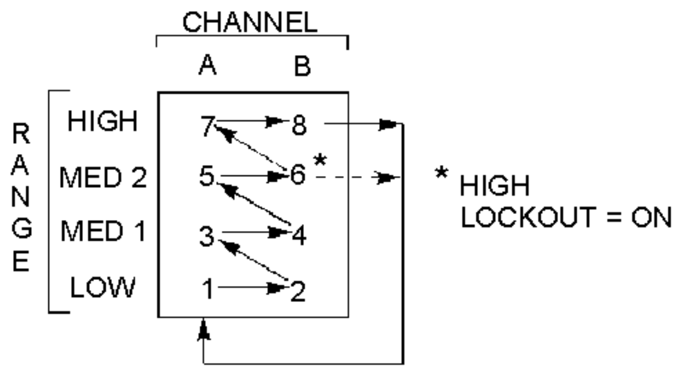

Figure 5-22.—AUTO/ALT sequence.

Frequency Selection

There are three test signal frequencies (50/60 Hz, 400 Hz, and 2000 Hz) that can be selected and then provided by pressing the appropriate front-panel push button. During most troubleshooting evolutions, the 50/60 Hz test signal is the best to start with. The 400 Hz and 2000 hz frequencies are generally used to view small amounts of capacitance or large amounts of inductance.

Pulse Generator

A built-in pulse generator is also provided with the Tracker 2000. It allows the technician to do dynamic, in-circuit testing of certain devices in their active mode. In addition to using the red and black probes, you can connect the output of the pulse generator to the control input of the device to be tested with one of the blue micro clips provided with the unit. The pulse generator has two outputs (G1 and G2 jacks) so that three devices can also be tested in the ALT (alternate) mode. Figure 5-23 shows a way of connecting the unit in the ALT mode using the pulse generator.

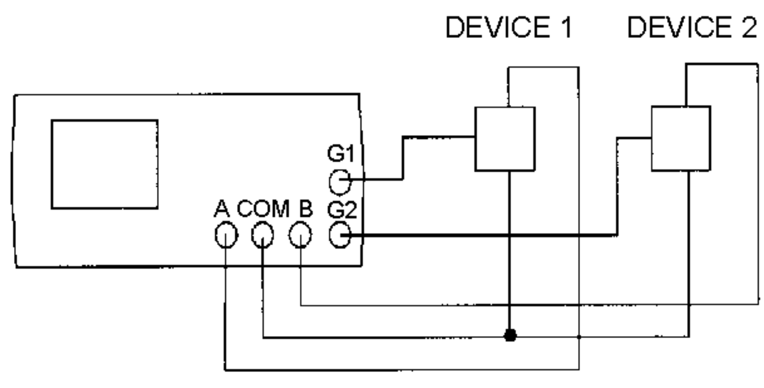

Figure 5-23.—Pulse generator comparison mode.

There are a variety of output waveforms available using the pulse generator selection buttons, as shown in figure 5-24. First, the technician must select the PULSE mode or DC mode using the PULSE/DC button located on the front panel. In the PULSE mode, the PULSE/DC LED flashes at a slow rate. While in the DC mode, this LED will be continuously on.

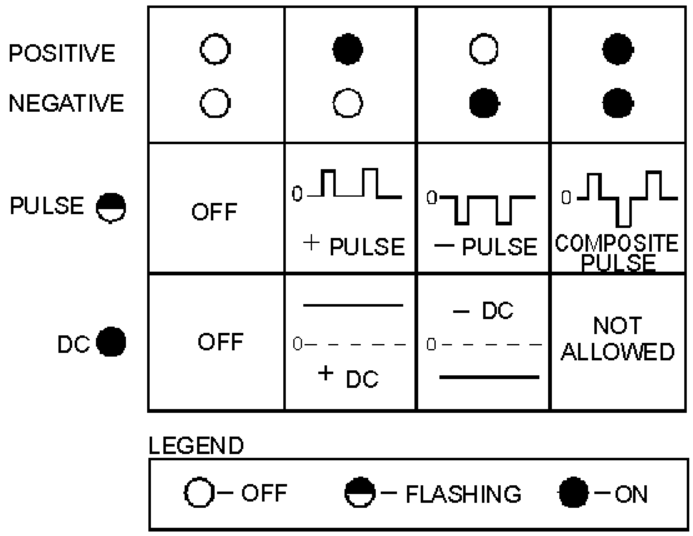

Figure 5-24.—Pulse generator selector chart.

Next, the technician needs to select the polarity of the output desired by using the positive (+) and/or negative (–) push buttons. All three buttons only function in a push-on/push-off mode and will only interact with each other to avoid the NOT ALLOWED state found in figure 5-24.

Once the specific output type has been selected, the output desired by the technician is set using the LEVEL and WIDTH controls. The LEVEL control is used to vary the magnitude of the output amplitude from zero to 5 volts (peak or DC). During the PULSE mode, the WIDTH control will adjust the cycle of the pulse output from low to 50 percent maximum (square wave).

The start of a pulse will be triggered by the appropriate zero crossing of the test signal, which results in the pulse frequency being equal to the selected test signal frequency.

The end of the pulse is determined by the WIDTH control setting, which determines the cycle length. The WIDTH control, however, has no effect when the DC mode is selected.

FUNCTIONAL OVERVIEW

There are six major sections in the Tracker 2000, as shown in the block diagram in figure 5-25. The control logic section controls the selection of the channel, frequency, impedance range, and pulse generator mode according to the front-panel buttons pushed by the technician. The oscillator provides the test signal that is used by the signal and pulse generator sections. In the signal section, the test jacks are driven by the test signal, while signal conditioners monitor the jacks and produce the horizontal and vertical signals used by the CRT section to produce a component signature on the display. The pulse generator provides an added source for testing three additional terminal devices. The power supply produces all the required voltages needed to operate the Tracker 2000.

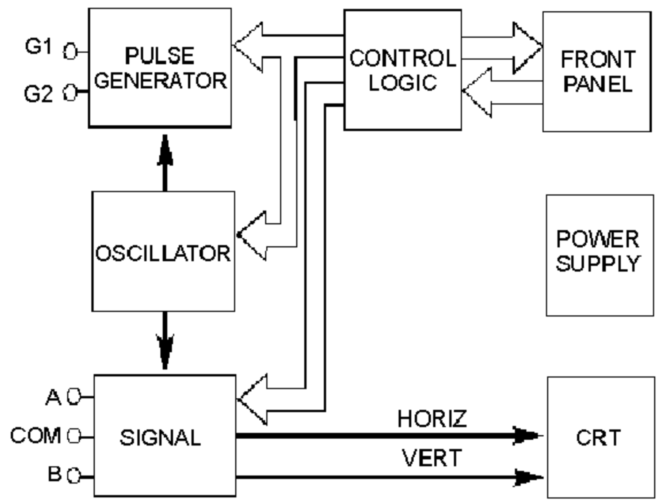

Figure 5-25.—Tracker 2000 block diagram.

Control Logic

The control logic senses which button is pushed on the front panel. Since the buttons are the momentary action type, the logic must remember what button was pushed, turn on the LED indicator within the button, and activate the appropriate configuration of the oscillator, signal, and pulse generator sections.

After a button is pushed, the unit will remain in that configuration until another selection is made or the power is secured. The HIGH LOCKOUT and PULSE GENERATOR push buttons are the only ones that require repetitive pressing to be turned on or off.

The channel relay is controlled by CHANNEL buttons A, ALT, and B. The relay is a single-pole, double-throw type and is de-energized for channel A and energized for channel B. If CHANNEL A is already selected and the CHANNEL B button is pressed, CHANNEL A will be canceled and CHANNEL B selected. When the ALT button is pressed, another control line is set, which enables an internal clock to toggle the channel relay on and off, causing the unit to alternate between channels A and B.

The internal clock is controlled by the RATE control knob on the front panel. When the ALT mode is active, the LEDs within the A and B buttons flash alternately, and the ALT LED is on continuously. Pressing either of the channel buttons will cancel the ALT mode, and the selected channel will then become active.

The FREQUENCY buttons (50/60, 400, and 2000 Hz) directly control the operation of the oscillator and the pulse generator. The RANGE buttons (LOW, MED 1, MED 2, and HIGH) control four relays in the signal section that select the appropriate terminal characteristics for each impedance range (table 5-4).

Table 5-4.—Terminal Characteristics for Impedance ranges

RANGE	OPEN CIRCUIT VOLTAGE (Vp)	SHORT CIRCUIT CURRENT (mAr)
High	60	0.57
Medium 2	20	0.53
Medium 1	15	8.5
Low	10	132

You can select the four ranges manually by pressing the RANGE button, or you can scan them automatically by using the AUTO function. When AUTO is activated, the control logic will follow the sequence LOW, MED 1, MED 2, and HIGH over and over if HIGH LOCKOUT is off. The current active range is always indicated by the LED for the range selected. The AUTO mode will stay active until you select a particular range by pressing its associated button. While AUTO is active, the AUTO LED is continuously on.

The speed at which the ranges are scanned is controlled by the front-panel RATE control knob. This allows you to adjust the time each range is displayed for signature analysis on the CRT display. If AUTO and ALT (alternate) are active at the same time, the RATE control affects the speed of both functions with ALT having priority. This is done so that the two channels can be compared to each other within one range before the next range is selected (figure 5-26).

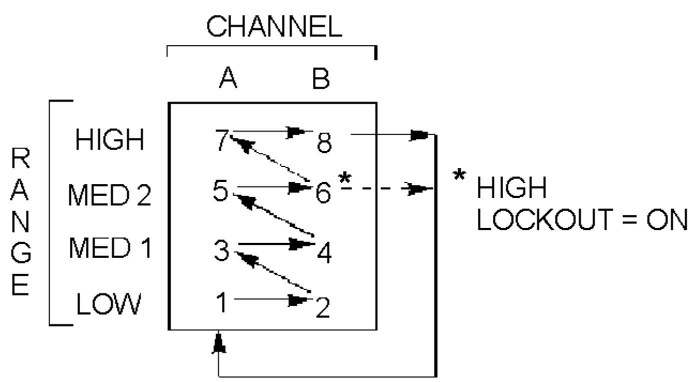

Figure 5-26.—Range scanning sequence with AUTO and ALT active.

The HIGH LOCKOUT function disables the HIGH range and limits the maximum test signal to 20 volts peak vice 60 volts peak. When you select the manual mode (AUTO off), activating the HIGH LOCKOUT prevents the HIGH range from being selected. If the HIGH range is active when the HIGH LOCKOUT is pressed, the HIGH range is canceled and the next lower range (MED 2) will be selected and become active. When you select the AUTO mode, the RANGE sequence with the HIGH LOCKOUT active will start with LOW, and sequence through MED 1, MED 2, back to LOW, and continue until the AUTO mode is stopped.

The PULSE GENERATOR buttons (positive [+], negative [–], and PULSE/DC) toggle control lines that change the polarity and output type of the pulse generator.

Oscillator

The oscillator produces a constant amplitude, low distortion sine wave test signal. The frequency of the test signal is programmable between one variable frequency (50/60 Hz), and two fixed frequencies (400 Hz and 2000 Hz). The variable frequency depends on the input power line used for the Tracker 2000; a 50-Hz line produces a 50-Hz test signal, and a 60-Hz line produces a 60-Hz test signal. If a 400-Hz power line is used, an 80-Hz test signal is provided. This versatility is built in to ensure you will always have low, medium, and high frequencies to work with.

Signal Section

The signal section is considered to be the heart of the Tracker 2000. In this section, the signal from the oscillator is applied across two terminals of a device being tested via the front-panel jacks.

The test signal causes a current to flow through the device and a voltage drop to occur across its terminals. The current flow causes a vertical deflection of the trace on the CRT display, while the voltage drop across the device causes a horizontal deflection of the trace on the CRT display. By combining these, the current-voltage signature of the device being tested is displayed on the CRT.

The test signal appears at the front-panel test jacks as though it is being originated by a voltage source (V_s) with a series output impedance (Z_s). An equivalent circuit of the signal section is shown in figure 5-27. As you can see, the figure also shows how the terminal voltage affects the horizontal deflection plates of the CRT, and how the current through the terminals affects the vertical deflection plates through current sensing point I.

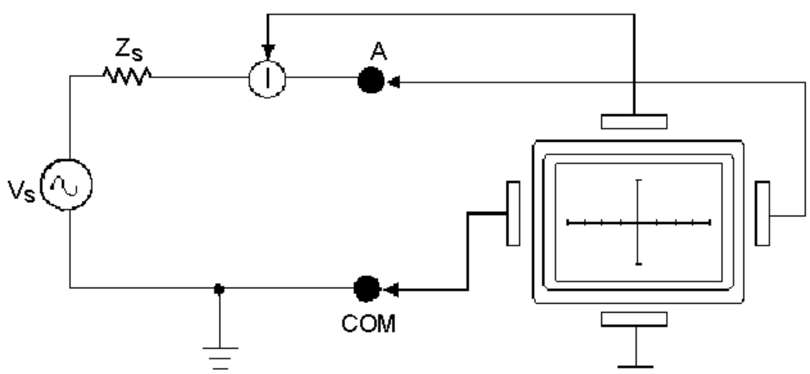

Figure 5-27.—Signal section equivalent circuit.

An open circuit has zero current flowing through the terminals and maximum voltage drop across the terminals. In all ranges, this is represented by a straight horizontal trace from left to right on the CRT display, as seen in figure 5-28 view A. When a short occurs, maximum current flows through the terminals, and the voltage drop is considered to be zero. This occurs in all ranges and is represented by a straight vertical trace from top to bottom of the CRT display, as seen in figure 5-28 view B.

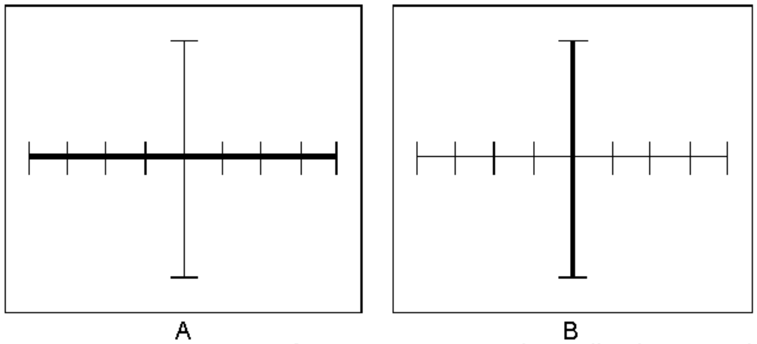

Figure 5-28.—Open and short circuit display.

Pulse Generator

The pulse generator provides dynamic testing for certain types of devices by driving the control input of the device under test. The normal two-terminal mode of testing can be considered a static test, since devices with three or more terminals are not tested in their active mode. However, with the pulse generator, an in-circuit active test is possible.

In the PULSE mode, this circuit uses the zero crossing of the test signal to trigger the start of the pulse. When positive (+) is enabled, a positive-going zero crossing triggers a positive pulse. When negative (−) is enabled, a negative-going zero crossing triggers a negative pulse. If both are enabled, then both positive and negative pulses are produced on alternate crossings (composite pulses). Once a pulse is triggered, its duration is set by the WIDTH control knob. Figure 5-29 shows the waveforms for three pulse polarity types at various settings of the WIDTH control.

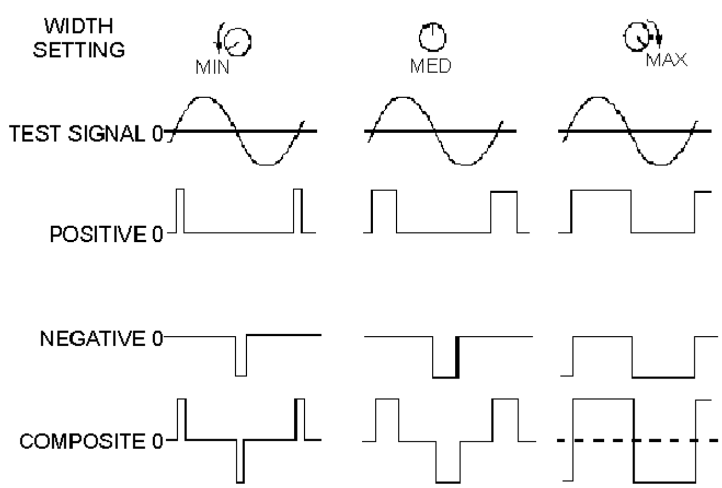

Figure 5-29.—Pulse generator waveforms.

The LEVEL control adjusts the peak of each pulse from zero to 5 volts with the polarity dependent on the pulse polarity selected. When an open circuit is present, a maximum output of 5 volts peak-to-peak is present with either positive or negative selected, and 10 volts peak-to-peak when the composite pulse is active.

Q-10. What minimum/maximum voltage level can be attained in the pulse generator section by adjusting the LEVEL control?

In the DC mode, a zero-to-5-volts DC level is produced at G1 and G2 on the front panel. The polarity of the level is controlled by the positive and negative buttons. By pressing the positive button, you enable a positive DC output and disable the negative button. By pressing the negative button, you enable a negative DC voltage only if the positive button is in the off position. The WIDTH control knob has no effect in the DC mode of operation.

CRT Display

The CRT deflection drivers boost the low-level outputs from the signal section to the higher voltage levels needed by the deflection plates in the CRT. The HORIZ (horizontal) and VERT (vertical) controls on the front panel adjust the position of the CRT trace. The TRACE ROTATE control on the front panel is used to adjust the short circuit vertical trace to be parallel with the vertical axis on the CRT graticule.

Three other controls (INTENSITY, FOCUS, and astigmatism) are used to adjust the proper brightness and clarity of the trace. The front-panel INTENSITY control is the primary way to adjust the visual quality of the trace. FOCUS is located on the back panel and is used as your trimming adjustment. Astigmatism is an internal adjustment and is set at the factory.

Power Supply

The power supply is an ac-line-operated power supply that is turned on and off by the POWER/INTENSITY knob located on the front panel. Once power is turned on, the power supply provides 12 V dc (nominal) and ±5 V dc (regulated) for normal circuit operational use in the oscillator, pulse generator, signal, and control logic sections of the Tracker 2000.

The other outputs from the power supply are provided to the CRT display section. The CRT is provided with a filament voltage of 6.3 V_{rms}, +180 V dc for the deflection driver circuits, and a regulated −1320 V dc for the CRT acceleration voltage.

COMPONENT TESTING

Now that you have a basic understanding of how the Tracker 2000 works, we will show you a few examples of different components with values and their associated displays. Because of the large number of different values that can be given to any component, this section will present only a few.

Testing Resistors

A resistance across the test probes will cause the trace of the Tracker 2000 to rotate in a counterclockwise direction around its center axis from an open circuit position. The degree of rotation is directly related to the resistance value. The higher the value, the less rotation will be observed.

LOW RANGE.—The low range is designed to test for resistance values between 1Ω and 1K. Figure 5-30 shows the effect of resistance on the angle of rotation in low range. A 1Ω resistor causes almost 90º of rotation, and a 50Ω resistor produces a 45º rotation. A 400Ω resistor causes a very small rotation angle. Resistors lower than 1Ω will appear as a short circuit (vertical trace), and resistance values above 400Ω will look like an open circuit (horizontal trace).

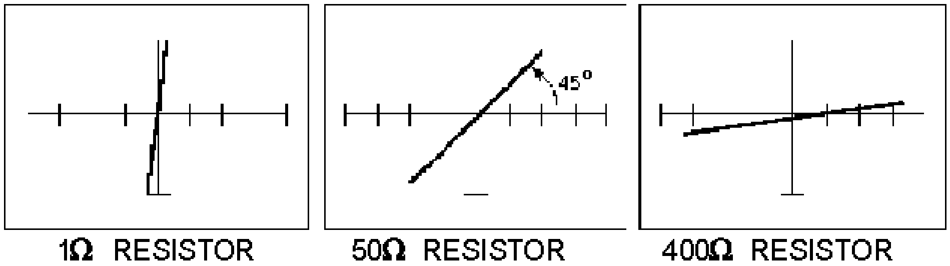

Figure 5-30.—Effects of resistance on the rotation angle in low range.

MEDIUM 1 RANGE.—The medium 1 range is designed to test for resistance values between 50Ω and 10KΩ. Figure 5-31 shows the signatures for a 50Ω resistor, a 1KΩ resistor, and a 10KΩ resistor using the medium 1 range. Resistors that are smaller than 50Ω display a signature that is almost a vertical line. A 1KΩ resistor causes a change in the angle of rotation of 45º, whereas the display of a 10KΩ resistor shows only a slight rotation. Resistance values under test higher than 10KΩ produce a signature with such a small rotation angle that it almost appears to be a horizontal line.

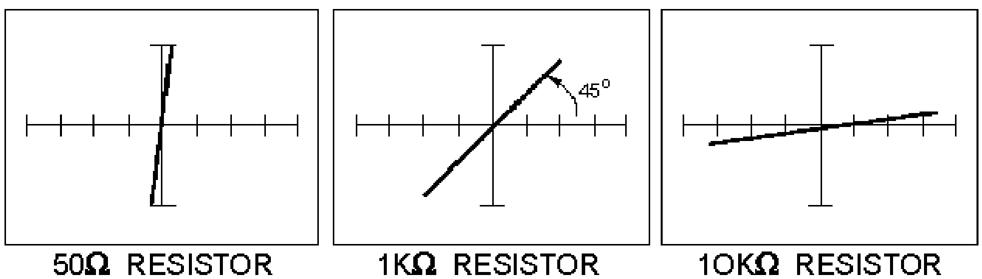

Figure 5-31.—Effects of resistance on the rotation angle in medium 1 range.

Q-11. Medium 1 range is designed to check what resistance values?

MEDIUM 2 RANGE.—The medium 2 range is designed to test for resistance values between 1KΩ and 200KΩ Figure 5-32 shows the signatures for a 1KΩ resistor, a 15KΩ resistor, and a 200KΩ resistor in the medium 2 range. Resistance values that are smaller than 1KΩ will appear to be almost a vertical line. A 15KΩ resistor causes a change in the angle of rotation of 45º, whereas the display for a 200KΩ resistor shows only a slight rotation. When resistance values being tested are higher than 200KΩ, the displayed signature that they produce will have such a small rotation that it appears to be almost a horizontal line.

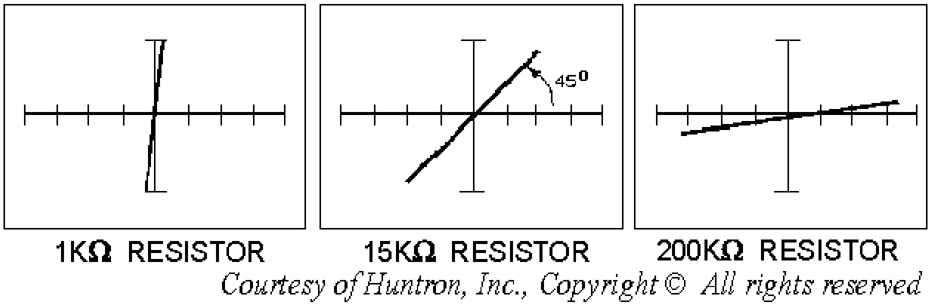

Figure 5-32.—Effects of resistance on the rotation angle in medium 2 range.

HIGH RANGE.—The high range is designed to test resistance values between 3KΩ and 1MΩ. Figure 5-33 shows the signatures that would be displayed for a 3KΩ resistor, a 50KΩ resistor, and a 1MΩ resistor using the high range. Resistors that are smaller than 3KΩ will appear to be almost a vertical line. A 50KΩ resistor will cause a change in the angle of rotation of 45º, whereas the display for a 1MΩ resistor shows only a slight rotation that is very close to a horizontal line. Resistance values higher than 1MΩ will produce such a small rotation that it appears to be a horizontal line.

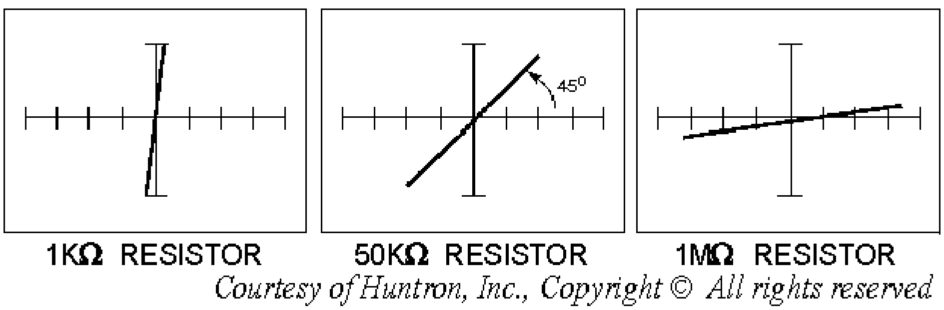

Figure 5-33.—Effects of resistance on the rotation angle in high range.

Testing Capacitors

When you test capacitors, the signature will be displayed as an ellipse. The size and shape of the ellipse depend on the capacitor value, test signal frequency, and the selected impedance range. Figure 5-34 shows the signature of a 0.22µF capacitor in each of the 12 combinations of range and frequency. As you review this figure, you will notice that the signature appears to be an open circuit in the low range at 60 Hz; while in the high range at 2000 Hz, the signature appears to be a short. Between these, the signatures displayed are a variety of ellipsoids, which demonstrates that certain range and frequency combinations are better than others for examining a capacitor.

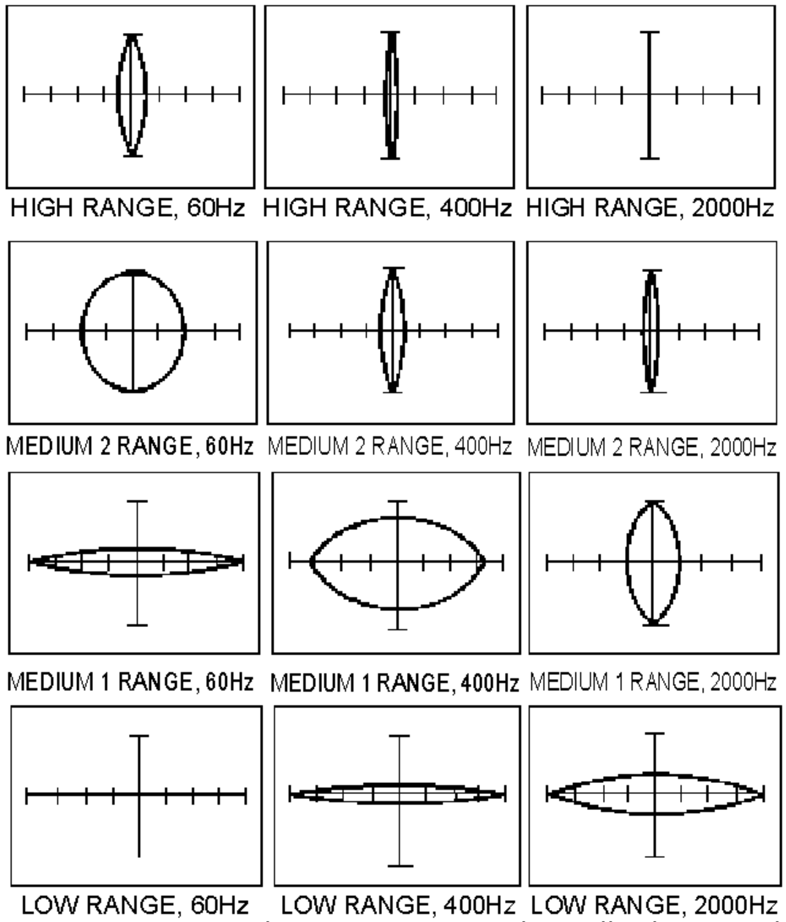

Figure 5-34.—Signature of a 0.22µF capacitor.

Table 5-5 lists the range of capacitance covered by each of the 12 range and frequency combinations for the Tracker 2000. The lowest value of capacitance in each combination will produce a signature of a very narrow horizontal ellipsoid. Capacitors with less of a value than these will appear to be an open. The uppermost value of capacitance in each combination will produce a very narrow vertical ellipsoid signature. Capacitors of greater value than these will appear as a vertical line signature of a short circuit.

Table 5-5.—Min/Max Capacitance Values

RANGE	TEST FREQUENCY		
	50/60 Hz	400 Hz	2000 Hz
HIGH	.001µF-1µF	500pF-.1µF	100pF-.02µF
MEDIUM 1	.01µF-2µF	.001µ-.5µF	200pF-.05µF
MEDIUM 2	.2µF-50µF	.02µF-5µF	.005µ-1µF
LOW	5µF-2000µF	.5mF-100µF	.2mF-25µF

Testing Inductors

Inductors, like capacitors, produce an elliptical signature on the Tracker 2000. Figure 5-35 shows you the signatures produced in each of the 12 range and frequency combinations by a 250mH inductor.

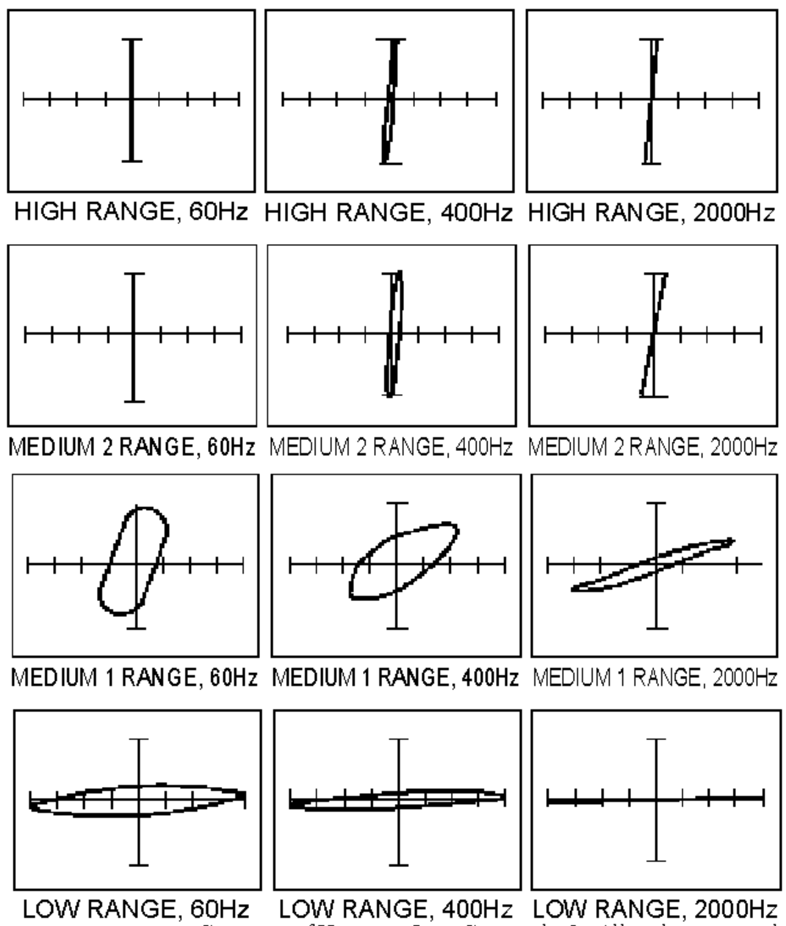

Figure 5-35.—Signatures of a 250mH inductor.

Ferrite inductors can also be checked using this unit; however, the signature produced will be different. Ferrite inductors operate well at high frequencies, but saturate at low frequencies. Figure 5-36 shows the signature of a 490mH ferrite inductor tested at 60 Hz. In low and medium 1, you can see that the signature shows distortion. However, in medium 2 and high ranges, the impedance of the inductor is low compared with the internal impedance of the Tracker 2000, so the signatures are a split vertical trace. Figures 5-37 and 5-38 show the same 490mH inductor being tested at 400 Hz and 2000 Hz.

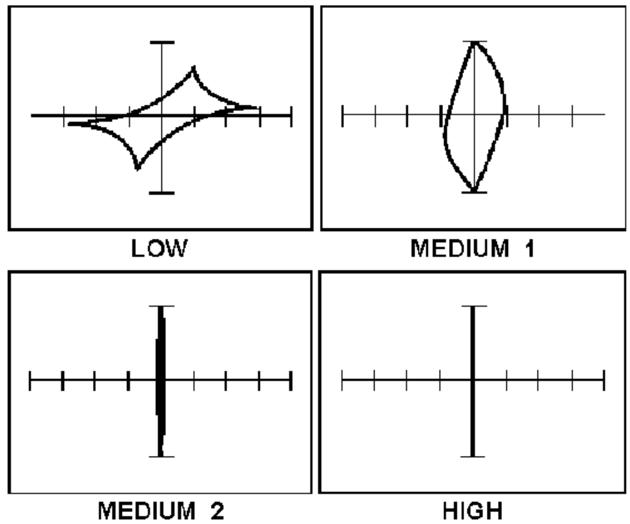

Figure 5-36.—Signatures of a 490mH ferrite inductor tested at 60 Hz.

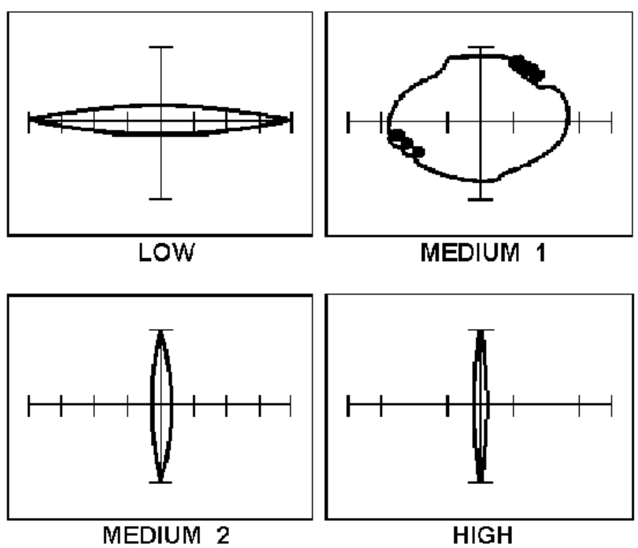

Figure 5-37.—Signature of a 490mH ferrite inductor at 400 Hz.

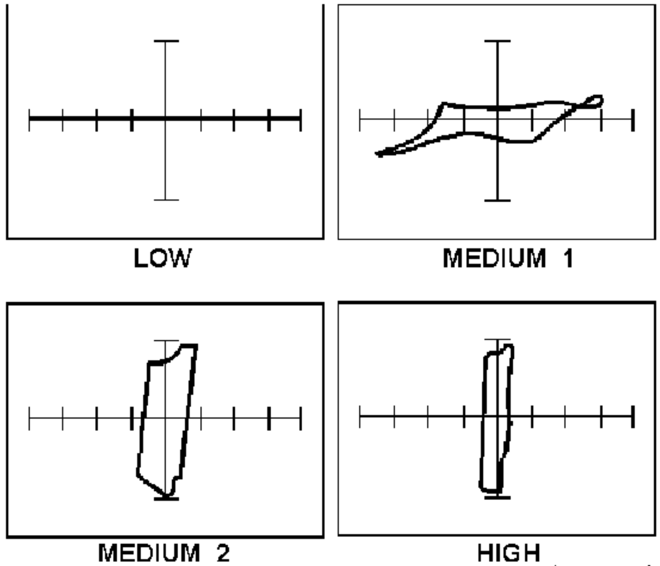

Figure 5-38.—Signature of a 490mH ferrite inductor at 2000 Hz.

SUMMARY

Now that we have completed this chapter, let's review the more important points.

The type of meter used to measure power is the **POWER METER**.

One type of wattmeter is the AN/URM-120. It is an **IN-LINE TYPE WATTMETER**.

The principal function of a **SIGNAL GENERATOR** is to produce an alternating voltage of the desired frequency and amplitude, which has the necessary modulation for the test or measurement concerned.

There are basically two types of signal generators: **AF** and **RF FREQUENCY GENERATORS**.

The instrument used to determine the frequency of a signal is the **FREQUENCY COUNTER**.

An instrument of great value to a technician in troubleshooting digital integrated logic circuits is the **LOGIC PROBE**.

The **HUNTRON TRACKER 2000** is a versatile piece of test equipment that is used to compare known good devices against those of unknown quality or troubleshoot to the component level after power is disconnected to the device under test.

ANSWERS TO QUESTIONS Q1. THROUGH Q11.

A-1. Load.

A-2. An unbalance in the metering bridge.

A-3. Attenuator.

A-4. Oscillator circuit, modulator, and output control circuit.

A-5. To produce an af (or video) signal that can be superimposed on the rf signal produced by the oscillator.

A-6. 1 MHz and 10 MHz.

A-7. DIM.

A-8. Positive voltage (+V) and negative current (–I).

A-9. TRACE ROTATE control.

A-10. 0 to 5 volts.

A-11. 50Ω to 10KΩ.

CHAPTER 6

THE OSCILLOSCOPE AND SPECTRUM ANALYZER

LEARNING OBJECTIVES

Upon completing this chapter, you should be able to:

1. Describe the purpose of the CRT used in the oscilloscope.
2. Explain the operation of an oscilloscope.
3. Describe the purpose of the controls and indicators found on an oscilloscope.
4. Describe the proper procedure for using a dual-trace oscilloscope.
5. Describe the accessory probes available for use with a dual-trace oscilloscope.
6. Explain the operation of the spectrum analyzer.
7. Describe the purpose of the controls and indicators found on the spectrum analyzer.

INTRODUCTION

One of the most widely used pieces of electronic test equipment is the OSCILLOSCOPE. An oscilloscope is used to show the shape of a video pulse appearing at a selected equipment test point. Although some oscilloscopes are better than others in accurately showing video pulses, all function in fundamentally the same way. If you learn how one oscilloscope operates, you will be able to learn others.

As you will learn in this chapter, there are many different types of oscilloscopes—varying in complexity from the simple to the complex. Before we get into our discussion of the dual-trace oscilloscope, we will first present a general overview of basic single-trace oscilloscope operation. Shortly, we will see how oscilloscopes use a CATHODE-RAY TUBE (CRT) in which controlled electron beams are used to present a visible pattern of graphical data on a fluorescent screen.

Another piece of test equipment used is the SPECTRUM ANALYZER. This test equipment is used to sweep over a band of frequencies to determine what frequencies are being produced by a specific circuit under test, and then the amplitude of each frequency component. An accurate interpretation of the display will allow you to determine the efficiency of the equipment being tested.

CATHODE-RAY TUBES

A detailed discussion of CATHODE-RAY TUBES (CRTs) is presented in NEETS, *Module 6, Electronic Emission, Tubes, and Power Supplies*. Before continuing with your study of CRTs in this section, you may want to review chapter 2 of that module.

Cathode-ray tubes used in oscilloscopes consist of an ELECTRON GUN, a DEFLECTION SYSTEM, and a FLUORESCENT SCREEN. All of these elements are enclosed in the evacuated space inside the glass CRT. The electron gun generates electrons and focuses them into a narrow beam. The deflection system moves the beam horizontally and vertically across the screen. The screen is coated with a phosphorous material that glows when struck by the electrons. Figure 6-1 shows the construction of a CRT.

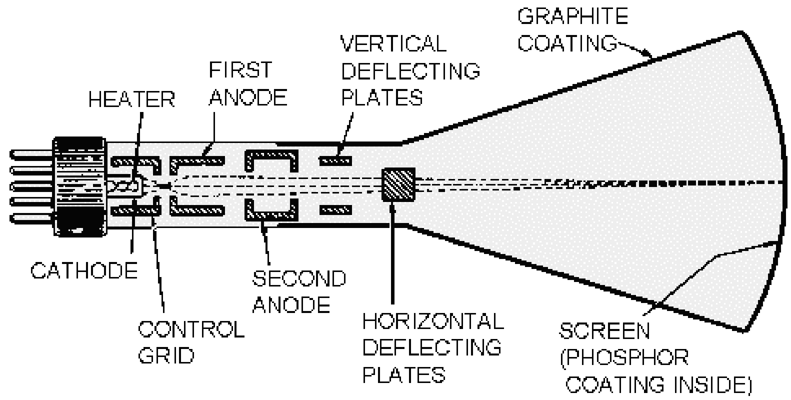

Figure 6-1.—Construction of a CRT.

ELECTRON GUN

The ELECTRON GUN consists of a HEATER and a CATHODE to generate electrons, a CONTROL GRID to control brightness by controlling electron flow, and two ANODES (FIRST and SECOND). The main purpose of the first (FOCUSING) anode is to focus the electrons into a narrow beam on the screen. The second (ACCELERATING) anode accelerates the electrons as they pass. The control grid is cylindrical and has a small opening in a baffle at one end. The anodes consist of two cylinders that contain baffles (or plates) with small holes in their centers.

Q-1. What element controls the number of electrons striking the screen?

Q-2. What element is controlled to focus the beam?

Cathode and Control Grid

As in most conventional electron tubes, the cathode is indirectly heated and emits a cloud of electrons. The control grid is a hollow metal tube placed over the cathode. A small opening is located in the center of a baffle at the end opposite the cathode. The control grid is maintained at a negative potential with respect to the cathode to keep the electrons bunched together.

A high positive potential on the anodes pulls electrons through the hole in the grid. Because the grid is near the cathode, it can control the number of electrons that are emitted. As in an ordinary electron tube, the negative voltage of the grid can be varied either to control electron flow or stop it completely. The brightness (intensity) of the image on the fluorescent screen is determined by the number of electrons striking the screen. This is controlled by the voltage on the control grid.

Electrostatic Lenses and Focusing

The electron beam is focused by two ELECTROSTATIC FIELDS that exist between the control grid and first anode and between the first and second anodes.

Figure 6-2 shows you how electrons move through the electron gun. The electrostatic field areas are often referred to as LENSES because the fields bend electron streams in the same manner that optical lenses bend light rays. The first electrostatic lens cause the electrons to cross at the first focal point within the field. The second lens bend the spreading streams and return them to a new, second focal point at the CRT.

Q-3. Why are the electrostatic fields between the electron gun elements called lenses?

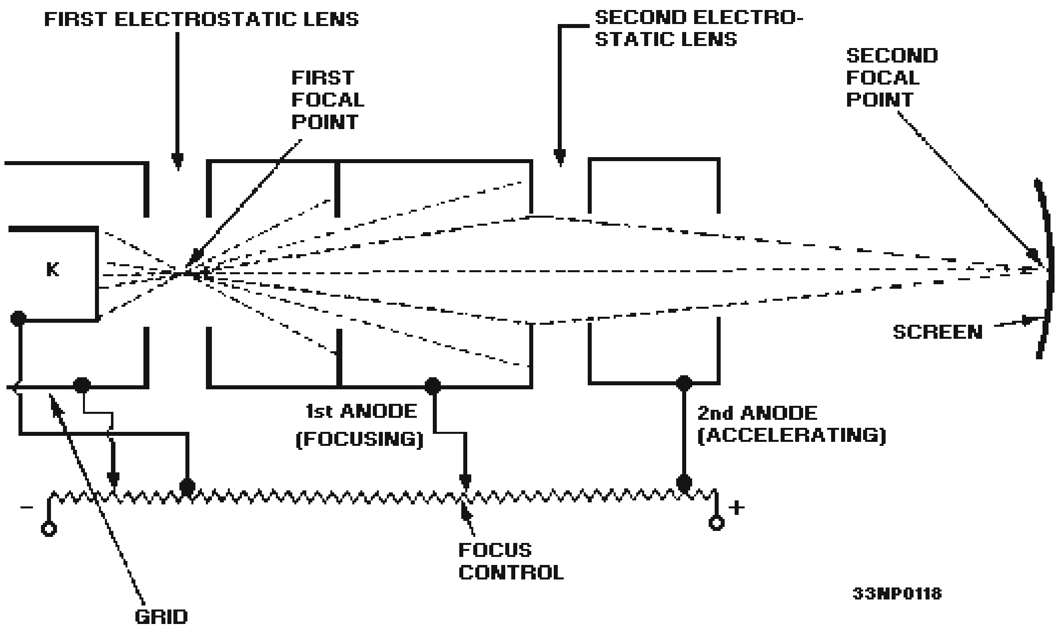

Figure 6-2.—Formation of an electron beam.

Figure 6-2 also shows the relative voltage relationships on the electron-gun elements. The cathode (K) is at a fixed positive voltage with respect to ground. The grid is at a variable negative voltage with respect to the cathode. A fixed positive voltage of several thousand volts is connected to the second (accelerating) anode. The potential of the first (focusing) anode is less positive than the potential of the second anode. The first anode can be varied to place the focal point of the electron beam on the screen of the tube. Control-grid potential is established at the proper level to allow the correct number of electrons through the gun for the desired image intensity.

Q-4. What is the function of the second anode?

ELECTRON BEAM-DEFLECTION SYSTEM

The electron beam is developed, focused, and accelerated by the electron gun. The beam appears on the screen of the CRT as a small, bright dot. If the beam is left in one position, the electrons will soon burn away the illuminating coating in that one area. To be of any use, the beam must be able to move. As you have studied, an electrostatic field can bend the path of a moving electron.

As you have seen in the previous illustrations, the beam of electrons passes through an electrostatic field between two plates. You should remember that electrons are negatively charged and that they will be deflected in the direction of the electric force (from negative to positive). This deflection causes the electrons to follow a curved path while in the electrostatic field.

When the electrons leave the electrostatic field, they will take a straight path to the screen at the angle at which they left the field. Because they were all deflected equally, the electrons will be traveling toward the same spot. Of course, the proper voltages must exist on the anodes to produce the electrostatic field. Changing these voltages changes the focal point of the beam and causes the electron beam to strike the CRT at a different point.

Factors Influencing Deflection

The ANGLE OF DEFLECTION (the angle the outgoing electron beam makes with the CRT center line axis between the plates) depends on the following factors:

- Length of the deflection field;
- Spacing between the deflection plates;
- The difference of potential between the plates; and
- The accelerating voltage on the second anode.

LENGTH OF DEFLECTION FIELD.—As shown in figure 6-3, a long field (long deflection plates) has more time to exert its deflecting forces on an electron beam than does a shorter field (short deflection plates). Therefore, the longer deflection plates can bend the beam to a greater deflection angle.

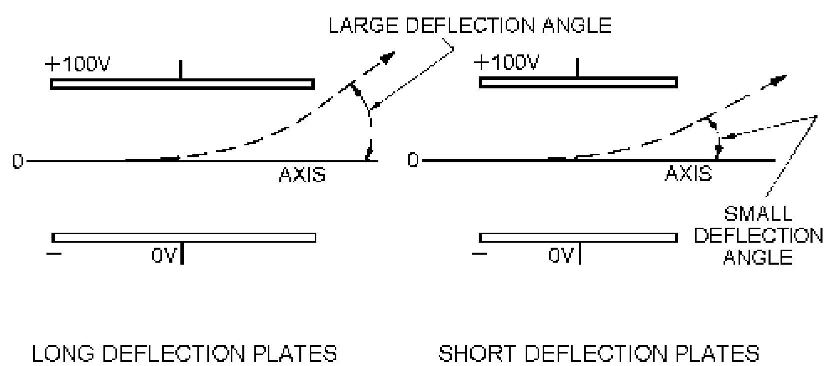

Figure 6-3.—Factors influencing length of field.

Q-5. What effect do longer deflection plates have on the electron beam?

SPACING BETWEEN PLATES.—As shown in figure 6-4, the closer together the plates, the more effect the electric force has on the deflection angle of the electron beam.

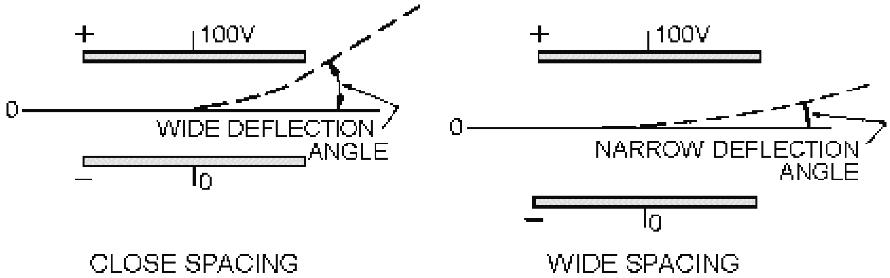

Figure 6-4.—Spacing between plates.

Q-6. What effect does closer spacing of plates have on the electron beam?

DIFFERENCE OF POTENTIAL.— The potential on the plates (figure 6-5) can be varied to cause a wider or narrower deflection angle. The greater the potential, the wider the deflection angle.

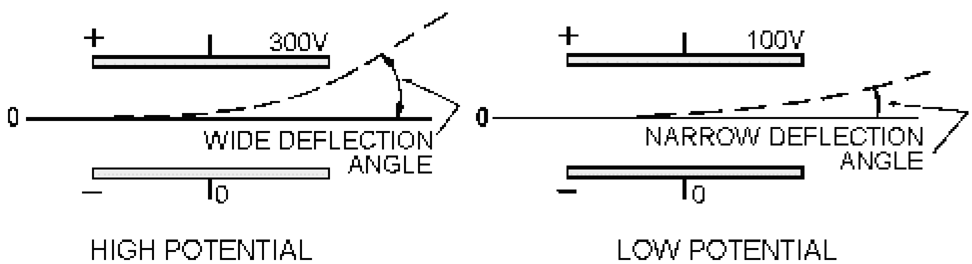

Figure 6-5.—Differences of potential.

Q-7. Is the deflection angle greater with higher or lower potential on the plates?

BEAM ACCELERATION.—The faster the electrons are moving, the smaller their deflection angle will be, as shown in figure 6-6.

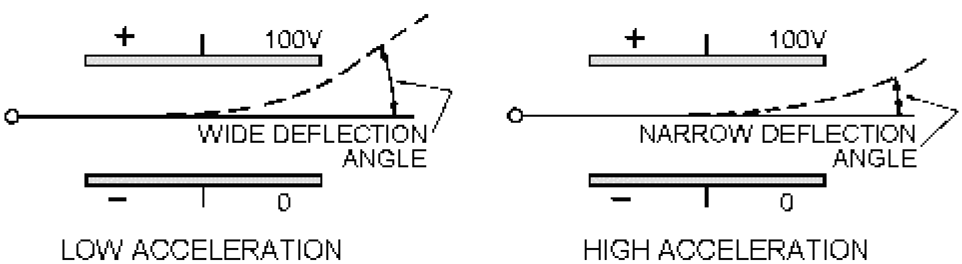

Figure 6-6.—Beam acceleration.

Q-8. Is the deflection angle greater when the beam is moving faster or slower?

Vertical and Horizontal Plates

If two sets of deflection plates are placed at right angles to each other inside a CRT (figure 6-7), the electron beam can be controlled in any direction. By varying the potential of the vertical-deflection plates, you can make the spot (beam) on the face of the tube move vertically. The distance the beam moves will be proportional to the change in potential difference between the plates. Changing the potential difference between the horizontal-deflection plates will cause the beam to move a given distance from one side to the other. Directions other than up-down and left-right are achieved by a combination of horizontal and vertical movement.

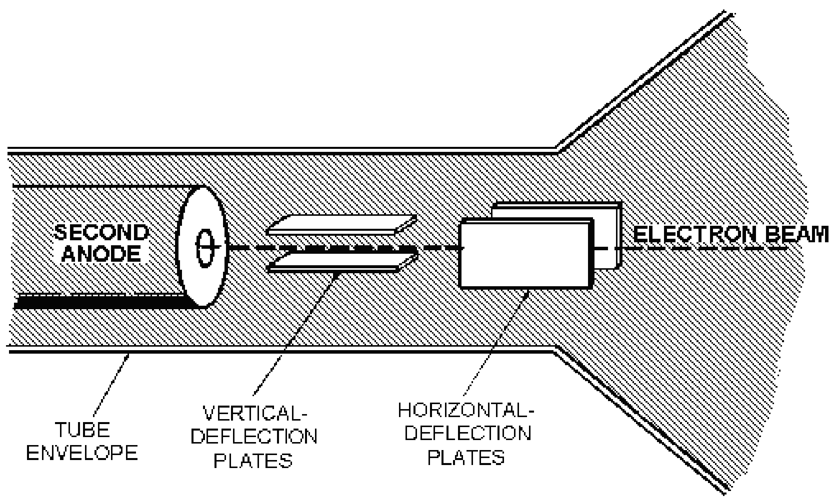

Figure 6-7.—Deflection plate arrangement.

As shown in figure 6-8, position X of the beam is in the center. It can be moved to position Y by going up 2 units and then right 2 units. Movement of the beam is the result of the simultaneous action of both sets of deflection plates. The electrostatic field between the vertical plates moves the electrons up an amount proportional to 2 units on the screen. As the beam passes between the horizontal plates, it moves to the right an amount proportional to 2 units on the screen.

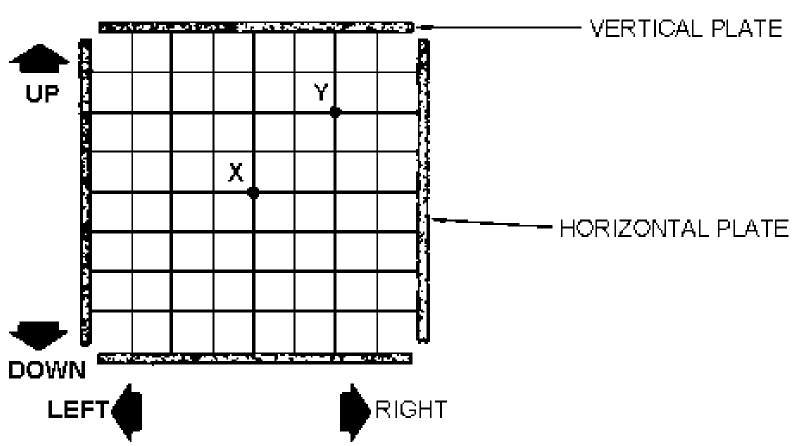

Figure 6-8.—Beam movement on the CRT.

If the amount of deflection from the left and down occurred so that each set of plates acted at the same time, the picture would be like the one in view A of figure 6-9. For example, if the vertical plates moved the beam downward (starting from point X) at the rate of 3 units per second and the horizontal plates moved it to the left at the rate of 1 unit per second, both movements would have been completed in 1 second at point Y. The result would be a straight line.

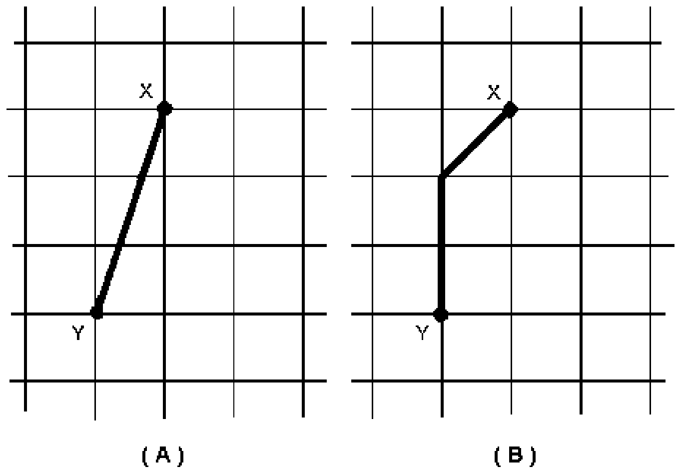

Figure 6-9.—Deflection of the beam.

In view B, the potentials on the vertical and horizontal plates change at the same rate. In the same time period, say 1 second, both plates move the beam 1 unit. The horizontal plates have completed their task at the end of 1 second, but the vertical plates have moved the beam only one-third of the required distance. In this case, the picture in view B would appear on the screen.

Beam-deflection Plate Action

Recall from your study of chapter 2 of this module that waveforms are described in terms of amplitude versus time. You have just seen how the movement of the CRT beam depends on both potential (amplitude) and time.

Q-9. Waveforms are described in terms of what two functions?

VERTICAL-DEFLECTION PLATES.—We will use figure 6-10 to explain the action of the vertical-deflection plates in signal amplitude measurements. As this discussion begins, remember that vertical-deflection plates are used to show amplitude of a signal, and horizontal-deflection plates are used to show time and/or frequency relationships.

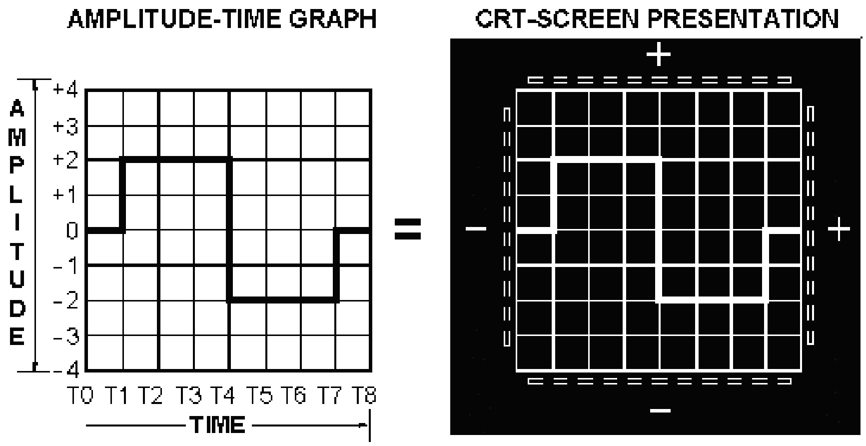

Figure 6-10.—Amplitude versus time.

1. From T0 to T1, the vertical plates maintain their static difference in potential and the beam stays at 0 units; the T0 to T1 change causes an increasing potential difference in the horizontal plates, and the beam moves 1 unit to the right.

2. At T1, a positive potential difference change in the vertical plates occurs, which causes the beam to move up (instantaneously) 2 units. This vertical (amplitude) beam location is maintained from T1 to T4; horizontal beam movement continues moving to the right as 3 units of time pass.

3. At T4, an instantaneous negative change in potential of 4 units in amplitude occurs, and the beam moves from +2 to −2 units.

4. From T4 to T7, the beam remains at −2 units. During this time period, the beam continues moving horizontally to the right, indicating the passage of time.

5. At T7, a positive increase of amplitude occurs, and the beam moves vertically from −2 to 0 units. From T7 to T8, no change occurs in vertical beam movement; however, horizontal movement continues with time.

The vertical-plate potential difference follows the voltage of the waveform. The horizontal-plate potential follows the passage of time. Together, they produce the image (trace) produced on the screen by the moving beam.

Q-10. The vertical-deflection plates are used to reproduce what function?

Q-11. The horizontal-deflection plates are used to produce what function?

HORIZONTAL-DEFLECTION PLATES.—Now let's look at horizontal-deflection action. Assume that the resistance of the potentiometer shown in figure 6-11 is spread evenly along its length. When the arm of the potentiometer is at the middle position, the same potential exists on each plate. Since there is zero potential difference between the plates, an electrostatic field is not moved downward at a uniform rate; the right plate will become more positive than the left (you are looking down through the top of the CRT). The electron beam will move to the right from screen point 0 through points 1, 2, 3, and 4 in equal time intervals.

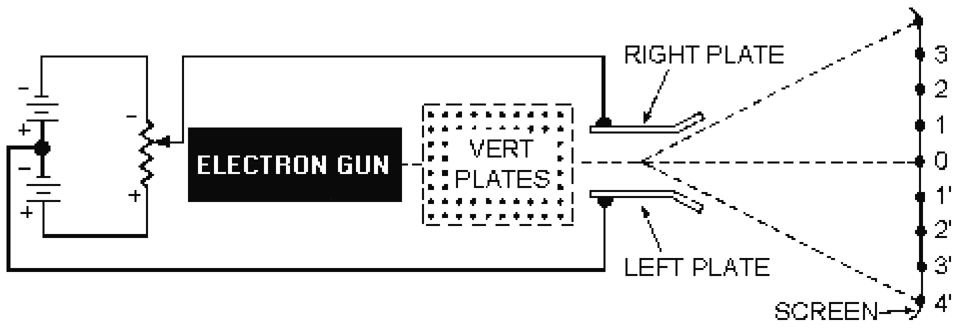

Figure 6-11.—Horizontal plates (top view).

If the potentiometer arm is moved at the same rate in the opposite direction, the right plate will decrease in positive potential until the beam returns to the 0 position. At that point, the potential difference between the plates is again zero. Moving the arm toward the other end of the resistance causes the left plate to become more positive than the right, and the beam moves from screen points 0 through 4. If the movement of the potentiometer arm is at a uniform (linear) rate, the beam moves at a uniform rate.

Notice that the ends of the deflection plates are bent outward to permit wide-angle deflection of the beam. The vertical plates are bent up and down in the same manner.

Q-12. Why are the ends of the deflection plates bent outward?

For ease of explanation, the manual movement of the potentiometer arm is satisfactory to introduce you to horizontal beam movement. However, in the oscilloscope this is not how horizontal deflection is accomplished. Beam movement voltages are produced much faster by sawtooth circuitry. You may want to review the sawtooth generation section in NEETS, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuitry* before continuing. Nearly all oscilloscopes with electrostatic deflection apply a sawtooth voltage to the horizontal plates to produce horizontal deflection of the beam, as shown in figure 6-12.

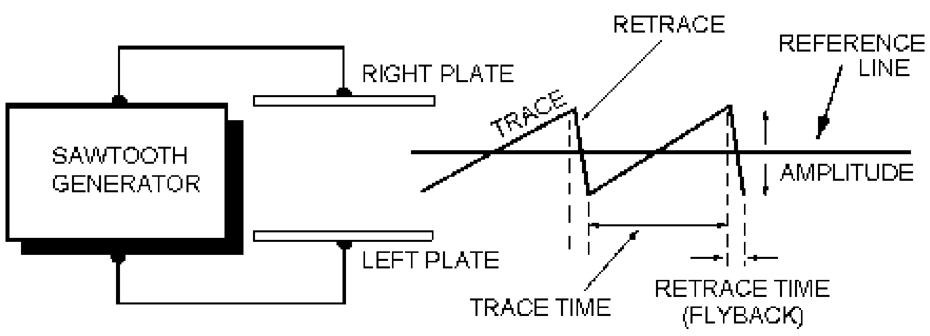

Figure 6-12.—Sawtooth generator.

In the figure, the sawtooth generator replaces the potentiometer and is connected to both horizontal plates of the CRT. At the reference line, the potential on both plates is equal. Below the line, the left plate is more positive and the right plate is less positive. This causes the beam to move left. Above the line, the right plate is made more positive than the left and the beam moves to the right. The waveform amplitude causes a uniform movement of the beam across the screen (called TRACE). RETRACE time, shown at the trailing edge of the waveform, quickly deflects the beam back to the starting point.

CRT GRATICULE

A GRATICULE was used in our previous discussion in figure 6-10. It is simply a calibrated scale (made of clear plastic) of amplitude versus time that is placed on the face of the CRT.

The graticule can be used to determine the voltage of waveforms because the DEFLECTION SENSITIVITY of a CRT is uniform throughout the vertical plane of the screen. Deflection sensitivity states the number of inches, centimeters, or millimeters a beam will be deflected for each volt of potential difference applied to the deflection plates. It is directly proportional to the physical length of the deflection plates and their distance from the screen and inversely proportional to the distance between the plates and to the second-anode voltage. Deflection sensitivity is a constant that is dependent on the construction of the tube.

Deflection sensitivity for a given CRT might typically be 0.2 millimeters per volt. This means the spot on the screen will be deflected 0.2 millimeters (about 0.008 inch) when a difference of 1 volt exists between the plates. Sometimes the reciprocal of deflection sensitivity (called DEFLECTION FACTOR) is given. The deflection factor for the example given would be 125 volts per inch (1/0.008).

Q-13. What term is used to describe the reciprocal of deflection sensitivity of a scope?

In the above example, 125 volts applied between one set of plates would deflect the beam 1 inch on the screen. This means that the deflection caused by small signals would likely not be observed. For this reason, the deflection plates are connected to amplifiers that magnify the signals applied to the vertical input of the scope.

Assume, for example, that a peak-to-peak value of a known voltage applied to the oscilloscope indicates that each inch marking on the graticule is equal to 60 volts. Each of the 10 subdivisions will, therefore, equal a value of 6 volts. Most oscilloscopes have ATTENUATOR controls to decrease or GAIN controls to increase the strength of a signal before it is placed on the deflection plates. Attenuator and gain settings must not be disturbed after the calibration has been made. For maximum accuracy, you should recalibrate the graticule each time a voltage is to be measured.

CRT DESIGNATIONS

Cathode-ray tubes are identified by a tube number, such as 2AP1, 2BP4, or 5AP1A. The first number identifies the diameter of the tube face. Typical diameters are 2 inches, 5 inches, and 7 inches. The first letter designates the order in which a tube of a given diameter was registered. The letter-digit combination indicates the type of phosphor (glowing material) used on the inside of the screen. Phosphor P1, which is used in most oscilloscopes, produces a green light at medium PERSISTENCE. Persistence refers to the length of time the phosphor glows after the electron beam is removed. P4 provides a white light and has a short persistence. If a letter appears at the end, it signifies the number of the modification after the original design.

OSCILLOSCOPE CONTROL COMPONENTS

Although the CRT is a highly versatile device, it cannot operate without control circuits. The type of control circuits required depends on the purpose of the equipment in which the CRT is used.

There are many different types of oscilloscopes. They vary from relatively simple test instruments to highly accurate laboratory models. Although oscilloscopes have different types of circuits, most can be divided into the basic sections shown in figure 6-13: (1) a CRT, (2) a group of control circuits that control the waveform fed to the CRT, (3) a power supply, (4) sweep circuitry, and (5) deflection circuitry.

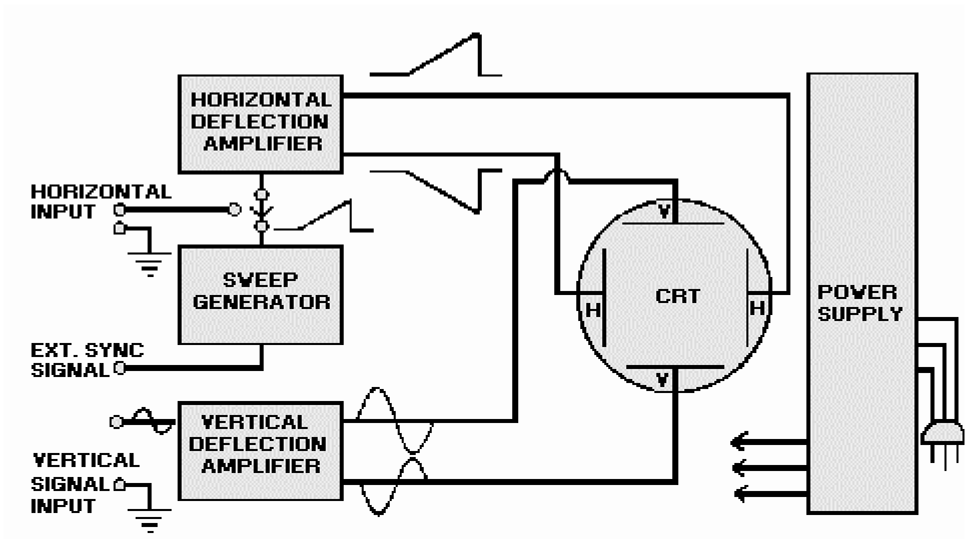

Figure 6-13.—Block diagram of an oscilloscope.

Q-14. List the circuits that all oscilloscopes have in common.

Figure 6-14 is a drawing of the front panel of a dual-trace, general-purpose oscilloscope. Oscilloscopes vary greatly in the number of controls and connectors. Usually, the more controls and connectors, the more versatile the instrument. Regardless of the number, all oscilloscopes have similar controls and connectors. Once you learn the fundamental operation of these common controls, you can move with relative ease from one model of oscilloscope to another. Occasionally, controls that serve similar functions will be labeled differently from one model to another. However, you will find that most controls are logically grouped and that their names usually indicate their function.

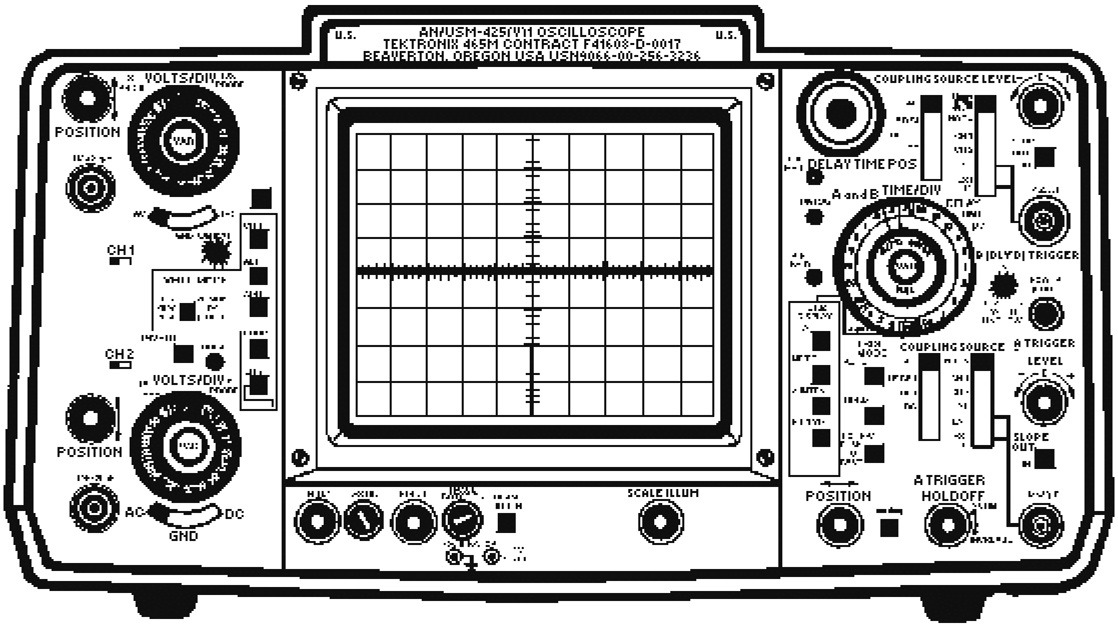

Figure 6-14.—Dual-trace oscilloscope.

The oscilloscope in figure 6-14 is called DUAL-TRACE because it can accept and display two vertical signal inputs at the same time—usually for comparison of the two signals or one signal and a reference signal. This scope can also accept just one input. In this case, it is used as a SINGLE-TRACE OSCILLOSCOPE. For the following discussion, we will consider this to be a single-trace oscilloscope. The oscilloscope in the figure is commonly used in the fleet. You are likely to use this one (model AN/USM-425) or one very similar to it. Let's now look at the front panel controls.

COMPONENTS USED TO DISPLAY THE WAVEFORM

The CRT DISPLAY SCREEN is used to display the signal (figure 6-15). It allows you to make accurate measurements using the vertical and horizontal graticules, as discussed earlier.

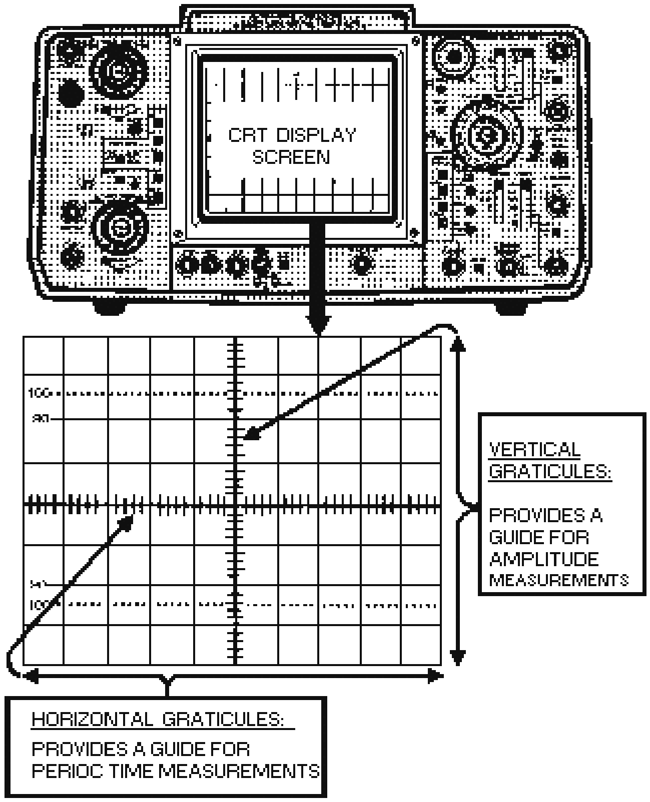

Figure 6-15.—CRT display and graticule.

COMPONENTS USED TO ADJUST CRT DISPLAY QUALITY

The controls in figure 6-16 allow you to adjust for a clear signal display. They also allow you to adjust the display position and magnify the horizontal trace by a factor of 10 (X10). Keep in mind that the controls may be labeled differently from one model to another, depending on the manufacturer. Refer to figure 6-16 as you study the control descriptions in the next paragraphs.

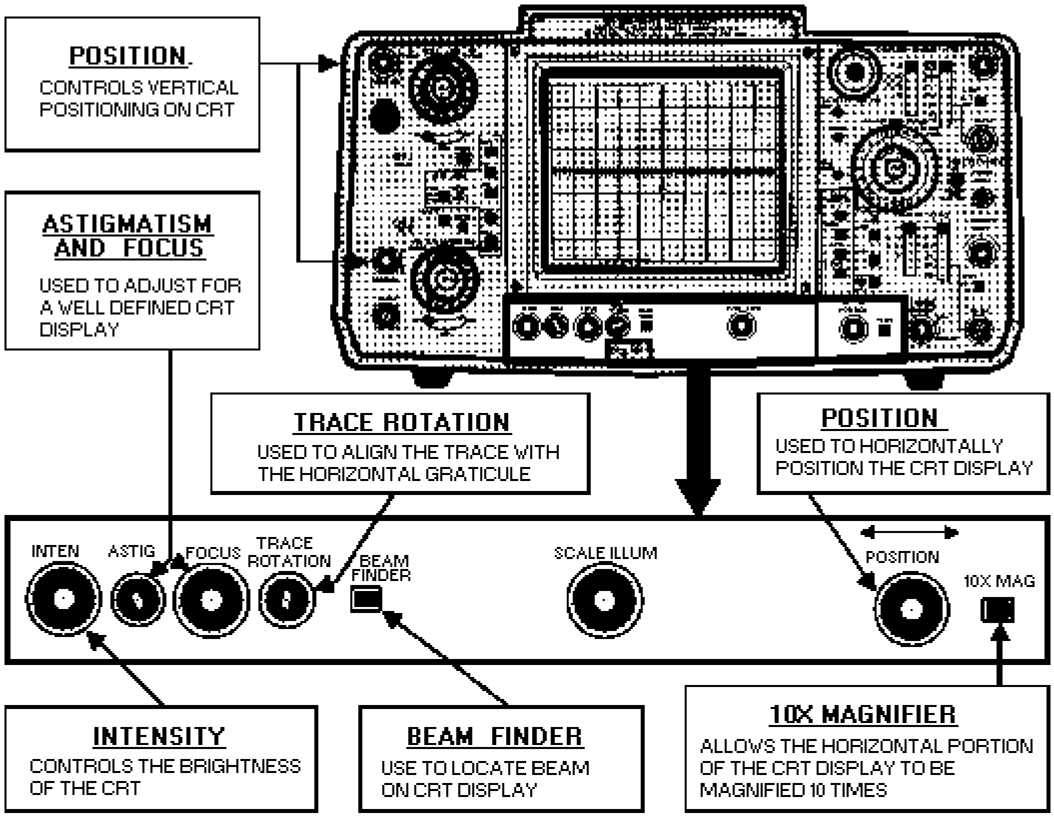

Figure 6-16.—Quality adjustment for CRT display.

INTEN (Intensity) Control

The INTEN (intensity) control (sometimes called BRIGHTNESS) adjusts the brightness of the beam on the CRT. The control is rotated in a clockwise direction to increase the intensity of the beam and should be adjusted to a minimum brightness level that is comfortable for viewing.

FOCUS and ASTIG (Astigmatism) Controls

The FOCUS control adjusts the beam size. The ASTIG (astigmatism) control adjusts the beam shape. The FOCUS and ASTIG controls are adjusted together to produce a small, clearly defined circular dot. When displaying a line trace, you will use these same controls to produce a well-defined line. Figure 6-17, view A, shows an out-of-focus beam dot. View B shows the beam in focus. Views C and D show out-of-focus and in-focus traces, respectively.

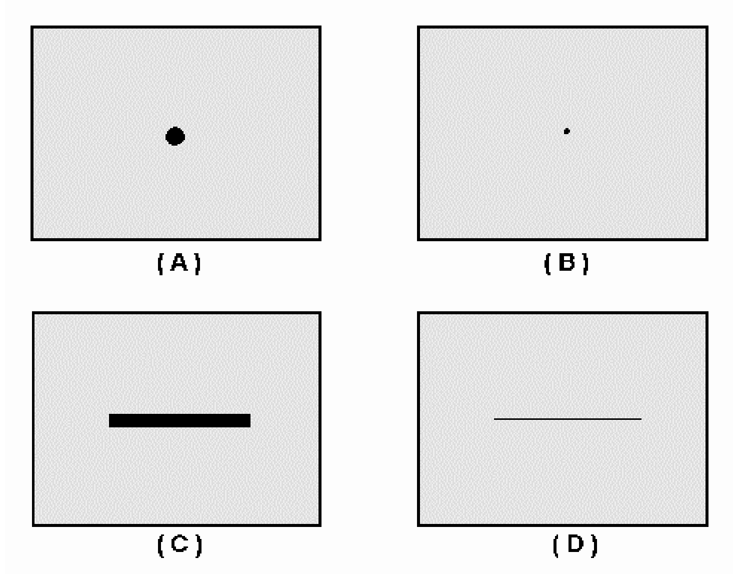

Figure 6-17.—Effects of FOCUS and ASTIG (astigmatism) controls.

TRACE ROTATION Control

The TRACE ROTATION control (figure 6-16) allows for minor adjustments of the horizontal portion of the trace so that you can align it with the horizontal lines on the graticule.

BEAM FINDER Control

Occasionally, the trace will actually be located off the CRT (up or down or to the left or right) because of the orientation of the deflection plates. When pushed, the BEAM FINDER (figure 6-16) pulls the beam onto the screen so that you can use the horizontal and vertical POSITION controls to center the spot.

Horizontal and Vertical POSITION Controls

The horizontal and vertical POSITION controls (figure 6-16) are used to position the trace. Because the graticule is often drawn to represent a graph, some oscilloscopes have the positioning controls labeled to correspond to the X and Y axes of the graph. The X axis represents horizontal movement; the Y axis represents the vertical movement. Figure 6-18 shows the effects of positioning controls on the trace.

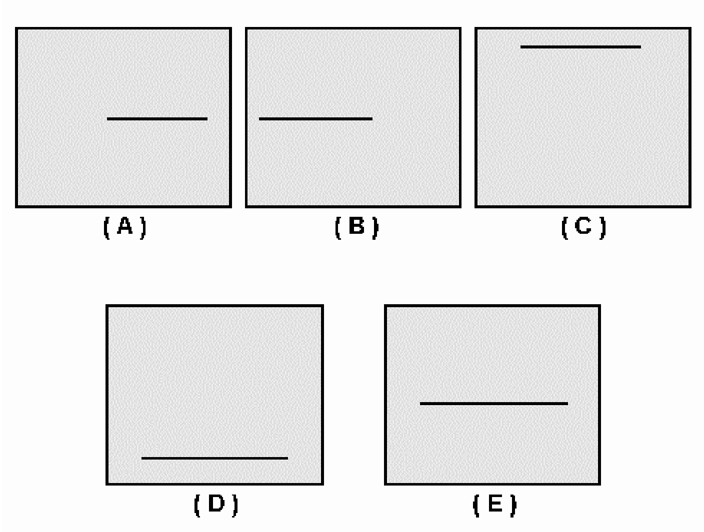

Figure 6-18.—Effects of horizontal and vertical controls.

In view A, the horizontal control has been adjusted to move the trace too far to the right; in view B, the trace has been moved too far to the left. In view C, the vertical POSITION control (discussed later) has been adjusted to move the trace too close to the top; in view D, the trace has been moved too close to the bottom. View E (figure 6-18) shows the trace properly positioned.

10X MAG (Magnifier) Switch

The 10X MAG (magnifier) switch (figure 6-16) allows you to magnify the displayed signal by a factor of 10 in the horizontal direction. This ability is important when you need to expand the signal to evaluate it carefully.

COMPONENTS USED TO DETERMINE THE AMPLITUDE OF A SIGNAL

We will now discuss the dual-trace components of the scope. You will use these components to determine the amplitude of a signal. Notice in figure 6-19 that the highlighted section at the upper left of the scope looks just the same as the section at the lower left of the scope. This reveals the dual-trace capability section of the scope. The upper left section is the CH (channel) 1 input and is the same as the CH 2 input at the lower left. An input to both inputs at the same time will produce two independent traces on the CRT and use the dual-trace capability of the scope.

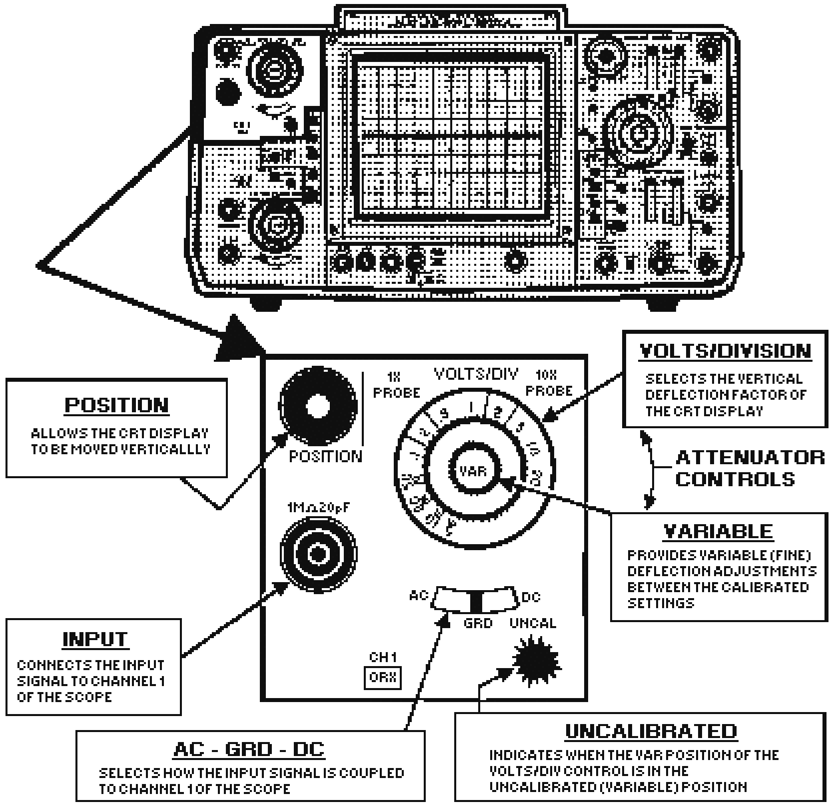

Figure 6-19.—Components that determine amplitude.

For purposes of this introductory discussion, we will present only CH (channel) 1. You should realize that the information presented also applies to CH 2.

Vertical POSITION Control

The vertical POSITION control allows you to move the beam position up or down, as discussed earlier.

Input Connector

The vertical input (or signal input) jack connects the signal to be examined to the vertical-deflection amplifier. Some oscilloscopes may have two input jacks, one labeled AC and the other labeled DC. Other models may have a single input jack with an associated switch, such as the AC GRD DC switch in figure 6-19. This switch is used to select the ac or dc connection. In the DC position, the signal is connected directly to the vertical-deflection amplifier; in the AC position, the signal is first fed through a capacitor. Figure 6-20 shows the schematic of one arrangement.

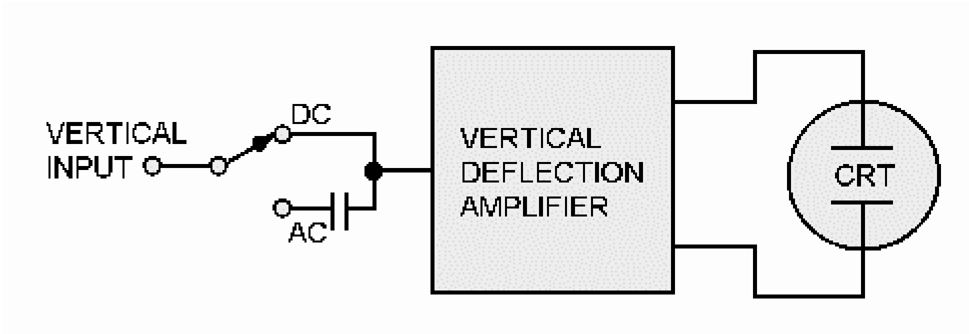

Figure 6-20.—Vertical input arrangement.

The VERTICAL-DEFLECTION AMPLIFIER increases the amplitude of the input signal level required for the deflection of the CRT beam. The deflection amplifier must not have any other effect on the signal, such as changing the shape (called DISTORTION). Figure 6-21 shows the results of distortion occurring in a deflection amplifier.

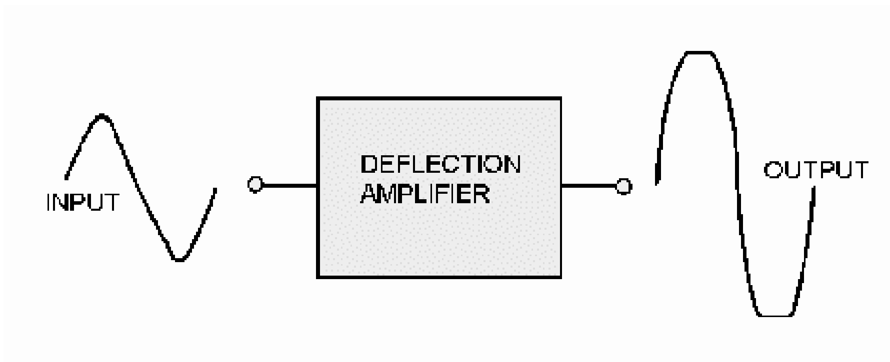

Figure 6-21.—Deflection amplifier distortion.

Attenuator Control

An amplifier can handle only a limited range of input amplitudes before it begins to distort the signal. Signal distortion is prevented in oscilloscopes by the incorporation of circuitry that permits adjustment of the input signal amplitude to a level that prevents distortion from occurring. This adjustment is called the ATTENUATOR control in some scopes (VOLTS/DIV and VAR in figure 6-19). This control extends the usefulness of the oscilloscope by enabling it to handle a wide range of signal amplitudes.

The attenuator usually consists of two controls. One is a multiposition (VOLTS/DIV) control, and the other is a variable (VAR) potentiometer. Each position of the control may be marked either as to the amount of voltage required to deflect the beam a unit distance, such as VOLTS/DIV, or as to the amount of attenuation (called the DEFLECTION FACTOR) given to the signal, such as 100, 10, or 1.

Suppose the .5 VOLTS/DIV position were selected. In this position, the beam would deflect vertically 1 division for every 0.5 volts of applied signal. If a sine wave occupied 4 divisions peak-to-peak, its amplitude would be 2 volts peak-to-peak (4×0.5), as shown in figure 6-22.

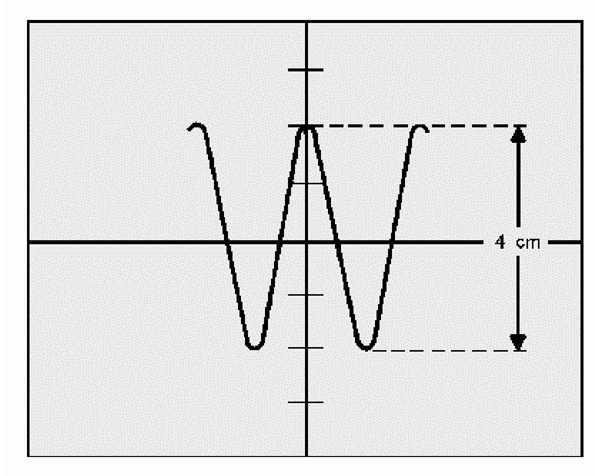

Figure 6-22.—Sine wave attenuation.

The vertical attenuator control (VOLTS/DIV in figure 6-19) provides a means of adjusting the input signal level to the amplifiers by steps. These steps are sequenced from low to high deflection factors. The potentiometer control (VAR in figure 6-19) provides a means of fine, or variable, control between steps. This control may be mounted separately, or it may be mounted on the attenuator control. When the control is mounted separately, it is often marked as FINE GAIN or simply GAIN. When mounted on the attenuator control, it is usually marked VARIABLE or VAR.

The variable control adds attenuation to the step that is selected. Since accurately calibrating a potentiometer is difficult, the variable control is either left unmarked or the front panel is marked off in some convenient units, such as 1-10 and 1-100. The attenuator control, however, can be accurately calibrated. To do this, you turn off the variable control to remove it from the attenuator circuit. This position is usually marked CAL (calibrate) on the panel, or an associated light indicates if the VAR control is on or off. In figure 6-19, the light called UNCAL indicates the VAR control is in the uncalibrated position.

COMPONENTS USED TO SELECT THE VERTICAL OPERATING MODE

As we discussed earlier, channel 1 is being used to discuss basic operating procedures for the oscilloscope. Figure 6-23 shows how the vertical mode of operation is selected. The VERT MODE section contains push-button switches that enable you to select channel 1, channel 2, and several other vertical modes of operation. For the present discussion, note only that CH 1 is selected by these switches.

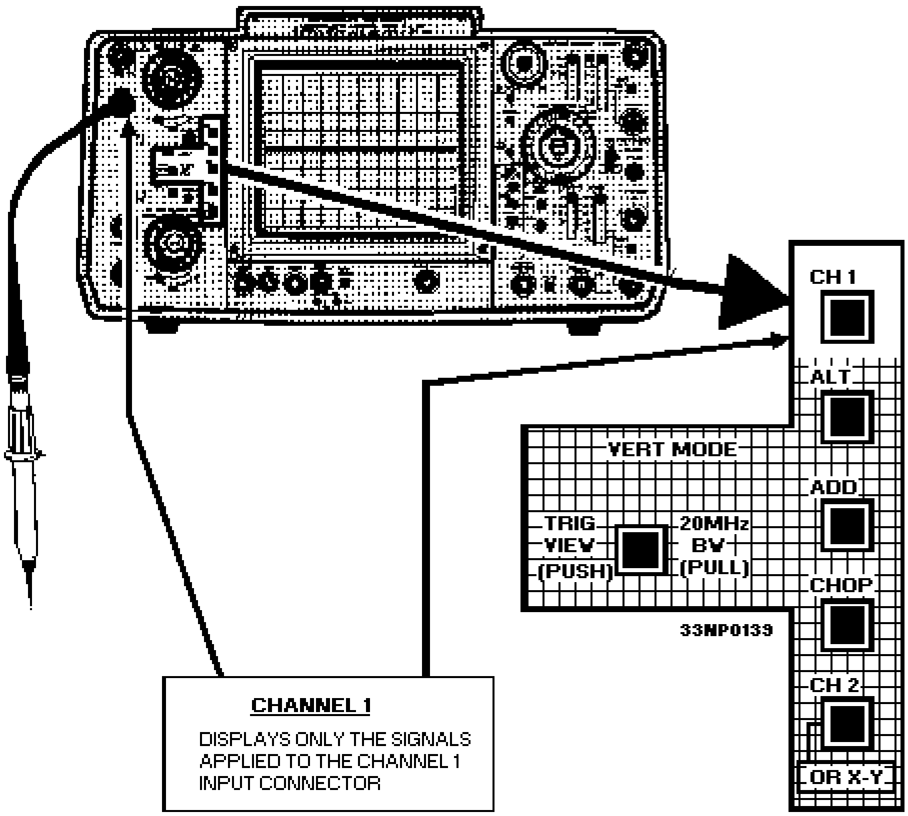

Figure 6-23.—Vertical-deflection controls.

COMPONENTS USED TO DETERMINE PERIOD TIME OF THE DISPLAY

The TIME/DIV (figure 6-24) controls on the scope determine the period time of the displayed waveform. As we discussed earlier, the sweep generator develops the sawtooth waveform that is applied to the horizontal-deflection plates of the CRT. This sawtooth voltage causes the beam to move across the screen. This trace (sometimes called SWEEP) sets the frequency of the TIME BASE of the oscilloscope. The frequency of the time base is variable, which enables the oscilloscope to accept a wide range of input frequencies. Again, two controls are used (figure 6-24). One is a multiposition switch (TIME/DIV) that changes the frequency of the sweep generator in steps. The second control is a potentiometer (VAR) that varies the frequency between steps. Each step on the TIME/DIV control is calibrated. The front panel has markings that group the numbers into microseconds and milliseconds.

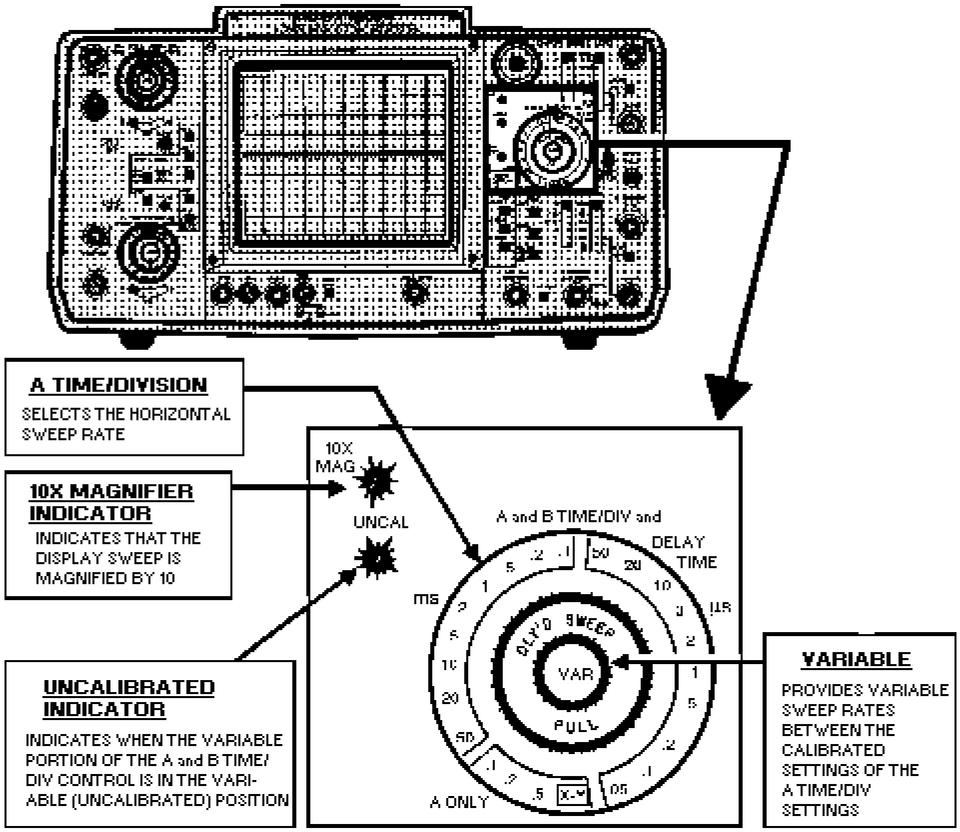

Figure 6-24.—Period time of the waveform (TIME/DIV).

The potentiometer is labeled VAR, and the panel has an UNCAL indicator that lights when the VAR control is in the variable position. When you desire to accurately measure the time of one cycle of an input signal, turn the VAR control to the CAL position and turn the TIME/DIV switch to select an appropriate time base. Suppose you choose the 10-microsecond position to display two cycles of an input signal, as shown in figure 6-25. One cycle occupies 3 centimeters (small divisions) along the horizontal axis. Each cm has a value of 10 microseconds. Therefore, the time for one cycle equals 30 microseconds (3×10). Recall that the frequency for a signal may be found by using the following procedure:

$$
\begin{aligned}
f &= \frac{1}{\text{time (t)}} \\
&= \frac{1}{30 \times 10^{-6}} \\
&= 33.33 \text{ kHz}
\end{aligned}
$$

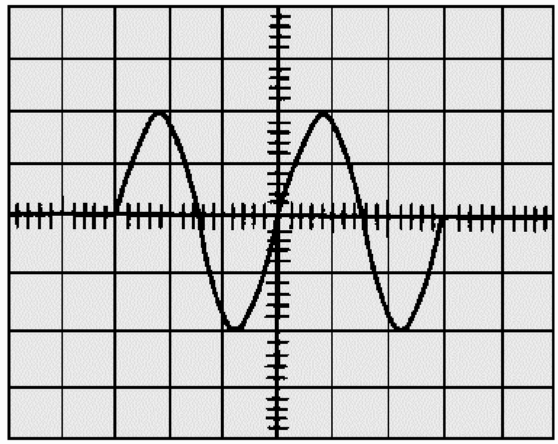

Figure 6-25.—Time measurement of a waveform (TIME/DIV).

In selecting a time base, you should select one that is lower in frequency than the input signal. If the input signal requires 5 milliseconds to complete one cycle and the sawtooth is set for 0.5 milliseconds per centimeter with a 10-centimeter-wide graticule, then approximately one cycle will be displayed. If the time base is set for 1 millisecond per centimeter, approximately two cycles will be displayed. If the time base is set at a frequency higher than the input frequency, only a portion of the input signal will be displayed.

In the basic oscilloscope, the sweep generator runs continuously (FREE-RUNNING); in more elaborate oscilloscopes, it is normally turned off. In the oscilloscope we're using as an example, the sweep generator can be triggered by the input signal or by a signal from some other source. (Triggering will be discussed later in this chapter.) This type of oscilloscope is called a triggered oscilloscope. The triggered oscilloscope permits more accurate time measurements to be made and provides a more stable presentation than the nontriggered-type oscilloscope.

On some oscilloscopes, you will find a 10 times (10X) magnification control. As previously mentioned, this allows the displayed sweep to be magnified by a factor of 10.

Q-15. When you select the time base to display a signal, should the time base be the same, higher, or lower than the input signal?

COMPONENTS USED TO PROVIDE A STABLE DISPLAY

The triggering and level controls are used to synchronize the sweep generator with the input signal. This provides a stationary waveform display. If the input signal and horizontal sweep generator are unsynchronized, the pattern tends to jitter, making observations difficult.

The A TRIGGER controls at the lower right of the scope (figure 6-26) are used to control the stability of the oscilloscope CRT display. They are provided to permit you to select the source, polarity, and amplitude of the trigger signal. These controls, labeled A TRIGGER, LEVEL, SOURCE, and SLOPE, are described in the following paragraphs.

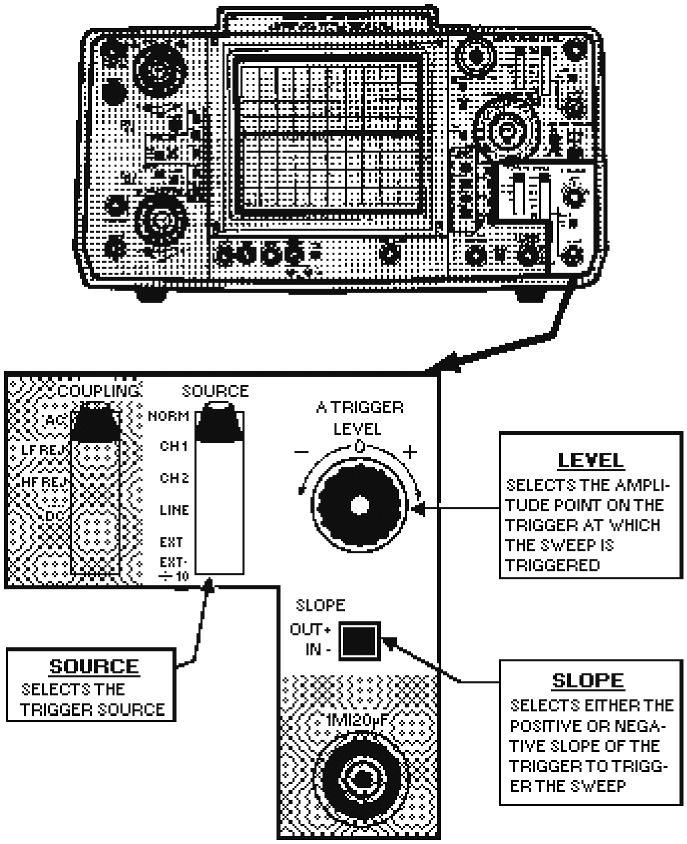

Figure 6-26.—Components that control stability.

SOURCE Control

The SOURCE control allows you to select the appropriate source of triggering. You can select input signals from channel 1 or 2, the line (60 hertz), or an external input.

TRIGGER LEVEL/SLOPE Controls

The LEVEL control allows you to select the amplitude point of the trigger signal at which the sweep is triggered. The SLOPE lets you select the negative or positive slope of the trigger signal at which the sweep is triggered.

The TRIGGER LEVEL (mounted with the TRIGGER SLOPE on some scopes) determines the voltage level required to trigger the sweep. For example, in the TRIGGER modes, the trigger is obtained from the signal to be displayed. The setting of the LEVEL control determines the amplitude point of the input waveform that will be displayed at the start of the sweep.

Figure 6-27 shows some of the displays for a channel that can be obtained for different TRIGGER LEVEL and TRIGGER SLOPE settings. The level is zero and the slope is positive in view A; view B also shows a zero level but a negative slope selection. View C shows the effects of a positive trigger level setting and positive trigger slope setting; view D displays a negative trigger level setting with a positive trigger slope setting. Views E and F have negative slope settings. The difference is that view E has a positive trigger level setting, whereas F has a negative trigger level setting.

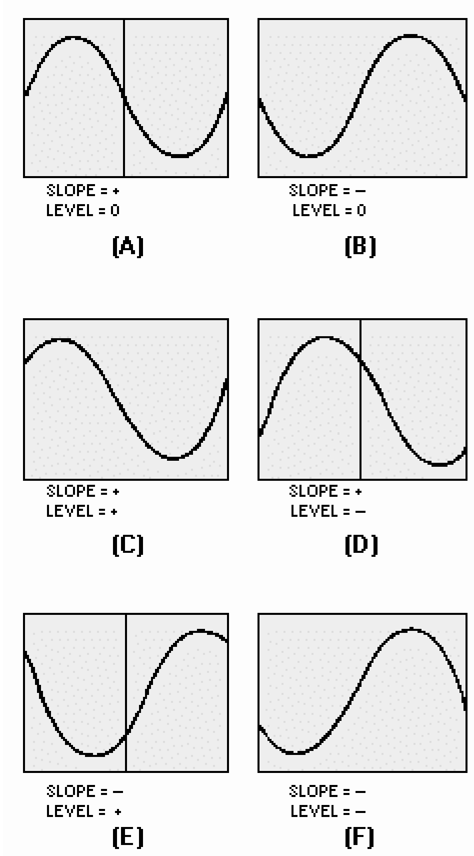

Figure 6-27.—Effects of SLOPE and TRIGGER LEVEL controls.

In most scopes, an automatic function of the trigger circuitry allows a free-running trace without a trigger signal. However, when a trigger signal is applied, the circuit reverts to the triggered mode of operation and the sweep is no longer free running. This action provides a trace when no signal is applied.

Synchronization is also used to cause a free-running condition without a trigger signal. Synchronization is not the same as triggering. TRIGGERING refers to a specific action or event that initiates an operation. Without this event, the operation would not occur. In the case of the triggered sweep, the sweep will not be started until a trigger is applied. Each succeeding sweep must have a trigger before a sweep commences. SYNCHRONIZATION, however, means that an operation or event is brought into step with a second operation.

A sweep circuit that uses synchronization instead of triggering will cause a previously free-running sweep to be locked in step with the synchronizing signal. The TRIGGER LEVEL control setting can be increased until synchronization occurs; but, until that time, an unstable pattern will appear on the CRT face.

COUPLING Section

The COUPLING section allows you to select from four positions: AC, LF REJ, HF REJ, and DC. The AC position incorporates a coupling capacitor to block any dc component. The LF and HF REJ positions reject low- and high-frequency components, respectively. The DC position provides direct coupling to the trigger circuits. This is useful when you wish to view only the LF or HF component of a signal.

COMPONENTS USED TO SELECT SCOPE TRIGGERING

The TRIG MODE section in figure 6-28 allows for automatic triggering or normal triggering. In AUTO (automatic), the triggering will be free-running in the absence of a proper trigger input or will trigger on the input signal at frequencies above 20 hertz. In NORM (normal), the vertical channel input will trigger the sweep.

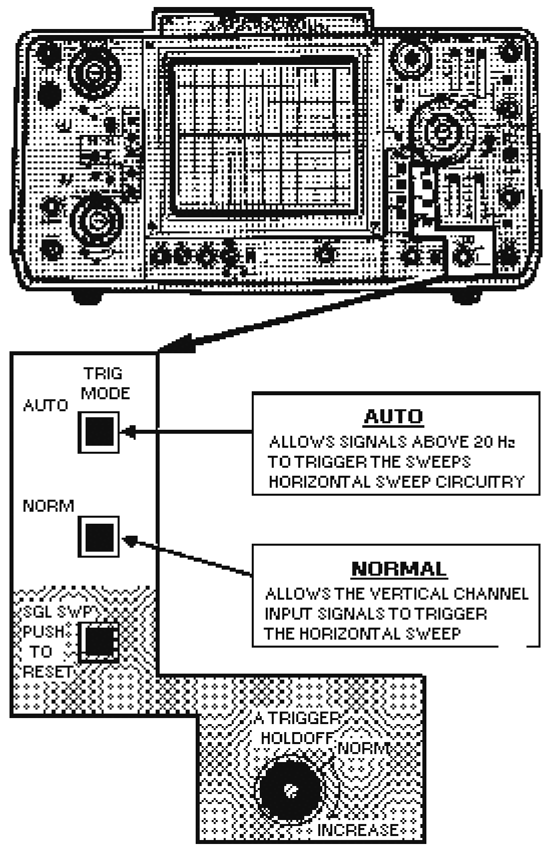

Figure 6-28.—Components to select triggering.

COMPONENTS USED TO SELECT HORIZONTAL-DEFLECTION MODE

For the present, notice only that the HORIZ DISPLAY (horizontal display) in figure 6-29 can be controlled by the TIME/DIV switch. Other switches in this section will be explained later in this chapter.

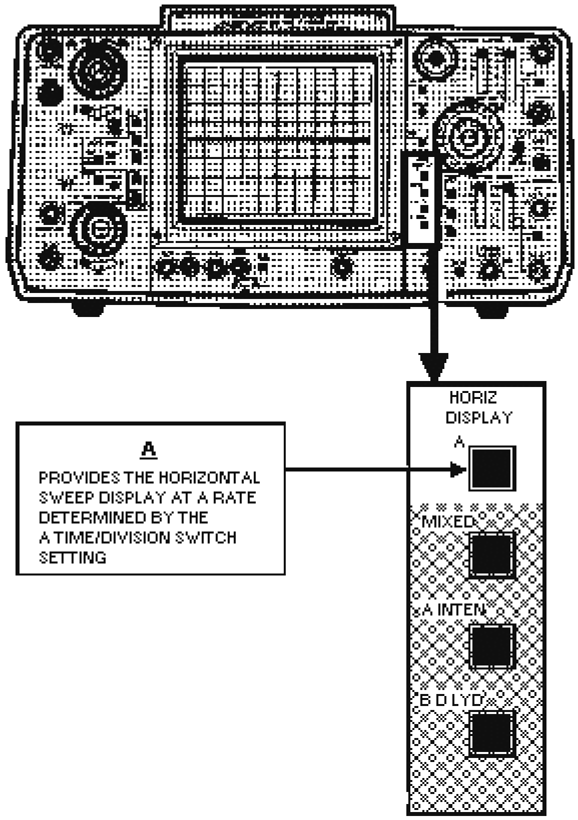

Figure 6-29.—Components to select mode of horizontal deflection.

COMPONENTS USED TO CALIBRATE THE PROBE OF THE SCOPE

In figure 6-30, you can see the components used to calibrate the test probe on the scope. A 1-volt, 2-kilohertz square wave signal is provided for you to adjust the probe for an accurate square wave and to check the vertical gain of the scope. You adjust the probe with a screwdriver, as shown in the figure.

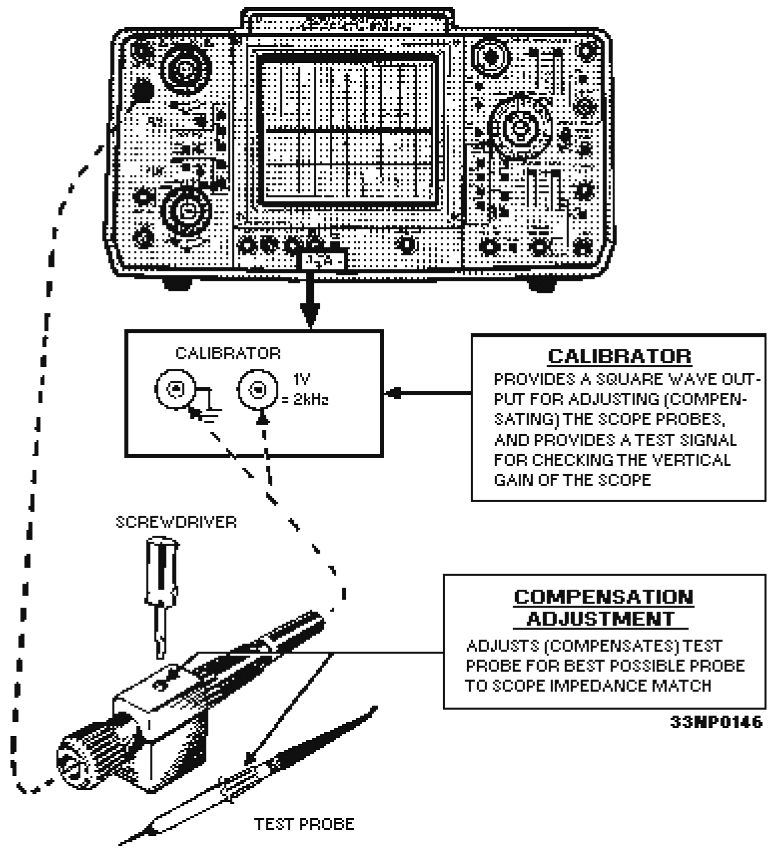

Figure 6-30.—Components to calibrate probe.

SIMILARITIES AMONG OSCILLOSCOPES

The oscilloscope you use may differ in some respects from the one just covered. Controls and circuits may be identified by different names. Many of the circuits will be designed differently. However, all the functions will be fundamentally the same. Before using an oscilloscope, you should carefully study the operator's manual that comes with it.

USING THE OSCILLOSCOPE

An oscilloscope can be used for several different types of measurements, such as time, phase, frequency, and amplitude of observed waveforms. Earlier in this chapter, you learned that the oscilloscope is most often used to study the shapes of waveforms when the performance of equipment is being checked. The patterns on the scope are compared with the signals that should appear at test points (according to the technical manual for the equipment under test). You can then determine if the equipment is operating according to peak performance standards.

Q-16. Oscilloscopes are used to measure what quantities?

TURNING ON THE SCOPE

Before turning on the scope, make sure it is plugged into the proper power source. This may seem obvious, but many technicians have turned all knobs on the front panel out of adjustment before they noticed that the power cord was not plugged in. On some scopes, the POWER switch is part of the INTEN (intensity) control. Turn or pull the knob until you hear a click or a panel light comes on (figure 6-31). Let the scope warm up for a few minutes so that voltages in all of the circuits become stabilized.

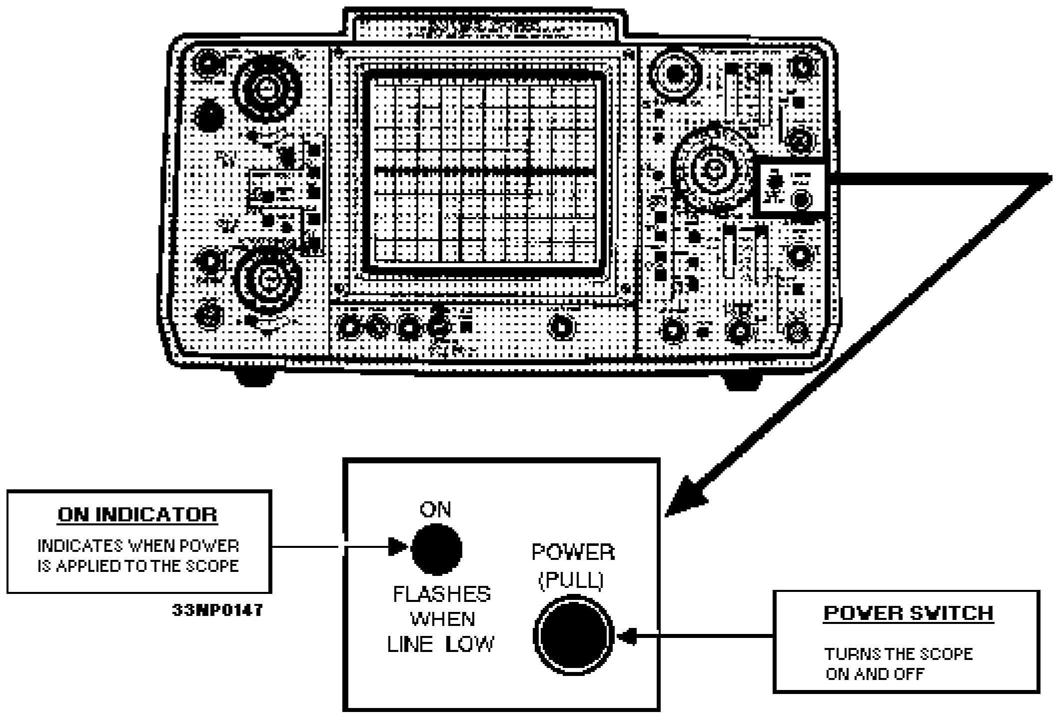

Figure 6-31.—Components to energize scope.

OBTAINING A PATTERN ON THE SCREEN

When adjusting a pattern onto the screen, adjust the INTEN (intensity) and FOCUS controls for a bright, sharp line. If other control settings are such that a dot instead of a line appears, turn down the intensity to prevent burning a hole in the screen coating. Because of the different speeds at which the beam travels across the screen, brightness and sharpness will vary at various frequency settings. For this reason, you may have to adjust the INTEN and FOCUS controls occasionally while taking readings.

NUMBER OF CYCLES ON THE SCREEN

Because distortion may exist at the beginning and end of a sweep, it is better to place two or three cycles of the waveform on the screen instead of just one, as shown in figure 6-32.

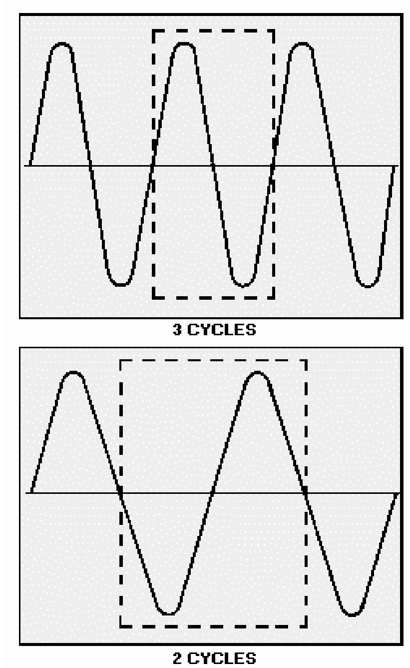

Figure 6-32.—Proper signal presentation.

The center cycle of three cycles provides you with an undistorted waveform in its correct phase. The center of a two-cycle presentation will appear inverted, but will be undistorted. To place waveforms on the CRT in this manner, you must understand the relationship between horizontal and vertical frequencies. The relationship between the frequencies of the waveform on the vertical plates and the sawtooth on the horizontal plates determines the number of cycles on the screen, as shown in figure 6-33.

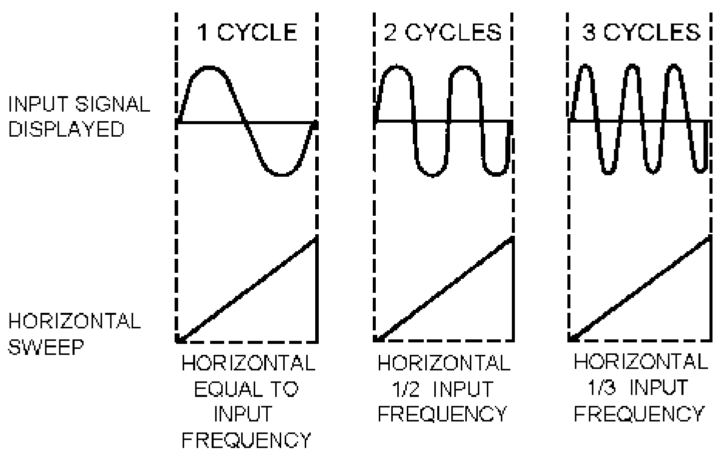

Figure 6-33.—Vertical versus horizontal relationship.

The horizontal sweep frequency of the scope should always be kept lower than, or equal to, the waveform frequency; it should never be higher. If the sweep frequency were higher, only a portion of the waveform would be presented on the screen.

If, for example, three cycles of the waveform were to be displayed on the screen, the sweep frequency would be set to one-third the frequency of the input signal. If the input frequency were 12,000 hertz, the sweep frequency would be set at 4,000 hertz for a three-cycle scope presentation. For two cycles, the sweep frequency would be set at 6,000 hertz. If a single cycle were desired, the setting would be the same as the input frequency, 12,000 hertz.

DUAL-TRACE OPERATION

The information presented in the previous sections served as a general overview of basic single-trace oscilloscope operation using one channel and operating controls. Now, you will be introduced to DUAL-TRACE operation.

Dual-trace operation allows you to view two independent signal sources as a dual display on a single CRT. This operation allows an accurate means of making amplitude, phase, time displacement, or frequency comparisons and measurements between two signals.

A dual-trace oscilloscope should not be confused with a dual-beam oscilloscope. Dual-beam oscilloscopes produce two separate electron beams on a single scope, which can be individually or jointly controlled. Dual-trace refers to a single beam in a CRT that is shared by two channels.

Q-17. Scopes that produce two channels on a single CRT with a single beam are referred to as what types of scopes?

Components Used to Select Vertical-Deflection Operating Mode

The VERT MODE controls (figure 6-34) allow you to select the operating mode of the scope for vertical deflection.

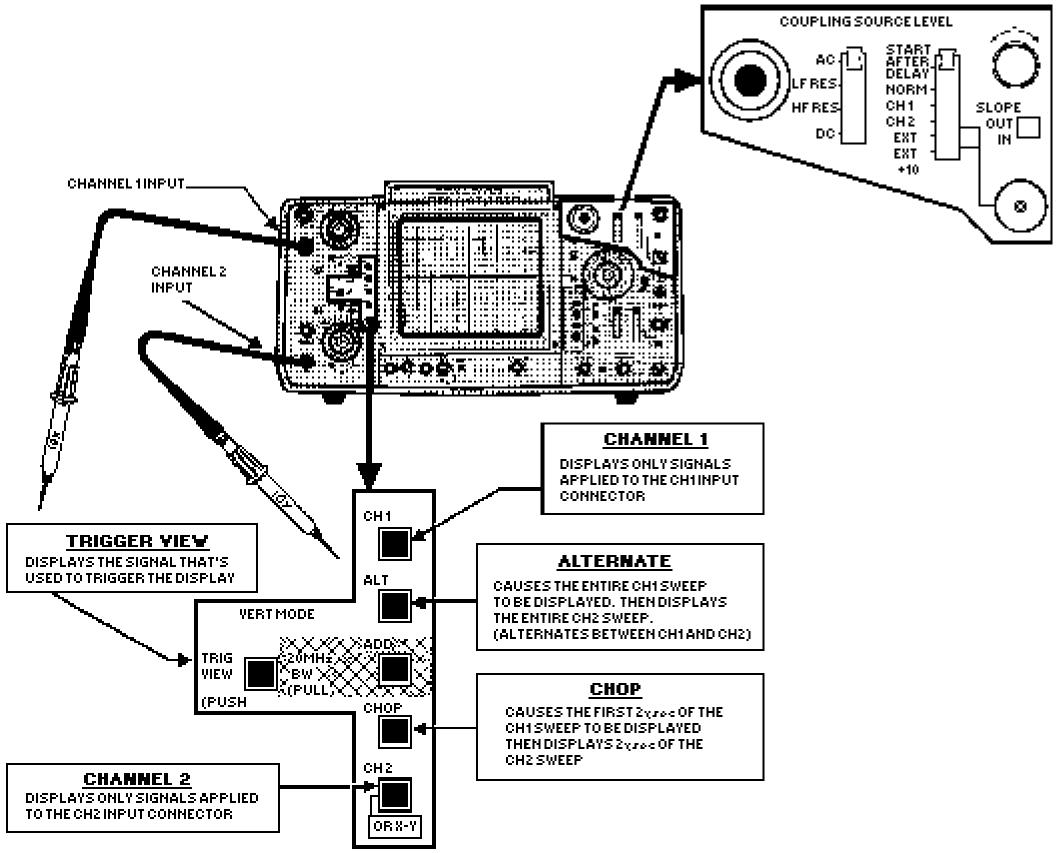

Figure 6-34.—Components to select vertical operating mode.

CH 1 AND CH 2.—These controls allow you to display signals applied to either channel 1 or channel 2, as discussed earlier.

TRIGGER VIEW.—The TRIG VIEW allows you to display the signal that is actually used to trigger the display. (Triggering was discussed earlier.)

ALT.—The ALT (alternate) mode (figure 6-35) of obtaining a dual trace uses the techniques of GATING between sweeps. This control allows the signal applied to channel 1 to be displayed in its entirety; then, channel 2 is displayed in its entirety. This method of display is continued alternately between the two channels. At slow speeds, one trace begins to fade while the other channel is being gated. Consequently, the ALT mode is not used for slow sweep speeds. The CHOP mode, shown in figure 6-36 (explained next), will not produce a satisfactory dual sweep at high speeds. The ALT mode is deficient at low speeds. Therefore, both are used on dual-trace oscilloscopes to complement each other and give the scope a more dynamic range of operation.

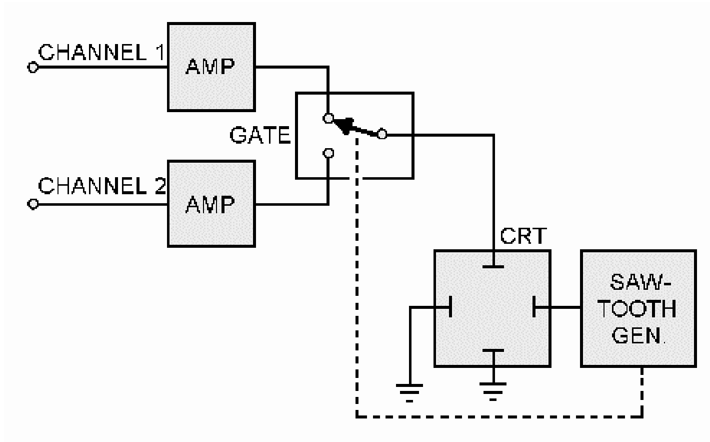

Figure 6-35.—ALT (alternate) mode.

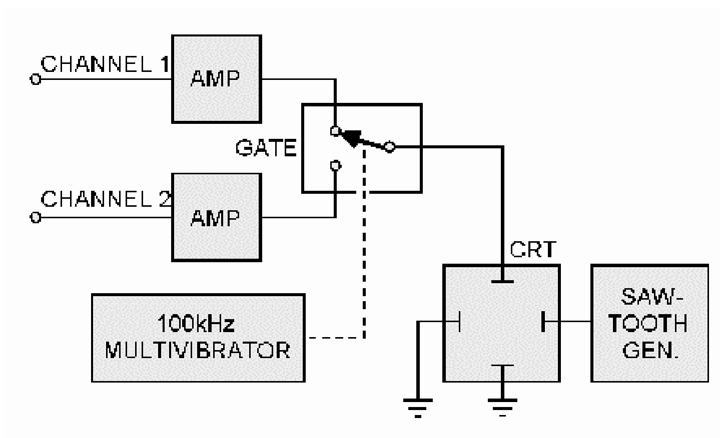

Figure 6-36.—CHOP mode.

The output dc voltage references on each of the amplifiers are independently adjustable. Therefore, the beam will be deflected by different amounts on each channel if the voltage reference is different at each amplifier output. The output voltage from each amplifier is applied to the deflection plates through the gate. The gate is actually an electronic switch. In this application, it is commonly referred to as a BEAM SWITCH.

Switching is controlled by a high-frequency multivibrator in the CHOP mode. That is, the gate selects the output of one channel and then the other at a high-frequency rate (1200 kilohertz in most oscilloscopes). Because the switching time is very short in a good-quality oscilloscope, the resultant display is two sets of horizontally dashed lines, as shown in figure 6-37, view A.

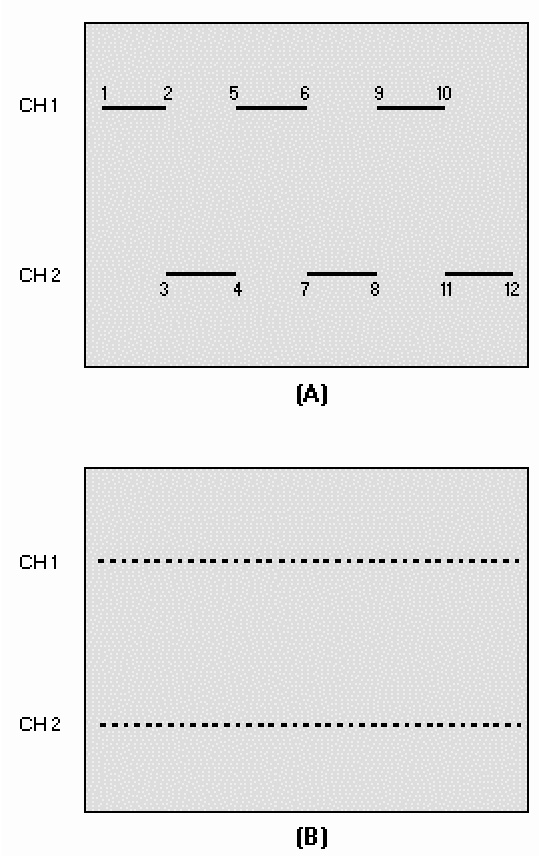

Figure 6-37.—Displaying CHOP mode.

Dashed line CH 1 is the output of one channel, while line CH 2 is the output of the other. The trace moves from left to right because of the sawtooth waveform applied to the horizontal plates. A more detailed analysis shows that the beam moves from CH 1 to CH 2 while the gate is connected to the output from one channel. Then, when the gate samples the output of the CH 2 during time 3 to 4, the beam is at a different vertical LOCATION. (This is assuming that CH 2 is at a different voltage reference.) The beam continues in the sequence 5 to 6, 7 to 8, 9 to 10, and 11 to 12 through the rest of one horizontal sweep.

When the chopping frequency is much higher than the horizontal sweep frequency, the number of dashes will be very large. For example, if the chopping occurs at 100 kilohertz and the sweep frequency is 1 kilohertz, each horizontal line would then appear as a series of closely spaced dots, as shown in figure 6-37 view B. As the sweep frequency becomes lower compared to the chopping frequency, the display will show apparently continuous traces; therefore, the CHOP mode is used at low sweep rates.

When signals are applied to the channel amplifiers (view A of figure 6-38), the outputs are changed according to the triggering signal (view B). The resultant pattern (view C) on the screen provides a time-base presentation of the signals of each channel.

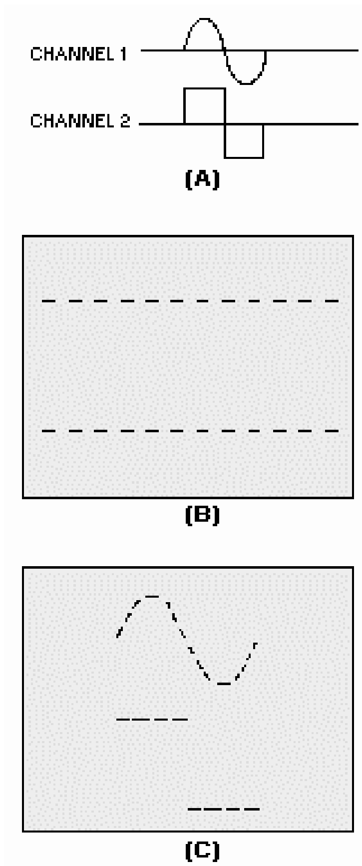

Figure 6-38.—Dual-channel display in CHOP mode.

ADD.—The ADD switch (shown earlier in figure 6-34) algebraically adds the two signals of channels 1 and 2 together for display.

Other Dual-Trace Oscilloscope Controls

Most dual-trace oscilloscopes have both an A and B time base for horizontal sweep control. Notice in the upper right corner on our example scope (figure 6-34) the COUPLING, SOURCE LEVEL, and SLOPE controls. These serve the same function as did those same controls in the A time-base section of the scope. The B time base is selected using the same A and B TIME/DIV control (pull out outer knob).

The use of the B time base is controlled by the HORIZ DISPLAY section discussed earlier in the A time-base section. However, inexperienced technicians generally do not use A and B time bases together in the MIXED, A INTEN (intensified), and B D'LYD (delayed) settings. These controls are fully explained in the applicable technical manuals; therefore, we will not discuss the controls in this chapter. Figure 6-39 is a block diagram of a basic dual-trace oscilloscope without the power supplies.

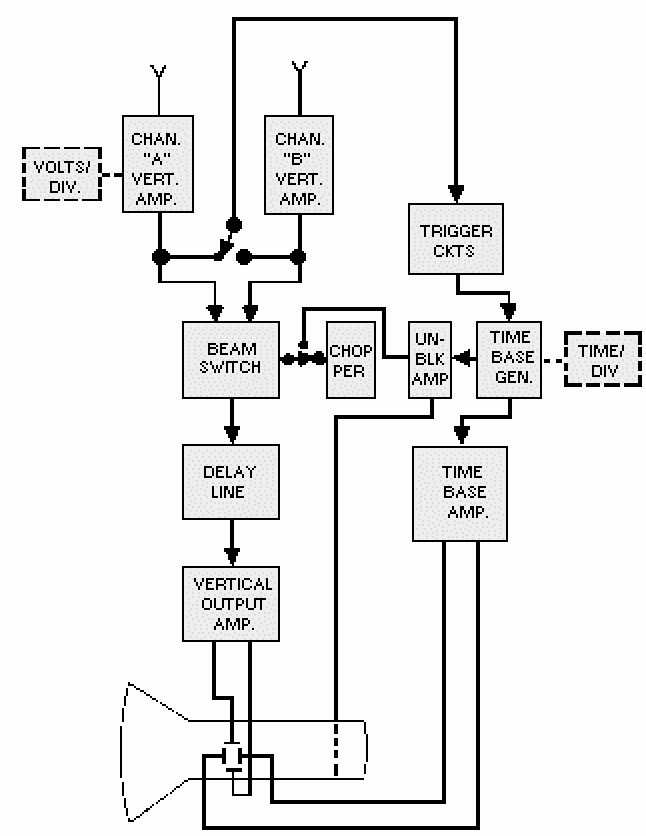

Figure 6-39.—Basic dual-trace oscilloscope block diagram.

ACCESSORIES

The basic dual-trace oscilloscope has one gun assembly and two vertical channels. However, there are many variations. The horizontal sweep channels vary somewhat from equipment to equipment. Some have one time-base circuit and others have two. These two are interdependent in some oscilloscopes and in others they are independently controlled. Also, most modern general-purpose oscilloscopes are constructed of modules. That is, most of the vertical circuitry is contained in a removable plug-in unit, and most of the horizontal circuitry is contained in another plug-in unit.

The main frame of the oscilloscope is often adapted for many other special applications by the design of a variety of plug-in assemblies. This modular feature provides much greater versatility than in a single-trace oscilloscope. For instance, to analyze the characteristics of a transistor, you can replace the dual-trace, plug-in module with a semiconductor curve-tracer plug-in module.

Other plug-in modules available with some oscilloscopes are high-gain, wide-bandwidth amplifiers; differential amplifiers; spectrum analyzers; physiological monitors; and other specialized units. Therefore, the dual-trace capability is a function of the type of plug-in unit that is used with some oscilloscopes.

To get maximum usefulness from an oscilloscope, you must have a means of connecting the desired signal to the oscilloscope input. Aside from cable connections between any equipment output and the oscilloscope input, a variety of probes are available to assist in monitoring signals at almost any point in a circuit. The more common types include 1-TO-1 PROBES, ATTENUATION PROBES, and CURRENT PROBES. Each of these probes may be supplied with several different tips to allow measurement of signals on any type of test point. Figure 6-40 shows some of the more common probe tips.

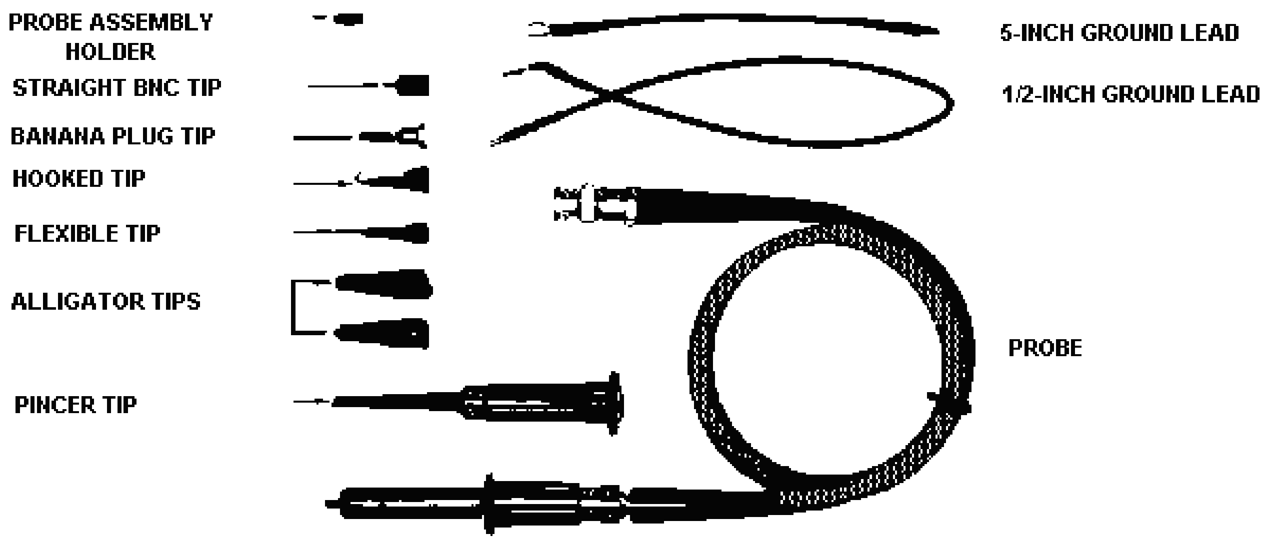

Figure 6-40.—Common probe tips.

In choosing the probe to use for a particular measurement, you must consider such factors as circuit loading, signal amplitude, and scope sensitivity.

The 1-to-1 probe offers little or no attenuation of the signal under test and is, therefore, useful for measuring low-level signals. However, circuit loading with the 1-to-1 probe may be a problem. The impedance at the probe tip is the same as the input impedance of the oscilloscope.

An attenuator probe has an internal high-value resistor in series with the probe tip. This gives the probe a higher input impedance than that of the oscilloscope. Because of the higher input impedance, the probe can measure high-amplitude signals that would overdrive the vertical amplifier if connected directly to the oscilloscope. Figure 6-41 shows a schematic representation of a basic attenuation probe. The 9-megohm resistor in the probe and the 1-megohm input resistor of the oscilloscope form a 10-to-1 voltage divider.

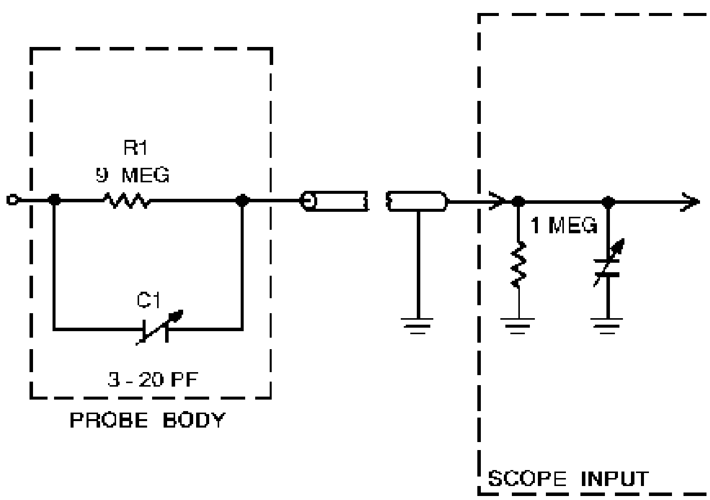

Figure 6-41.—Basic attenuation probe.

Since the probe resistor is in series, the oscilloscope input resistance is 10 megohms when the probe is used. Thus, using the attenuator probe with the oscilloscope causes less circuit loading than using a 1-to-1 probe.

Before using an attenuator probe for measurement of high-frequency signals or for fast-rising waveforms, you must adjust the probe compensating capacitor (C1) according to instructions in the applicable technical manual. Some probes will have an IMPEDANCE EQUALIZER in the end of the cable that attaches to the oscilloscope. The impedance equalizer, when adjusted according to manufacturer's instructions, assures proper impedance matching between the probe and oscilloscope. An improperly adjusted impedance equalizer will result in erroneous measurements, especially when you are measuring high frequencies or fast-rising signals.

More information on oscilloscope hook-ups can be found in Electronics Information Maintenance Books (EIMB), *Test Methods and Practices*.

Special current probes have been designed to use the electromagnetic fields produced by a current as it travels through a conductor. This type of probe is clamped around a conductor without disconnecting it from the circuit. The current probe is electrically insulated from the conductor, but the magnetic fields about the conductor induce a potential in the current probe that is proportional to the current through the conductor. Thus, the vertical deflection of the oscilloscope display will be directly proportional to the current through the conductor.

SPECTRUM ANALYZER

The spectrum analyzer is used to examine the frequency spectrum of radar transmissions, local oscillators, test sets, and any other equipment operating within its testable frequency range. With experience, you will be able to determine definite areas of malfunctioning components within equipment. Successful spectrum analysis depends on the proper operation of a spectrum analyzer and your ability to correctly interpret the displayed frequencies. Although there are many types of spectrum analyzers, we will use the Tektronix, Model 492 for our discussion.

The spectrum analyzer accepts an electrical input signal and displays the frequency and amplitude of the signal on a CRT. On the vertical, or Y, axis, the amplitude is plotted. The frequency would then be found on the horizontal, or X, axis. The overall pattern of this display (figure 6-42) indicates the proportion of power present at the various frequencies within the spectrum (fundamental frequency with sideband frequencies).

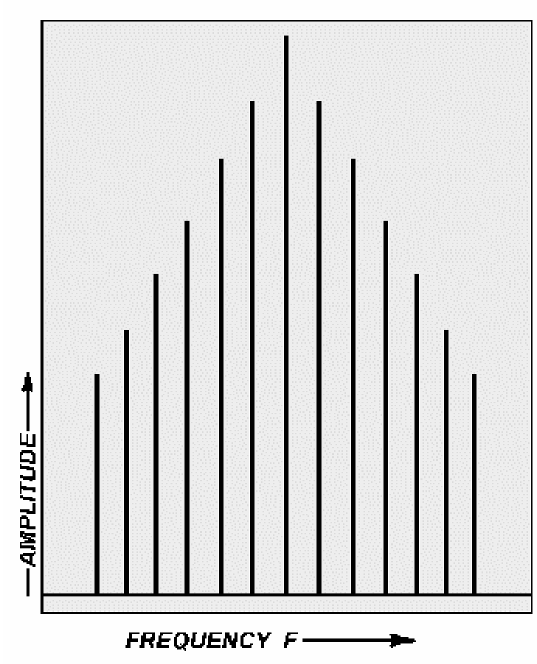

Figure 6-42.—Spectrum analyzer pattern.

BASIC FUNCTIONAL DESCRIPTION

The model 492 analyzer can be divided into six basic sections, as follows:

- Converter section;
- Intermediate frequency (IF) section;
- Display section;
- Frequency control section;
- Digital control section; and
- Power and cooling section.

Converter Section

The converter section actually consists of three frequency converters, made up of a mixer, local oscillator (LO), and required filters. Only one frequency can be converted at a time and pass through the filters to reach the next converter. The analysis frequency can, however, be changed by altering the frequency of the LO and adjusting the FREQUENCY control knob.

FIRST CONVERTER.—The first (front end) converter changes the input signal to a usable IF signal that will either be 829 MHz or 2072 MHz. The IF signal to be produced is dependent on which measurement band selection is currently being used. The 829 MHz IF signal will be selected for bands 2 through 4, while the 2072 MHz IF signal is selected for bands 1 and 5 through 11.

Q-18. The first converter is also known by what other name?

SECOND CONVERTER.—The second converter actually contains two converters. Only one of these two converters in this section is ever operational, and selected as a result of the measurement band currently being used. The selected converter will convert the frequency received from the first converter to a usable (110 MHz) IF signal, which is then provided to the third converter.

THIRD CONVERTER.—This converter takes the 110 MHz IF signal, amplifies it, and then converts it to the final IF of 10 MHz. This signal, in turn, is then passed on to the IF section.

IF Section

The IF section receives the final IF signal and uses it to establish the system resolution by using selective filtering. System resolution is selected under microcomputer control among five bandwidths (1 MHz, 100 kHz, 10 kHz, 1 kHz, and 100 Hz). The gain for all bands are then leveled and logarithmically amplified. This is done so that each division of signal change on the CRT display remains equal in change to every other division on the CRT. For example, in the 10-dB-per-division mode, each division of change is equal to a 10 dB difference, regardless of whether the signal appears at the top or bottom of the CRT. The signal needed to produce the video output to the display section is then detected and provided.

Display Section

The display section provides a representative display of the input signal on the CRT. It accomplishes this by performing the following functions:

- Receives the video signals from the IF section and processes these signals to adjust the vertical drive of the CRT;
- Receives the sweep voltages and processes these signals to produce the horizontal CRT drive plate voltage;
- Receives character data information and generates CRT plate drive signals to display alpha and numeric characters on the CRT;
- Receives control levels from the front panel beam controls and generates unblanking signals to control display presence, brightness, and focus.

The vertical deflection of the beam is increased as the output of the amplitude detector increases. The horizontal position is controlled by the frequency control section and is the frequency analyzed at that instant. The beam sweeps from left to right, low to high frequencies during its analysis. During this analysis, any time a signal is discovered, a vertical deflection will show the strength of the signal at the horizontal position that is the frequency. This results in a display of amplitude as a function of frequency.

Frequency Control Section

The frequency control section accomplishes the tuning of the first and second LOs within the converter section. The frequency immediately being analyzed is controlled by the current frequencies of the LOs. To analyze another frequency, you must change an LO frequency to allow the new frequency to be converted to a 10 MHz signal by the converter section. Periodically, the unit sweeps and analyzes a frequency range centered on the frequency set by the FREQUENCY knob. Adjusting the FREQUENCY knob will cause the LOs to be tuned to the new frequency. Only the LOs of the first two converters can be changed to vary the frequency being analyzed.

Digital Control Section

All the internal functions are controlled from the front panel through the use of a built-in microcomputer. The microcomputer uses an internal bus to receive or produce all communication or control to any section of the analyzer.

Power and Cooling Section

The main power supply provides almost all the regulated voltages required to operate the unit. The display section provides the high voltage necessary for CRT operation.

The cooling system allows fresh cool air to be routed to all sections of the unit in proportion to the heat that is generated by each section.

SPECTRUM ANALYZER FRONT PANEL CONTROLS, INDICATORS, AND CONNECTORS

This section will describe the function of the front panel controls, indicators, and connectors. For a complete description of each function, refer to table 6-1 while reviewing the front panel in figure 6-43. The numbers located in column 1 of table 6-1 equate to the same numbers found on the front panel of figure 6-43. Because most operational functions of this spectrum analyzer are microprocessor-controlled, they are switch-selected rather than adjusted.

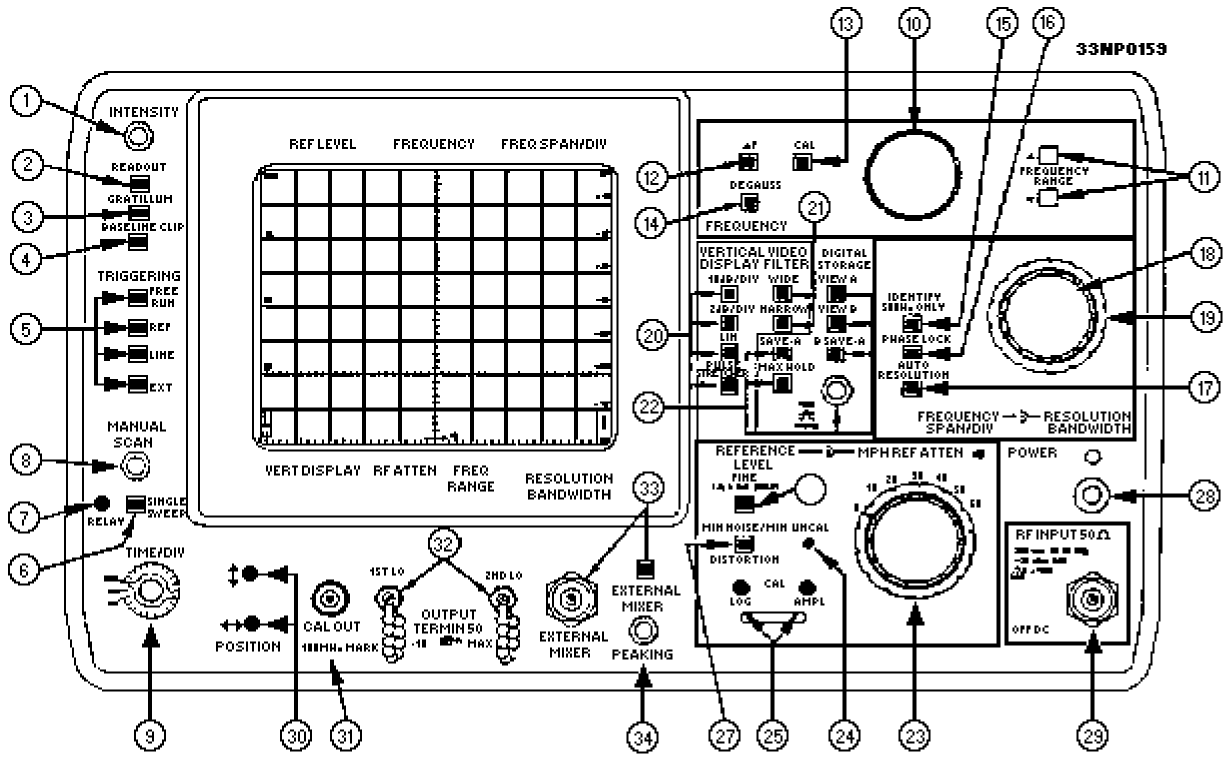

Figure 6-43.—Spectrum analyzer front panel controls, indicators, and connectors.

Table 6-1.—Description of Front Panel Controls, Indicators, and Connectors

ITEM	FUNCTION	DESCRIPTION
1	INTENSITY	This knob controls the brightness of the CRT trace and the CRT readout display. The focus is electronically adjusted.
2	READOUT	This push button switches the readout display on and off. All spectrum analyzer parameters are displayed except TIME/DIV. The brightness for this display is proportional to the trace brightness and can be readjusted on internal controls only by a qualified technician.
3	GRATILLUM	This push button switches the graticule light on and off.
4	BASELINE CLIP	This push button, when activated, clips (subdues) the intensity at the baseline.
5	TRIGGERING	This area allows one of four triggering modes to be selected by push buttons that illuminate when active. When any of these four are selected, the others are canceled.
5a	FREE RUN	When activated, the sweep is free-running without regard to trigger signals.
5b	INT	When activated, the sweep is triggered by any signal at the left edge of the display with an amplitude of 1.0 divisions of the graticule or more.
5c	LINE	When activated, a sample of the ac power line voltage is used to trigger the sweep.
5d	EXT	When selected, the sweep is triggered by an external signal (applied through the back panel IN HORZ/TRIG connector) between a minimum and maximum of 0.5 and 50 volt peak.
6	SINGLE SWEEP	This push button, plus a ready indicator (No. 7), provides the single sweep operation. When this operation is selected, one sweep is initiated after the sweep circuit has been triggered. Pushing this button does not cancel the other trigger modes. When single sweep is first selected, the present sweep is aborted, but the sweep circuit is not yet armed. An additional push is required to initially arm the sweep. The button must be pushed again to rearm the sweep circuit each time the sweep has run. To cancel single sweep, you must select one of the four trigger mode selections.
7	READY	When single sweep is selected, this indicator lights while the sweep circuit is armed and ready for a trigger signal. The indicator stays lit until the sweep is complete.
8	MANUAL SCAN	When the TIME/DIV (No. 9c) selector is in the MNL position, this control will manually vary the CRT beam across the full horizontal axis of the display.
9	TIME/DIV	Is used to select sweep rates from 5 μsec/div to 20 μsec/div. This switch also selects AUTO, EXT, and MNL modes.
9a	AUTO	In this position, the sweep rate is selected by the microcomputer to maintain a calibrated display for any FREQ SPAN/DIV, RESOLUTION, and VIDEO FILTER combination.
9b	EXT	When selected, this control allows an external input source to be used with the sweep rates.
9c	MNL	When selected, this control is used in conjunction with No. 8 (see MANUAL SCAN, No. 8).
10	FREQUENCY	This control is manually turned to allow you to tune to the center frequency.
11	FREQUENCY RANGE (band)	These two push buttons are used to shift the center frequency up or down. Frequency range on the band is displayed on the CRT readout.
12	F	This control is used for measuring the frequency difference between signals. When selected, the frequency readout goes to zero. It will then read out the deviation from this reference to the next frequency desired as the FREQUENCY knob is adjusted.

Table 6-1.—Description of Front Panel Controls, Indicators, and Connectors—Continued

ITEM	FUNCTION	DESCRIPTION
13	CAL	When this is activated, the frequency readout can be calibrated to center the center frequency by adjusting the FREQUENCY control for the correct reading. When accomplished, you should deactivate the CAL mode.
14	DEGAUSS	When this button is pressed, current through the local oscillator system is reduced to zero in order to minimize magnetism build-up around the LOs. This is done to enhance the center frequency display and amplitude accuracy. You should do this after every significant frequency change and before calibrating the center frequency.
15	IDENTIFY 500 kHz ONLY	The signal identify feature can become functional only when the FREQ SPAN/DIV is set to 500 kHz. When activated (button lit), true signals will change in amplitude on every sweep. Images and spurious response signals will shift horizontally or go completely off the CRT display. To ensure that the signal is changing amplitude every sweep, you should decrease the sweep rate so that each sweep can be analyzed.
16	PHASE LOCK	When this control is activated (button lit), it will reduce residual FM when narrow spans are selected. In narrow spans, the phase lock can be turned off or back on by pressing the button. Switching the PHASE LOCK off may cause the signal to shift position. In narrow spans, the signal could shift off the display; however, it will usually return to its phase locked position after a few moments. The microcomputer automatically selects PHASE LOCK for a span/division of 50 kHz or below in bands 1 through 3, 100 kHz or below for band 3, and 200 kHz for bands 5 and above.
17	AUTO RESOLUTION	This push button, when activated, will automatically select the bandwidth for FREQ SPAN/DIV, TIME/DIV, and VIDEO FILTER. The internal microcomputer selects the bandwidth to maintain a calibrated display. This can be checked by changing the FREQ SPAN/DIV and observing the bandwidth change on the display.
18	FREQ SPAN/DIV	This is a continuous detent control that selects the frequency span/div. The span/div currently selected is displayed on the CRT. The range of the span/div selection is dependent on the frequency band selected: <u>BAND</u> / <u>NARROW SPAN</u> / <u>WIDE SPAN</u> 1-3 (0-7.1GHz) / 10kHz/Div / 200MHz/Div 4-5 (5.4-21GHz) / 50 kHz/Div / 500 MHz/Div 6 (18-26GHz) / 50 kHz/Div / 1 GHz/Div 7-8 (26-60GHz) / 100 kHz/Div / 2 GHz/Div 9 (60-90GHz) / 200 kHz/Div / 2 GHz/Div 10 (90-140GHz) / 500 kHz/Div / 5 GHz/Div 11 (140-220GHz) / 500 kHz/Div / 10 GHz/Div Two additional bands are provided: full band (max span) and 0 Hz span. When max span is selected, the span displayed is the full band. When zero span is selected, time/div is read out instead of span/div.
19	RESOLUTION BANDWIDTH	This is also a continuous detent control that selects the resolution bandwidth. The bandwidth is shown on the CRT display. The range of adjustment is from 1 kHz to 1 MHz in decade steps. When you change the resolution bandwidth with this control, it will deactivate the AUTO RESOLUTION.
20	VERTICAL DISPLAY	These four push buttons select the display mode. The scale factor can be seen on the CRT display.
20a	10dB/DIV	When this is activated, the dynamic range of the display is calibrated to 80 dB, with each major graticule representing 10 dB.

Table 6-1.—Description of Front Panel Controls, Indicators, and Connectors—Continued

ITEM	FUNCTION	DESCRIPTION
20b	2dB/DIV	When activated, this will increase the resolution so that each major graticule division represents 2 dB.
20c	LIN	When activated, this selects a linear display between zero volts (bottom graticule line) and the reference level (top graticule line) scaled in volts/division (see REFERENCE LEVEL, No. 23a).
20d	PULSE STRETCHER	When selected, this increases the fall time of the pulse signals so that very narrow pulses in a line spectrum display can be observed.
21	VIDEO FILTER	One of two (NARROW OR WIDE) filters can be activated to reduce video bandwidth and high-frequency components for display noise averaging. The narrow filter is approximately 1/300th of the selected resolution bandwidth with the wide filter being 1/30th the bandwidth. Activating either one will cancel the other. To disable, completely switch filter off.
22	DIGITAL STORAGE	Five push buttons and ON control operate the digital storage functions. With none of the push buttons activated, the display will not be stored.
22a	VIEW A, VIEW B	When either or both of these push buttons are selected, the push button illuminates, and the contents of memory A and/or memory B are displayed. With Save A mode off, data in a memory is interlaced with data from B memory.
22b	B-SAVE A	When activated, the differential (arithmetic difference) of data in B memory and the saved data in memory A are displayed. SAVE A mode is activated and SAVE A button will be lit.
22c	MAX HOLD	When activated, the digital storage memory retains the maximum signal amplitude at each memory location. This permits visual monitoring of signal frequency and amplitude at each memory location over an indefinite period of time. This feature is used to measure drift, stability, and record peak amplitude.
22d	PEAK/AVERAGE	This control selects the amplitude at which the vertical display is either peak detected or averaged. Video signals above the level set by the control (shown by a horizontal line or cursor) are peak detected and stored while video signals below the cursor are digitally averaged and stored.
23	MIN RF ATTEN	This control is used to set the minimum amount of RF attenuation. Changing RF LEVEL will not decrease RF attenuation below that set by the MIN RF ATTEN selector.
23a	REFERENCE LEVEL	This is a continuous control that requests the microcomputer to change the reference level one step for each detent. In the 10 dB/DIV vertical-display mode, the steps are 1 dB or 0.25 dB if the FINE mode (No. 26) is selected.
23b	MIN RF ATTEN DB	This selects the lowest value of attenuation allowed: Actual RF attenuation is set by the microcomputer according to the logarithm selected by the MIN NOISE/MIN DISTORTION (No. 27) button. If RF attenuation is increased by changing MIN RF ATTEN, the microcomputer automatically changes IF gain to maintain the current reference level.
24	UNCAL	This indicator lights when the display amplitude is no longer calibrated (selecting a sweep rate that is not compatible with the frequency span/div and resolution bandwidth).
25	LOG and AMPL CAL	These adjustments calibrate the dynamic range of the display. The LOG calibrates any logarithm gain dB/Div, and the AMPL calibrates the reference level of the top graticule line at the top of the display.
26	FINE	When activated, the REFERENCE LEVEL (No. 23a) switches in 1 dB increments for 10 dB/Div display mode, 0.25 dB for 2 dB/Div, and volts 1 dB for LIN display mode.

Table 6-1.—Description of Front Panel Controls, Indicators, and Connectors—Continued

ITEM	FUNCTION	DESCRIPTION
27	MIN NOISE/MIN DISTORTION	This selects one of two logarithms used to control attenuator and IF gain. MIN NOISE (button illuminated) reduces the noise level by reducing attenuation and IF gain 10 dB. MIN DISTORTION (button not illuminated) reduces distortion to its minimum. To observe any changes, the RF attenuation displayed on the CRT readout must be 10 dB higher than that set by the MIN RF ATTEN selector.
28	POWER	This is a pull switch that turns power on when extended.
29	RF INPUT	This is a 50 ohm coaxial input jack used to input signals of 21GHz or below. The maximum nondestructive input signal level that can be applied to this input is +13 dBm or 30 mW. Signals above 10 dB may cause signal compression.
30	POSITION	These controls are used to position the display on the horizontal and vertical axes.
31	CAL OUT	This is an output jack that has a calibrated 20 dBm 100 MHz signal, with frequency markers spaced 100 MHz apart. The calibrated 100 MHz marker is used as a reference for calibrating the reference level and log scale. The combination of 100 MHz markers is used to check span and frequency readout accuracy.
32	OUTPUT 1ST AND 2ND LO	These jacks provide access to the output of the respective LOs. The jacks must have 50 ohm terminators installed when not connected to an external device.
33	EXTERNAL MIXER	When the EXTERNAL MIXER button is activated, bias is provided out the EXTERNAL MIXER port for external waveguide mixers. The IF output from the EXTERNAL MIXER is then applied through the EXTERNAL MIXER port to the second converter for use.
34	PEAKING	This control varies the mixer bias for external mixers in the EXTERNAL MIXER mode. This control should be adjusted for maximum signal amplitude.

NORMAL INDICATIONS UPON POWER ON

With power applied (power knob pulled out), the spectrum analyzer will automatically (upon microcomputer control) go into the following conditions. If you do not find these indications, there is a probably a problem with the unit.

- Vertical display: 10 dB/div;
- Frequency: 0.00 MHz;
- REF level: +30 dB;
- RF attenuation: 60 dB;
- Frequency range: 0.0 to 1.8 GHz;
- Auto resolution: 1 MHz;
- Resolution bandwidth: 1 MHz;
- Freq Span/Div: Max;
- Triggering: Free run;
- Readout: On;
- Digital storage: View A/View B On;

- All other indicators off or inactive.

SUMMARY

Now that we have completed this chapter, we will briefly review the more important points covered.

A **CATHODE-RAY TUBE (CRT)** is used in an oscilloscope to display the waveforms.

The CRT used in oscilloscopes consists of an **ELECTRON GUN**, a **DEFLECTION SYSTEM**, and a **FLUORESCENT SCREEN**.

The **ELECTRON BEAM** in an oscilloscope is allowed to be controlled in any direction by means of **HORIZONTAL-** and **VERTICAL-DEFLECTION PLATES**.

VERTICAL-DEFLECTION PLATES are used to show **AMPLITUDE** of a signal.

HORIZONTAL-DEFLECTION PLATES are used to show **TIME** and/or **FREQUENCY** relationship.

A **GRATICULE** is a calibrated scale of **AMPLITUDE VERSUS TIME** that is placed on the face of the CRT.

A **DUAL-TRACE OSCILLOSCOPE** is designed to accept two vertical inputs at the same time. It uses a single beam of electrons shared by two channels.

The **SPECTRUM ANALYZER** accepts an electrical input signal and displays the signal's frequency and amplitude on a CRT display.

ANSWERS TO QUESTIONS Q1. THROUGH Q18.

A-1. Control grid.

A-2. The first anode.

A-3. Because they bend electron streams in much the same manner that optical lenses bend light rays.

A-4. It accelerates the electrons emerging from the first anode.

A-5. A greater deflection angle.

A-6. A greater deflection angle.

A-7. Higher potential.

A-8. Slower beam.

A-9. Amplitude and time.

A-10. Amplitude.

A-11. Time and/or frequency relationships.

A-12. To permit wide-angle deflection of the beam.

A-13. Deflection factor.

A-14. A CRT, a group of control circuits, power supply, sweep circuitry, and deflection circuitry.

A-15. Lower.

A-16. Amplitude, phase, time, and frequency.

A-17. Dual-trace oscilloscopes.

A-18. Front end.

APPENDIX I

GLOSSARY

ABSORPTION WAVEMETER—An instrument used to measure audio frequencies.

AMMETER—A meter used to measure current.

BACK RESISTANCE—The larger resistance value observed when you are checking the forward resistance of a semiconductor.

BAND PASS FILTER—A tuned circuit that passes only a specific frequency.

BAND REJECT FILTER—A tuned circuit that does not pass a specified band of frequencies.

BARRETTER—A type of bolometer characterized by an increase in resistance as the dissipated power rises.

BEAT FREQUENCY—The difference between the oscillator frequency and the unknown audio frequency.

BEL—The unit that expresses the logarithmic ratio between the input and output of any given component, circuit, or system.

BOLOMETER—A loading device that undergoes changes in resistance as changes in dissipated power occur.

CAVITY WAVEMETER—An instrument used to measure microwave frequencies.

CONTINUITY—An uninterrupted, complete path for current flow.

CORRECTIVE MAINTENANCE—Used to isolate equipment failures. Includes replacement of defective parts to return equipment to proper performance.

DAMPING—The process of smoothing oscillations of the meter pointer.

D'ARSONVAL METER MOVEMENT—The permanent-magnet moving coil movement used in most meters.

dBm—An abbreviation used to represent power levels above or below a 1-milliwatt reference.

DUMMY ANTENNA—See DUMMY LOAD.

DUMMY LOAD—A resistor used to replace the normal load, which is specifically designed to have low reactance and possess the ability to dissipate required amounts of power.

ELECTRODYNOMETER METER MOVEMENT—A meter movement using fixed field coils and a moving coil; usually used in wattmeters.

EXTERNALLY EXCITED METER—A term used to describe meters that get their power from the circuit to which they are connected.

FORWARD RESISTANCE—The smaller resistance value observed when you are checking the forward resistance of a semiconductor.

FREQUENCY METER—An instrument used to measure the rate at which ac voltages are generated.

GALVANOMETER—A meter used to measure small values of current by electromagnetic or electrodynamic means.

GENERAL PURPOSE ELECTRONIC TEST EQUIPMENT (GPETE)—Test equipment that has the capability, without modification, to generate, modify, or measure a range of electronic functions required to test two or more equipments or systems of basically different designs.

INDUCTANCE BRIDGE—An ac bridge circuit used to measure an unknown value of inductance.

MAINTENANCE—Work done to correct, reduce, or counteract wear, failure, and damage to equipment.

MEASURE (Metrology Automated System for Uniform Recall and Reporting)—A Navy standardized system designed to provide the recall, scheduling, and documenting of test equipment into calibration facilities.

MECHANICAL-ROTATION FREQUENCY—The speed in revolutions per minute of armatures in electric motors and engine-driven generators; blade speed in turbines.

MEGGER—A meter used to measure insulation resistance.

METER MOVEMENT—The part of the meter that moves to indicate some electrical value.

METER SHUNT—A resistor placed in parallel with the meter terminals; used to provide increased range capability.

OHMMETER—A meter used to measure resistance.

POWER FACTOR—An indication of the various losses of a capacitor, such as current leakage and dielectric absorption.

PREVENTIVE MAINTENANCE—Consists of mechanical, electrical, and electronic checks; used to determine whether or not equipment is operating properly.

SCAT CODES—A four-digit subcategory code used to identify the functional measurement parameters that can be satisfied by any one of many pieces of test equipment.

SELF-EXCITED METER—A term used to describe meters that operate from their own power sources.

SENSITIVITY—(1) For an ammeter, the amount of current that will cause full-scale deflection of the meter. (2) For a voltmeter, the ratio of the voltmeter resistance divided by the full-scale reading of the meter; expressed in ohms per volt.

SCLSIS (Ship Configuration and Logistics Support Information System)—This encompasses the automated data processing system and all practices and procedures used for identification and status accounting of ship's configuration, logistics, technical data reviews, and equipment configuration audits.

SHORT CIRCUIT—An unintentional current path between two components in a circuit or between a component and ground; usually caused by a circuit malfunction.

SPECIAL PURPOSE ELECTRONIC TEST EQUIPMENT (SPETE)—Test equipment that is specifically designed to generate, modify, or measure a range of electronic functions of a specific or peculiar nature on a single system or equipment.

STROBOSCOPE—An instrument that allows viewing of rotating or reciprocating objects by producing the optical effect of a slowing down or stopping motion.

SYMPTOM ELABORATION—Using built-in indicating instruments or other aids to define an equipment malfunction.

SYMPTOM RECOGNITION—Recognition of a situation in equipment operation that is not normal.

TACHOMETER—An instrument that measures the rate at which a shaft is turning.

TEST EQUIPMENT INDEX—The Navy guide used to assist in identifying portable electrical/electronic test equipment required for support of prime electrical/electronic, IC, weapons, and reactor instrumentation systems.

TEST POINTS—Locations in equipment that are accessible to the technician's probes where operating voltages or signals can be monitored.

THERMISTOR—A type of bolometer characterized by a decrease in resistance as the dissipated power increases.

TROUBLESHOOTING—A procedure used to evaluate equipment performance and repair equipment when it fails to operate properly.

TUNED CIRCUIT—A circuit that is used as a filter which passes or rejects specific frequencies.

VOLTMETER—A meter that is used to measure voltage.

WATT—The unit of electrical power that is the product of voltage and current.

WATTMETER—An electrodynamometer type meter used to measure electrical power.

WAVEFORM ANALYSIS—Observation of displays of voltage and current variations with respect to time or by harmonic analysis of complex signals.

WAVEMETER—Calibrated resonant circuits that are used to measure frequency.

WHEATSTONE BRIDGE—An ac bridge circuit used to measure unknown values of resistance, inductance, or capacitance.

Assignment Questions

<u>Information</u>: The text pages that you are to study are provided at the beginning of the assignment questions.

ASSIGNMENT 1

Textbook assignment: Chapter 1, "Test Equipment Administration and USE," pages 1-1 through 1-33. Chapter 2, "Miscellaneous Measurements," pages 2-1 through 2-27.

1-1. What system is currently used by U.S. military services to identify electronic equipment with standardized nomenclature?

1. Joint Electronic Type Designation System (JETDS)
2. Joint Electronics Type Category System (JETCS)
3. Army-Navy (AN) System
4. Navy Tactical Data Systems (NTDS)

1-2. Which of the following categories of test equipment is/are designed to test, without modification, a range of electronic parameters needed for two or more systems that are different in design?

1. GPETE
2. SPETE
3. Both 1 and 2 above
4. Installed

1-3. For what purpose was the ETE classification board established?

1. To control inventory limits
2. To control the increase of nonstandard GPETE
3. To control the increase of nonstandard SPETE
4. To become final approval authority for SPETE

1-4. Which of the following systems provides an inventory of test equipment actually located in the fleet?

1. 3M
2. SCLSIS
3. STEED
4. SPETREL

1-5. You can determine if a piece of test equipment has been calibrated by checking which of the following documents?

1. The test equipment logbook
2. A directive from the EMO
3. The completed maintenance action form for the instrument
4. A tag or label attached to the instrument

1-6. What label is used to identify a test instrument that is within tolerance on all parameters?

1. INACTIVE
2. CALIBRATED
3. CALIBRATED—Refer to report
4. ORGANIZATION LEVEL CALIBRATED

1-7. Which of the following conditions warrants the use of one of the SPECIAL CALIBRATION labels and/or tags?

1. Calibration deviates from the usual tolerances
2. The instrument has more than one calibration interval
3. The instrument is too large to move and requires in-place calibration
4. Each of the above

1-8. Under what circumstances should the USER CALIBRATION label be affixed to a piece of test equipment?

1. When a certain calibration schedule is assigned
2. When user calibration is required before, during, or after use
3. When the equipment is out for calibration
4. Each of the above

1-9. Which of the following statements must appear on the CALIBRATION NOT REQUIRED label affixed to an instrument?

1. By what authority the label was affixed
2. The reason no calibration is required
3. The date the label was affixed
4. The METRL page number

1-10. Which of the following labels is attached to an unusable instrument, and may have an additional tag attached?

1. INACTIVE
2. REJECTED
3. CALIBRATED
4. SPECIAL CALIBRATION

1-11. A test instrument that has plug-in modules and/or easily accessible potentiometer or controls which affect the calibration of the instrument should have which of the following labels attached?

1. CALIBRATED
2. CALIBRATION NOT REQUIRED
3. CALIBRATED—REFER TO REPORT
4. CALIBRATION VOID IF SEAL BROKEN

1-12. A replacement part needed by an IMA to repair a piece of test equipment should be ordered by the activity sending the inoperative equipment for repair and calibration. For which of the following reasons is this a good practice?

1. IMAs are not allowed to order repair parts
2. The ship has more repair funds than the IMA
3. The ship is usually able to obtain the parts more quickly
4. It is more likely the technician on the ship will obtain the correct part

1-13. When maintenance personnel are not authorized to make repairs to a piece of test equipment, what items, if any, must be sent to the calibration repair facility with the equipment?

1. The unit and its power cord
2. All the accessories
3. Standards used to calibrate
4. None

1-14. In what type of environment should test equipment be stowed?

1. Dry
2. Dark and damp
3. High humidity and low temperature
4. High temperature and high humidity

1-15. In a stowage space aboard ship, what device(s) should be used to hold the test equipment in place?

1. Set clasp springs
2. Tie down cord
3. Steel straps
4. Stretch seat-belt-type straps

1-16. What system is used to provide for a standardized recall and scheduling of test equipment into calibration facilities?

1. MDCC
2. SCLSIS
3. METER
4. MEASURE

1-17. The meter card is used to provide what information concerning test equipment?

1. Changes
2. Additions
3. Deletions
4. All of the above

1-18. Which of the following actions would be classified as preventive maintenance?

1. Purchasing a new piece of test equipment
2. Isolating an equipment failure to the component level
3. Aligning a servo assembly after a repair
4. Replacing a defective transistor

1-19. Which of the following actions would be regarded as part of corrective maintenance?

1. Routine lubrication of a radar pedestal
2. Mechanical inspection of a bearing assembly in a motor housing
3. Alignment of a servo assembly after a repair
4. Cleaning a filter in accordance with a maintenance requirement card

1-20. Troubleshooting electrical and electronic equipment includes which of the following actions?

1. Fault isolation
2. Equipment repair
3. Equipment performance evaluation
4. Each of the above

1-21. The initial operating conditions of newly installed equipment are referred to as

1. alignment data
2. manufacturer's specifications
3. baseline operating characteristics
4. expected operation characteristics

1-22. When working on energized equipment, you should follow which of the following practices?

1. Work alone
2. Work with both hands
3. Insulate yourself from ground
4. Wear rubber gloves at all times

1-23. When measuring 300 volts or more, you should first take what step?

1. Turn off equipment power
2. Ground all components capable of retaining an electrical charge
3. Short-circuit all components capable of retaining an electrical charge
4. Connect the meter leads to the points to be measured

1-24. Which of the following insulating materials is suitable for covering a grounded metal work bench?

1. Dry insulating material that contains no holes or conductors
2. Dry canvas that has holes in it
3. Dry phenolic material that has conductors embedded in it
4. Damp plywood

1-25. Prior to working on a circuit, you use a shorting probe discharge which of the following types of components?

1. Capacitors only
2. Cathode-ray tubes only
3. Capacitors and cathode-ray tubes
4. Inductors

1-26. If a 28 volt 6 ampere fuse blows, the proper procedure is to replace it with which of the following devices?

1. A larger fuse until the cause of the overload has been determined
2. A fuse of the same voltage and current rating
3. A fuse rated 20 percent lower than the blown fuse
4. A copper strap until the cause of the overload is determined

1-27. Before electrical equipment is overhauled or repaired, what general safety precaution, if any, should be followed?

1. The fuse for the associated circuits should be replaced with circuit breakers
2. The main supply switches should temporarily be shorted out
3. The power switches should be secured open and tagged out of service
4. None

1-28. After work on equipment is complete, who should remove any attached tags?

1. The job inspector
2. The repair crew leader
3. Any member of the repair crew
4. The person who signed and attached the tag

1-29. What is the purpose of the grounding cable attached to the frame of a generator aboard ship?

1. Create a potential difference between the frame and the ship
2. Conduct power to the generator under emergency conditions
3. Ensure equipment is at same ground potential as the ship
4. Break the circuit between the frame and the power supply under emergency conditions

1-30. Which of the following steps should you take to help ensure that metal-case test equipments are safe to use?

1. Energize the instrument to test the ground
2. Ensure the equipment is grounded
3. Insulate the metal case from ground
4. Connect all metal cases to a common ungrounded lead

1-31. Which of the following precautions should you observe when using measuring instruments?

1. Avoid strong magnetic fields
2. Avoid excessive current
3. Avoid mechanical shock
4. Each of the above

1-32. The meter movement in a voltmeter can be easily damaged by excessive current if you do not follow certain procedures. When setting up the meter to read voltage, the RANGE SWITCH should first be set to (a) what relative range and then changed to (b) what relative range?

1. (a) Highest
   (b) Closest to the voltage to be read
2. (a) Highest
   (b) Lower than the voltage to be read
3. (a) Lowest
   (b) Lower than the voltage to be read
4. (a) Lowest
   (b) Closest to the voltage to be read

A.	Place one hand in your pocket or behind your back.
B.	Turn on the power.
C.	Connect the meter ground to the equipment ground.
D.	Place the positive meter lead on the test point; select for positive or negative polarity.

Figure 1A.—Procedures

IN ANSWERING QUESTION 1-33, REFER TO THE PROCEDURES IN FIGURE 1A.

1-33. When you measure voltages less than 300 volts, in what order should you complete the task?

1. A B C D
2. B C D A
3. C A D B
4. D C B A

IN ANSWERING QUESTIONS 1-34 THROUGH 1-37, SELECT FROM THE MEASUREMENT COLUMN BELOW THE ANSWER THAT MATCHES THE SITUATION BEING DESCRIBED.

MEASUREMENT

1. Current
2. Inductance
3. Resistance
4. Capacitance

1-34. This measurement is rarely taken in preventive or corrective maintenance or testing because unsoldering is usually required. Ohm's law is normally applied to determine this value.

1-35. This is a valuable aid in locating faults during corrective maintenance, but cannot be made with power applied. Many technical manuals contain charts that indicate the test points for this measurement.

1-36. This measurement provides an indication of dielectric strength and is used to determine the power factor.

1-37. This measurement is seldom taken during troubleshooting. It can be taken using a bridge or another instrument that is primarily designed to measure another quantity; however, a conversion chart is required.

1-38. The power factor is an indication of the losses caused by which of the following conditions?

1. Excessive voltage
2. Dielectric absorption
3. Current leakage
4. Both 2 and 3 above

1-39. The Wheatstone bridge can be used for precision measurements of which of the following quantities?

1. Voltage
2. Current
3. Impedance
4. Resistance

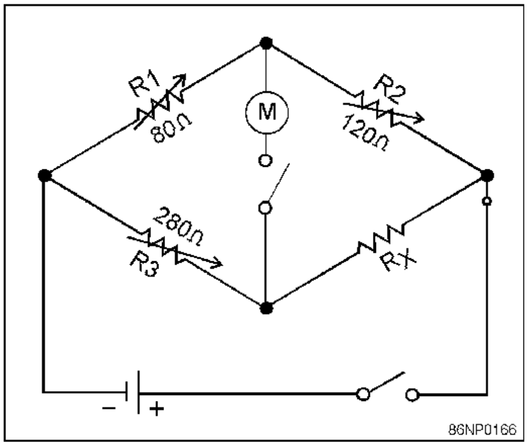

Figure 1B.—Dc resistance bridge.

IN ANSWERING QUESTION 1-40, REFER TO FIGURE 1B.

1-40. In the dc resistance bridge, what is the value of Rx?

1. 42 ohms
2. 400 ohms
3. 420 ohms
4. 4,200 ohms

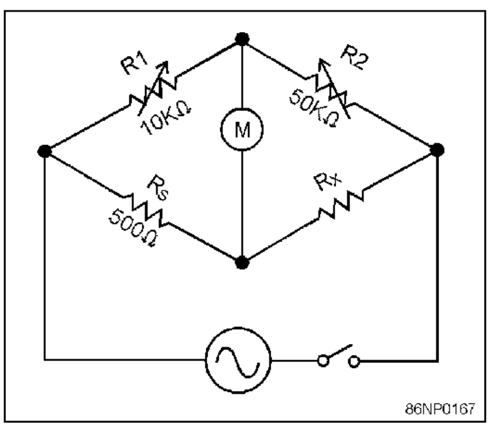

Figure 1C.—Ac resistance bridge.

IN ANSWERING QUESTION 1-41, REFER TO FIGURE 1C.

1-41. In the ac resistance bridge, what is the value of R_x?

1. 25 ohms
2. 250 ohms
3. 2,500 ohms
4. 25,000 ohms

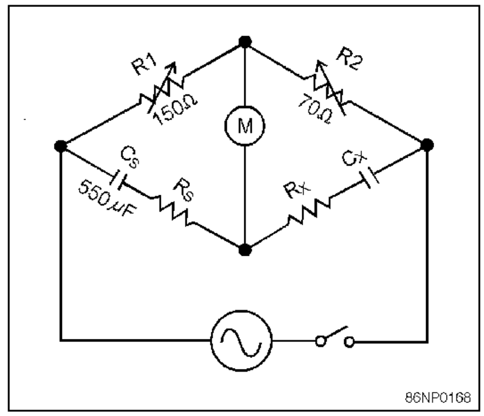

Figure 1D.—Capacitance bridge.

IN ANSWERING QUESTION 1-42, REFER TO FIGURE 1D.

1-42. In the capacitance bridge, what is the value of C_x?

1. 25 microfarads
2. 117 microfarads
3. 256 microfarads
4. 1,178 microfarads

1-43. Dc power is stated in which of the following units?

1. Watts
2. Farads
3. Amperes
4. Henries

1-44. Power in an audio-frequency circuit is stated in which of the following units?

1. Decibels (dB) only
2. Decibels referenced to 1 milliwatt (dBm) only
3. Both dB and dBm
4. Volt units (Vu)

1-45. The bel is a unit of measurement used with voltage, current, or power that compares which of the following circuit values?

1. The input to the output
2. The output to a reference
3. The voltage to power
4. The current to power

1-46. What is the relationship between the values of the bel and the decibel?

1. The bel is twice the decibel
2. The decibel is twice the bel
3. The bel is 1/10 the decibel
4. The decibel is 1/10 the bel

1-47. What is the corresponding increase in dBm each time power is doubled?

1. +1 dB
2. +2 dB
3. +3 dB
4. +10 dB

1-48. A thermocouple ammeter is used to measure which of the following quantities?

1. Rf current
2. Af current
3. Motor current
4. Generator current

1-49. A bolometer is a power meter that measures power in certain frequency ranges. Which of the following methods is/are used by the bolometer to measure power values?

1. A barretter detects increases in power when its resistance increases
2. A thermistor detects increases in power when its resistance decreases
3. Both 1 and 2 above
4. Power is measured directly

THIS SPACE LEFT BLANK INTENTIONALLY.

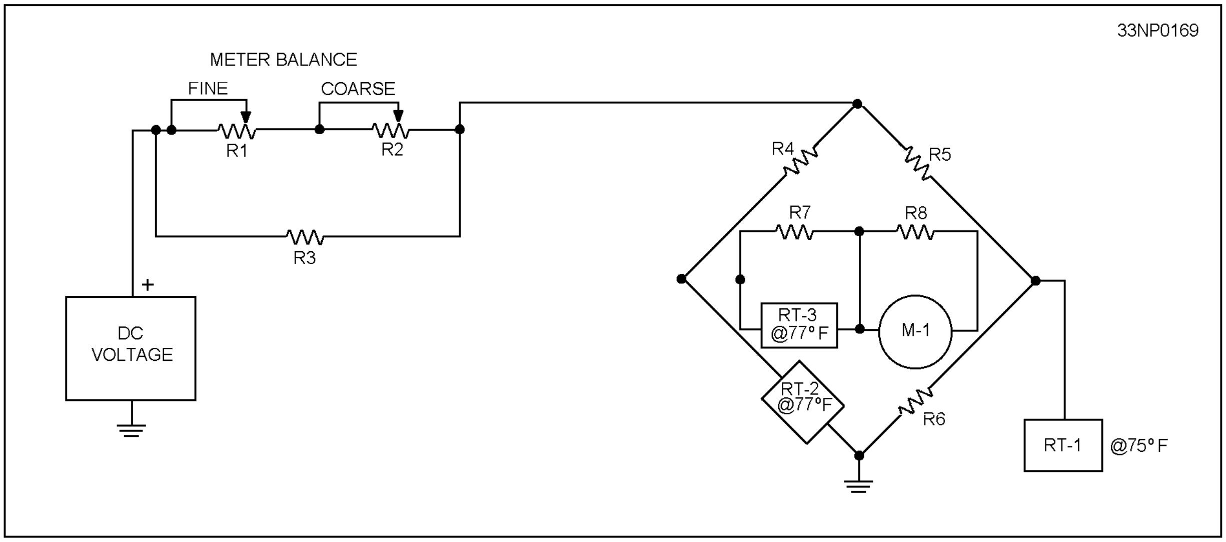

Figure 1E.—Thermistor bridge.

IN ANSWERING QUESTION 1-50, REFER TO FIGURE 1E.

1-50. In the thermistor bridge, what is the purpose of RT-1 and RT-3?

1. To compensate for power used by RT-2
2. To compensate for temperature changes outside the waveguide
3. To control the amount of rf energy applied to RT-2
4. To control the temperature of the waveguide

1-51. To measure shaft rotation rate on an engine, you should use, which, if any, of the following instruments?

1. An ammeter
2. A bolometer
3. A tachometer
4. None of the above

1-52. In the centrifugal tachometer, what component restricts the action on the lower collar that is produced by centrifugal force?

1. The spring
2. The pointer
3. The upper collar
4. The lower collar

1-53. What is the usual speed range (in feet per minute) of a chronometric tachometer?

1. 0 to 30
2. 0 to 300
3. 0 to 3,000
4. 0 to 30,000

1-54. You are measuring the speed of a fan blade by using a stroboscopic tachometer. Setting the flash at a rate 5 rpm SLOWER than the fan speed will cause the blades to appear to move (a) in what relative direction and (b) at what speed?

1. (a) Forward (b) 5 rpm
2. (a) Forward (b) 10 rpm
3. (a) Backward (b) 10 rpm
4. (a) Backward (b) 5 rpm

1-55. The flashing rate of a strobotac is controlled by which of the following circuits?

1. An electronic pulse generator
2. A frequency divider
3. A power supply
4. An amplifier

1-56. The flashing rate of the strobotron tube affects its life expectancy. What is the range (in hours) of life expectancy of the strobotron tube?

1. 15 to 24
2. 25 to 49
3. 50 to 99
4. 100 to 250

1-57. The vibrating-reed frequency meter is a delicate instrument and should not be subjected to vibrations, such as those associated with motor-generators or their associated control panels.

1. True
2. False

1-58. When using the vibrating-reed frequency meter, you take the reading in which of the following ways?

1. Read the digital readout
2. Read the dial indication
3. Read the mechanical setting
4. Read the reed that vibrates the most

1-59. Bandpass filters and band reject filters are tuned circuits that either pass or reject specific frequencies. In these filters, (a) what type offers very high impedance to currents at its resonant frequency, and (b) what type offers a very low impedance to currents at its resonant frequency?

1. (a) Parallel-tuned (b) series-tuned
2. (a) Parallel-tuned (b) parallel-tuned
3. (a) Series-tuned (b) parallel-tuned
4. (a) Series-tuned (b) series-tuned

1-60. When you are zero beating an unknown frequency with a frequency provided by a calibrated, high-precision oscillator within a heterodyne frequency meter, what will be the indication when the two frequencies are matched?

1. One dot of light on the screen will be superimposed on the other
2. One vertical line on the screen will be superimposed on the other
3. The two tones in the headset will achieve the same pitch, at which time a series of clicks will begin
4. The tone in the headset will decrease in pitch and be replaced by clicks that will become slow or nonexistent

THIS SPACE LEFT BLANK INTENTIONALLY.

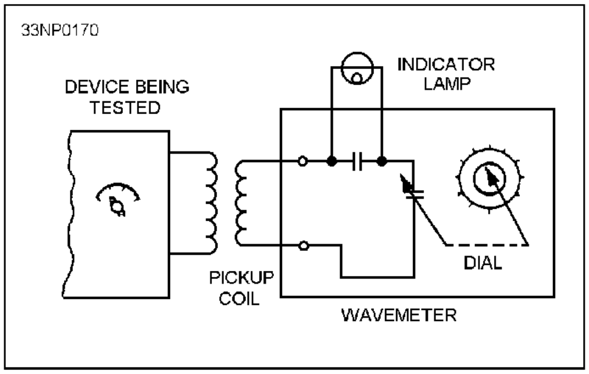

Figure 1F.—Absorption wavemeter circuit.

IN ANSWERING QUESTION 1-61, REFER TO FIGURE 1F.

1-61. When you are using an absorption wavemeter to measure frequency, the greatest accuracy may be obtained by loosely coupling the pickup coil so that the indicator lamp burns (a) with what degree of brilliance (b) under what resonance condition?

1. (a) Maximum brilliance
   (b) when tuned to the resonant frequency
2. (a) Maximum brilliance
   (b) when not tuned to the resonant frequency
3. (a) Dimly
   (b) when not tuned to the resonant frequency
4. (a) Dimly
   (b) when tuned to the resonant frequency

1-62. Which of the following instruments should be used to accurately measure a frequency in the shf range?

1. Absorption wavemeter
2. Resonant, cavity-type wavemeter
3. Resonant, coaxial-line-type wavemeter
4. Both 2 and 3 above

1-63. In a cavity wavemeter, moving the plunger farther into the cavity space causes which of the following changes to (a) the cavity size and (b) the resonant frequency of the cavity?

1. (a) Decrease (b) increase
2. (a) Decrease (b) decrease
3. (a) Increase (b) decrease
4. (a) Increase (b) increase

1-64. For which of the following purposes is a cathode-ray oscilloscope used?

1. To measure microwave energy
2. To visually analyze waveforms
3. To provide frequency modulation
4. To locate stray radio interference

1-65. The synchroscope contains which of the following circuits?

1. Retrace blanking circuit
2. A wide band amplifier
3. A trigger sweep
4. All of the above

THIS SPACE LEFT BLANK INTENTIONALLY.

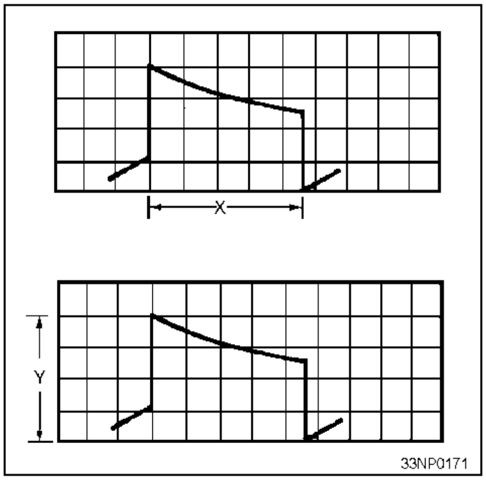

Figure 1G.—Waveform display.

IN ANSWERING QUESTION 1-66, REFER TO FIGURE 1G. MEASUREMENT X REPRESENTS THE HORIZONTAL DISTANCE OF THE WAVEFORM; MEASUREMENT Y REPRESENTS THE VERTICAL DISTANCE OF THE WAVEFORM.

1-66. In the figure, (a) time is represented by what measurement, and (b) amplitude is represented by what measurement?

1. (a) X (b) X
2. (a) X (b) Y
3. (a) Y (b) Y
4. (a) Y (b) X

1-67. An oscilloscope measures voltage and displays waveforms. It can be used to measure currents, temperatures, speeds, and accelerations if they are first converted to

1. heat
2. light
3. voltages
4. pressures

1-68. The spectrum analyzer is used to display which of the following quantities?

1. Amplitude within each frequency component in a circuit
2. Proportions of power within each frequency component in the spectrum
3. Frequencies produced in a circuit
4. Each of the above

1-69. While testing a semiconductor diode, you determine that the forward resistance value is 60 ohms. You should consider the diode good if the backward resistance is at least which of the following values?

1. 6 ohms
2. 60 ohms
3. 600 ohms
4. 6,000 ohms

1-70. When you are using an oscilloscope to test a crystal diode, what is shown by (a) the vertical deflection and (b) the horizontal deflection?

1. (a) Crystal current
   (b) voltage applied to the diode
2. (a) Crystal current
   (b) power developed in the diode
3. (a) Crystal voltage
   (b) power developed in the diode
4. (a) Crystal voltage
   (b) voltage applied to the diode

1-71. When you are using the oscilloscope to test the Zener diode, what is represented by (a) vertical deflection and (b) horizontal deflection?

1. (a) Zener current
   (b) Zener power
2. (a) Zener current
   (b) applied voltage
3. (a) Applied voltage
   (b) Zener power
4. (a) Applied voltage
   (b) Zener current

1-72. When troubleshooting transistorized circuits, you should first check the condition of which of the following circuits?

1. Counters
2. Amplifiers
3. Oscillators
4. Power supplies

1-73. Which of the following instruments is used to check transistors for collector leakage current and current gain?

1. Ohmmeter
2. Voltmeter
3. Wheatstone bridge
4. Semiconductor test set

1-74. When making base-to-emitter bias voltage checks on a transistor, you should read which of the following voltage ranges?

1. 5 to 20 microvolts
2. 50 to 200 millivolts
3. 5 to 20 volts
4. 50 to 200 volts

1-75. When making resistance measurements on a transistor with an ohmmeter, you should allow what maximum current in the transistor?

1. milliampere
2. milliampere
3. microampere
4. microampere

ASSIGNMENT 2

Textbook assignment: Chapter 3, "Basic Meters," pages 3-1 through 3-34. Chapter 4, "Common Test Equipment," pages 4-1 through 4-10.

2-1. What are the two basic components of a galvanometer?

1. A movable permanent magnet and a movable coil
2. A stationary permanent magnet and a stationary coil
3. A stationary permanent magnet and a movable coil
4. A stationary coil and a movable coil

2-2. The coil in a galvanometer rotates to allow measurement of current. Which of the following actions causes this reaction?

1. Current flowing in opposite directions through two coils
2. Tension of the hairspring and the magnetism produced by the permanent magnet
3. Magnetism produced by current flowing in the movable coil and the tension of the hairspring
4. Magnetism of the permanent magnet and magnetism produced by current in the movable coil

2-3. In a galvanometer, the phosphor bronze ribbon serves which of the following functions?

1. Provides a conduction path from the circuit being tested to the coil
2. Restores the coil to its original position
3. Allows the coil to twist
4. Each of the above

2-4. In galvanometers, which of the following components is/are used to indicate the value of the current being measured?

1. Pointer
2. Light and mirror
3. Both 1 and 2 above
4. Digital readout

2-5. The phosphor bronze ribbon in the galvanometer serves the same purpose as what component in the D'Arsonval meter?

1. Hairspring
2. Movable coil
3. Fixed iron core
4. Permanent magnet

2-6. The direction in which the D'Arsonval meter pointer deflects depends on what characteristic of the current applied to the coil?

1. Phase
2. Polarity
3. Frequency
4. Amplitude

2-7. The D'Arsonval meter movement is damped to prevent which of the following conditions?

1. Oscillating readings
2. Inconsistent readings
3. Consistently low readings
4. Consistently high readings

2-8. The weight of the rotating coil assembly and the type of bearings used in the D'Arsonval meter are factors that affect which of the following characteristics of the meter?

1. The accuracy and the linearity of the meter scales
2. The amount of restraining force required of the hairspring
3. The maximum current that can be measured
4. The sensitivity

2-9. For a meter to read linearly, its face is divided into equal segments. What meter feature makes this possible?

1. The curved poles of the permanent magnet
2. The jeweled bearings in the meter movement
3. An additional coil placed in the meter circuit
4. A long, lightweight meter pointer

2-10. What is the purpose of a shunt in a dc ammeter?

1. To decrease the sensitivity of the meter
2. To increase the linearity of the meter movement
3. To increase the current range of the meter
4. To decrease meter damping

2-11. A particular D'Arsonval meter has a full-scale current reading of 1 milliampere. A full-scale reading of 100 milliamperes may be achieved by using which of the following components?

1. A low-value resistance placed in series with the meter terminals
2. A high-value resistance placed in series with the meter terminals
3. A movable coil composed of large-diameter wire
4. A resistance of proper value placed in parallel with the meter terminals

2-12. To measure 10 milliamperes on a 1-milliampere D'Arsonval meter movement, a shunt resistance is added that will carry 9 milliamperes. What maximum value of current will pass through the meter movement?

1. 1 milliampere
2. 3 milliamperes
3. 6 milliamperes
4. 9 milliamperes

2-13. In a meter movement, shunt strips with a zero temperature coefficient are used instead of regular carbon resistance for which of the following reasons?

1. Because regular carbon resistances cause interfering magnetic fields
2. Because regular carbon resistances are too large to be used
3. Because regular carbon resistances are not able to handle the current changes
4. Because regular carbon resistances are affected by heat due to current and cause readings to vary

2-14. One consideration in choosing the value of a meter shunt resistance is that the meter readings should be in the midscale range. Which of the following factors is another consideration?

1. Meter switching is easier for midscale deflection
2. Meter shielding against magnetic interference is greatest near midscale
3. Minimum loading effect will be experienced near midscale
4. The meter is protected from unexpected surge currents

2-15. For which of the following current ranges would you likely use a meter that contains internal shunt?

1. 1 to 10 amperes
2. 11 to 30 amperes
3. 31 to 50 amperes
4. All of the above

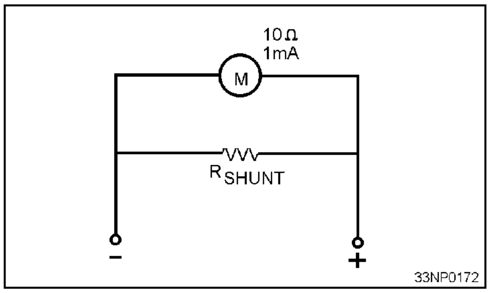

Figure 2A.—Shunt ammeter.

IN ANSWERING QUESTIONS 2-16 THROUGH 2-19, REFER TO FIGURE 2A. THE METER IN THE CIRCUIT IS DESIGNED FOR MAXIMUM OF .001 AMPERE AND HAS AN INTERNAL RESISTANCE OF 10 OHMS. YOU ARE FIGURING THE SHUNT RESISTANCE NECESSARY TO MEASURE 5 AMPERES.

2-16. What is the voltage drop across the meter coil?

1. .01 volt
2. .005 volt
3. .0001 volt
4. .0005 volt

2-17. What is the voltage drop across the shunt resistance?

1. .01 volt
2. .005 volt
3. .0001 volt
4. .0005 volt

2-18. When the meter is deflected full scale and is measuring 5 amperes, what is the maximum value of current flow through the shunt resistance?

1. 0.010 ampere
2. 0.490 ampere
3. 4.999 ampere
4. 5 amperes

2-19. What is the approximate value of the shunt resistance?

1. .001 ohm
2. .002 ohm
3. .003 ohm
4. .004 ohm

2-20. Simple range-switching arrangements for current meters are less satisfactory than other methods of range switching for which of the following reasons?

1. Meter damage can occur when line current momentarily flows through the meter
2. Resistance in the contacts may cause inaccurate readings
3. Both 1 and 2 above
4. Resistor damage may occur

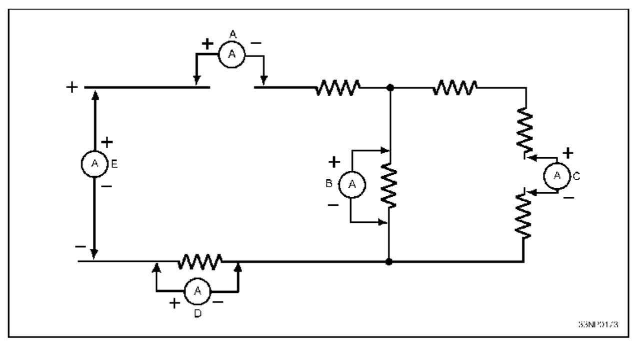

Figure 2B.—Ammeter connections.

IN ANSWERING QUESTION 2-21, REFER TO FIGURE 2B.

2-21. In the figure, five ammeters are connected to the circuit resistors. Of those five, which one(s) is/are connected correctly?

1. E only
2. A and E
3. A and C
4. A, B, and D

2-22. What will be the probable result of connecting an ammeter (or milliammeter) in PARALLEL with a source of voltage or a circuit component?

1. A burned-out meter that will provide no useful readings
2. A higher than normal meter reading
3. A lower than normal meter reading
4. A normal meter reading

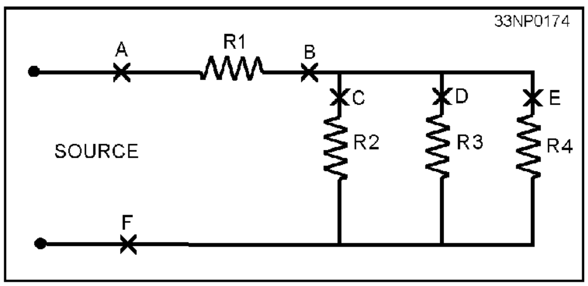

Figure 2C.—Series-parallel circuit.

IN ANSWERING QUESTIONS 2-23 AND 2-24, REFER TO FIGURE 2C.

2-23. To measure total circuit current, you should break the circuit to connect an ammeter at which of the following points?

1. A only
2. B or C
3. C, D, or E
4. A, B, or F

2-24. To measure the current flow through resistor R2 only, you should break which of the following points to connect the ammeter?

1. A
2. B
3. C
4. F

2-25. Meter sensitivity is determined by the amount of current required by the ammeter coil to provide full-scale deflection of the pointer. An ammeter coil requiring which of the following current values provides the greatest sensitivity?

1. 1 milliampere
2. 10 milliamperes
3. 100 microamperes
4. 500 microamperes

2-26. Circuits in which low-sensitivity ammeters are used are said to be "loaded." Which of the following statements describes the cause of circuit loading?

1. The ammeter circuit draws NO current from the circuit being tested
2. The ammeter circuit draws MINIMUM current from the circuit being tested
3. The ammeter circuit draws EXCESSIVE current from the circuit being tested
4. The ammeter circuit INDUCES current into the circuit being tested

2-27. In which of the following electronic circuits does the use of a meter with low sensitivity have the greatest loading effect?

1. High-power circuits
2. Low-current circuits
3. High-current circuits
4. High-voltage circuits

2-28. A basic D'Arsonval meter is used to measure voltage by connecting its meter coil to (a) what type of component in (b) what circuit arrangement?

1. (a) Multiplier resistor
   (b) series
2. (a) Multiplier resistor
   (b) parallel
3. (a) Capacitor
   (b) parallel
4. (a) Capacitor
   (b) series

2-29. In a voltmeter, the D'Arsonval meter movement is caused to move by what electrical action?

1. Power
2. Voltage
3. Current
4. Conductance

2-30. In a voltmeter, the meter scale is calibrated in which of the following categories?

1. Power
2. Voltage
3. Current
4. Conductance

2-31. To figure the total value of series resistance needed to extend the range of a voltmeter, you need to know the value of current to cause full-scale deflection of the meter and what other value?

1. Minimum applied voltage
2. Maximum applied voltage
3. Maximum applied current
4. Minimum applied current

2-32. Your voltmeter has four ranges: 1V, 10V, 100V, and 1,000V. To measure an unknown voltage in an amplifier, you should first select what range?

1. 1 V
2. 10 V
3. 100 V
4. 1,000 V

2-33. Which of the following types of circuits are most affected by the loading effect of voltmeters?

1. Low-voltage
2. Low-resistance
3. High-resistance
4. High-current

2-34. A voltmeter with a 10-microampere meter movement has a sensitivity of how many maximum ohms per volt?

1. 1,000
2. 10,000
3. 100,000
4. 1,000,000

2-35. A megger is widely used for which of the following purposes?

1. To make voltage checks
2. To make continuity checks
3. To measure insulation resistance
4. To measure resistance of components

2-36. Before you can take an accurate resistance measurement with an ohmmeter, what meter adjustment must you complete?

1. Zero voltage
2. Zero resistance
3. Maximum voltage
4. Maximum resistance

2-37. When the leads of an ohmmeter are placed across a resistor, that resistor adds to the internal series coil resistance of the meter. The pointer is deflected to the left of its full-scale position, giving a reading in ohms for the resistor being tested. Which of the following reasons explains why the pointer moves to less than full-scale?

1. Because voltage in the meter circuit is greater than full-scale voltage
2. Because current in the meter circuit is greater than full-scale current
3. Because current in the meter circuit is less than full-scale current
4. Because voltage in the meter circuit is less than full-scale current

2-38. With the ohmmeter range switch set at R X 100, the pointer of the meter indicates 850. What is the actual value of the resistor?

1. 8.5 kilohms
2. 85 kilohms
3. 850 kilohms
4. 8.5 megohms

RANGE SCALE		RESISTOR VALUE
A.	R×1	50 kilohms
B.	R×10	500 kilohms
C.	R×100	5 megohms

Figure 2D.—Range scales and resistance values.

IN ANSWERING QUESTION 2-39, REFER TO FIGURE 2D.

2-39. You are measuring resistors using range settings as shown in the figure. What condition listed in the figure, if any, will cause the greatest amount of current to move through the ohmmeter coil circuit?

1. A
2. B
3. C
4. None; they all allow the same amount of current

2-40. Which of the following locations on the meter scale provides the most accurate reading for resistance?

1. To the far left side of the scale
2. To the far right side of the scale
3. Halfway between the left side and center of the scale
4. Near the center of the scale

2-41. An ordinary ohmmeter is unsuitable for measuring insulation resistance for which of the following reasons?

1. Voltage is present in the conductors attached to the insulating materials being measured
2. Insulation resistance values are too great for an ohmmeter to measure
3. Ohmmeter current will damage insulation material
4. The accuracy of an ohmmeter is too low to measure insulation resistance

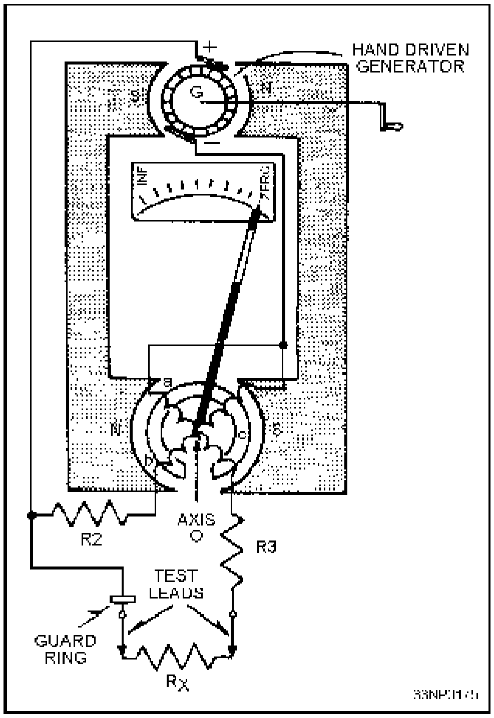

Figure 2E.—Megger circuit.

IN ANSWERING QUESTION 2-42, REFER TO FIGURE 2E.

2-42. In the megger circuit, what component prevents leakage current from affecting ohmmeter measurements?

1. Guard ring
2. Generator
3. Resistor R3
4. Coil

2-43. When a megger is used to measure an unknown resistance, what circuit action causes the pointer to come to rest at the correct resistance value?

1. The current flow in coil A
2. The current flow in coil B
3. The interaction between the currents in coils A and B
4. The interaction between the restraining springs of the meter and the current in coil A

2-44. A megger uses high voltage to check the insulation leakage in the megohm range. What is the source of this voltage?

1. Batteries
2. The ship's ac power
3. The ship's dc power
4. A hand-driven dc generator

2-45. Meggers with which of the following maximum voltage ratings are commonly found in the fleet?

1. 500 volts
2. 700 volts
3. 1,000 volts
4. 2,500 volts

2-46. When a megger is used to measure the resistance of an electrical cable, what does a reading of infinity indicate?

1. The meter is faulty
2. The cable is shorted
3. The cable is grounded
4. The resistance is too large to measure

2-47. A megger is prevented from exceeding its rated output voltage by which of the following actions?

1. Battery discharge limits the voltage
2. Tension in the cable
3. Friction clutch slippage
4. Current leaks through internal insulation

2-48. When the crank of a 500-volt megger is rotated faster than its designed rate, what maximum output voltage does it produce?

1. 100 volts
2. 500 volts
3. 520 volts
4. 550 volts

2-49. The galvanometer-type meter movement differs from the electrodynamometer meter movement in that the electrodynamometer type uses which of the following components to produce the magnetic field?

1. Two sets of coils
2. Two permanent magnets
3. One fixed and one movable coil
4. One movable coil and one permanent magnet

2-50. The fixed coils in the electrodynamometer-type movement are wound with heavy wire to enable the instrument to measure which of the following values?

1. Rf currents
2. High voltage
3. Large currents
4. High resistance

2-51. An advantage that the electrodynamometer has over the standard galvanometer in measuring ac is that the electrodynamometer requires

1. no rectifying device
2. a less complicated rectifying device
3. less current to obtain a full-scale deflection
4. fewer multiplier resistors to cover the measurement range

THIS SPACE LEFT BLANK INTENTIONALLY.

2-52. When power is being measured with a wattmeter, why is it important to strictly observe the safe rating limits for current and voltage?

1. Because the meter pointer will likely hit against the upper limit of the dial and be damaged
2. Because the pointer does not give an indication to alert the user when the internal coils are overloaded
3. Because a false reading may be obtained
4. Because the meter pointer will likely hit against the lower limit of the dial and be damaged

2-53. The reading of a wattmeter is dependent upon which of the following circuit characteristics?

1. Current
2. Voltage
3. Power factor
4. All of the above

2-54. A continuity test is performed on a piece of electronic equipment to discover what kind of fault?

1. High voltage
2. Low voltage
3. Open circuits
4. Changes in component values

2-55. Which of the following meters is recommended for circuit continuity tests?

1. A megger
2. An ammeter
3. A voltmeter
4. An ohmmeter

2-56. When preparing to use an ohmmeter to test a circuit for grounds, you should first take which of the following actions?

1. Energize the circuit
2. Disconnect all intentional grounds
3. Measure the circuit voltage at the power source
4. Connect all intentional grounds

2-57. When preparing to use a voltmeter to measure voltage in a circuit, you should first take which of the following actions?

1. Set the meter to the lowest voltage range
2. Remove the suspected component from the circuit
3. Check the voltage from the power source to ensure it is correct
4. Check the current flow through the circuit with an ammeter

2-58. It is important to set a voltmeter on its highest range scale before taking a measurement for which of the following reasons?

1. To protect the meter from damage
2. To decrease the effects of input impedance
3. To increase the sensitivity of the measurement
4. To protect the equipment being tested from damage

THIS SPACE LEFT BLANK INTENTIONALLY.

2-59. An accurate measurement of a particular resistor in a set of parallel resistors may be obtained by performing which of the following procedural steps?

1. Connecting the ohmmeter leads across the resistor while in place
2. Disconnecting the resistor from the set before taking the measurement
3. Grounding the resistance set before taking the measurement
4. Using the highest ohmmeter range

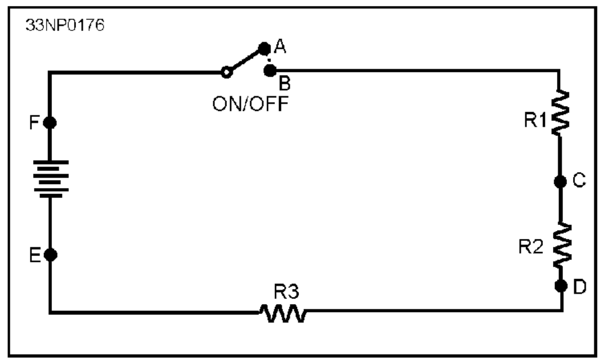

Figure 2F.—Circuit.

IN ANSWERING QUESTION 2-60, REFER TO FIGURE 2F.

2-60. To measure R2 with an ohmmeter, (a) in what position should the ON/OFF switch be placed, and (b) where should the test probes be placed?

1. (a) Off (b) at B and C
2. (a) Off (b) at C and D
3. (a) On (b) at C and D
4. (a) On (b) at B and C

2-61. In what arrangement is an ammeter connected to a circuit?

1. In series
2. In parallel
3. In a series-parallel combination
4. In a parallel-series combination

2-62. When you are measuring voltage using a voltmeter, where should you stand to view the meter reading?

1. To the right of the meter only
2. To the left of the meter only
3. To the right or left of the meter, depending on your handedness
4. Directly in front of the meter

2-63. A multimeter is used to measure which of the following electrical properties?

1. Voltage
2. Current
3. Resistance
4. Each of the above

2-64. Which of the following characteristics is an advantage of a volt-ohm meter?

1. It replaces three separate meters
2. There are no calibrations to be made
3. It is the most accurate meter available
4. It cannot be damaged

A. SELECT RANGE SCALE
B. SHORT ENDS OF PROBES TOGETHER
C. ZERO THE METER USING THE ZERO ADJUST CONTROL

Figure 2G.—Zeroadjust steps.

IN ANSWERING QUESTION 2-65, REFER TO FIGURE 2G.

2-65. Before you measure resistance, it is important that you calibrate (zero) the ohmmeter. In what order should the actions in the figure be performed?

1. A, B, and C
2. B, C, and A
3. C, B, and A
4. B, A, and C

2-66. On an ohmmeter, which of the following switches allows selection of ac or dc readings?

1. ZERO-OHMS
2. FUNCTION
3. RANGE
4. RESET

2-67. Which of the following actions MUST be taken before resistance measurements are made in a circuit?

1. All semiconductor devices must be removed from the circuit
2. Expected measurements must be recorded
3. The circuit must be completely de-energized
4. The high range of the ohmmeter must be selected

2-68. The power required to operate a basic ohmmeter comes from which of the following sources?

1. Batteries
2. An ac power supply
3. Both 1 and 2 above
4. A hand crank

THIS SPACE LEFT BLANK INTENTIONALLY.

	POINTER LOCATION
1.	EXTREME RIGHT
2.	EXTREME LEFT
3.	MIDSCALE

Figure 2H.—Ohmeter pointer location

IN ANSWERING QUESTIONS 2-69 THROUGH 2-72, REFER TO FIGURE 2H AND SELECT THE OHMMETER POINTER LOCATION THAT RESULTS FROM THE CONDITION GIVEN.

2-69. Both test leads are touching the metal chassis of a piece of equipment.

2-70. The test leads are shorted together.

2-71. The test leads are separated from each other and not touching anything else.

2-72. An accurate resistance reading is being made.

2-73. The function of the ZERO OHM control on a multimeter is to compensate for which of the following conditions?

1. Meter battery aging
2. Large values of resistance in the circuit to be measured
3. Inter-electrode capacitance in the circuit to be measured
4. Stray voltages in the circuit under test

2-74. When using a multimeter to measure an output voltage, you should ensure that the dc voltage component does not exceed what maximum voltage?

1. 100 volts
2. 200 volts
3. 300 volts
4. 400 volts

2-75. When measuring unknown currents, you should determine the range scale that is appropriate in what way?

1. Start with the expected scale
2. Start with the lowest scale and work up
3. Start with the highest scale and work down
4. Use the highest scale only

ASSIGNMENT 3

Textbook assignment: Chapter 4, "Common Test Equipment," pages 4-11 through 4-28. Chapter 5, "Special Application Test Equipment," pages 5-1 through 5-40. Chapter 6, "The Oscilloscope and Spectrum Analyzer," pages 6-1 through 6-46.

3-1. Compared to the VOM, the electronic digital multimeter has which of the following advantages?

1. It has higher input impedance
2. It can be read directly without using a scale
3. It has little or no loading effect on the circuit under test
4. All of the above

3-2. Digital multimeters can be divided into three functional sections: (1) signal conditioning, (2) analog-to-digital, and what third section?

1. Display
2. Amplifier
3. Oscillator
4. Power supply

3-3. What section in the electronic multimeter decodes the digital (binary) information from the a/d converter section?

1. Display
2. Analog ic
3. Digital ic
4. Signal conditioning

3-4. The ac/dc differential voltmeter is capable of performing which of the following functions?

1. Voltage readings as an electronic voltmeter
2. Voltage readings as a precision potentiometer
3. Voltage variation readings about some known value
4. Each of the above

3-5. In a differential voltmeter, an adjustable reference voltage can be produced in increments as small as how many microvolts?

1. 1
2. 2
3. 5
4. 10

3-6. When you are taking ac or dc voltage readings, the differential voltmeter will not load the circuit under test.

1. True
2. False

3-7. Which of the following transistor parameters are measured with the transistor tester?

1. Collector leakage and cutoff current
2. Collector leakage and maximum power dissipation
3. Collector leakage and current gain
4. Emitter leakage and power gain

3-8. When you are disconnecting a transistor from the transistor tester, in what position should the POLARITY switch be placed?

1. ON
2. OFF
3. PNP
4. NPN

3-9. When you are testing a transistor with a transistor tester, for the reading to have ±15 percent accuracy, the resistance from emitter to base must be what minimum value?

1. 100 ohms
2. 200 ohms
3. 300 ohms
4. 50 ohms

3-10. When you are testing an in-circuit diode with the transistor tester, the meter pointer deflects below the midscale point. What does this indicate?

1. The diode is normal
2. The diode is faulty
3. The circuit impedance is 8 ohms
4. The POLARITY switch is in the PNP position

3-11. The RCL bridge measures an unknown resistance by balancing the resistance value of the unknown component with that of known components inside the test set. What type of circuit is used in this method of measurement?

1. O'Neill bridge
2. Wheatstone bridge
3. Colpitts oscillator
4. D'Arsonval movement

3-12. The RCL bridge is used to measure which of the following quantities?

1. Resistance, capacitance, and inductance
2. Capacitor quality
3. The turns ratio of transformers
4. Each of the above

3-13. To make an inductance measurement on the model 250DE, you must first adjust the DET GAIN control to what position?

1. 1
2. 2
3. 3
4. 4

3-14. The direct-measuring power meter is used for which of the following types of measurements?

1. Incident power
2. Reflected power
3. Both 1 and 2 above
4. Average power

3-15. When you are selecting forward or reverse power measurements, what component(s) of the rf wattmeter is/are restricted to a 180°; rotation range?

1. The coupler-detector
2. The POWER RANGE knob
3. The u-type connector
4. Both 2 and 3 above

3-16. Of the following available rf wattmeter power ranges, which one should you select when measuring an unknown power?

1. 10 watts
2. 100 watts
3. 500 watts
4. 1000 watts

THIS SPACE LEFT BLANK INTENTIONALLY.

IN ANSWERING QUESTIONS 3-17 AND 3-18, ASSUME THAT YOU HAVE OBTAINED THE FOLLOWING RF POWER MEASUREMENTS:

— INCIDENT POWER, 144 WATTS
— REFLECTED POWER, 1 WATT

3-17. What is the approximate standing wave ratio?

1. .85 to 1
2. 1 to 1
3. .08 to 1
4. 1.2 to 1

3-18. What total amount of power is absorbed by the load?

1. 1 watt
2. 13 watts
3. 143 watts
4. 173 watts

3-19. To take power readings, you connect an in-line rf power meter in what configuration in the transmission line?

1. Series
2. Parallel
3. Series-parallel
4. Horizontal

3-20. Which of the following test instruments produces a standard of measurement of ac energy for testing electronics equipment?

1. Power meter
2. Oscilloscope
3. Signal generator
4. Frequency counter

3-21. Signal generators are equipped with attenuators for which of the following purposes?

1. To regulate the output frequency
2. To regulate the output signal level
3. To determine the modulating frequency
4. To set the level of internal modulation

3-22. Which of the following signal generators should you select to test audio equipment?

1. Af signal generator
2. Fm signal generator
3. Rf signal generator
4. Video signal generator

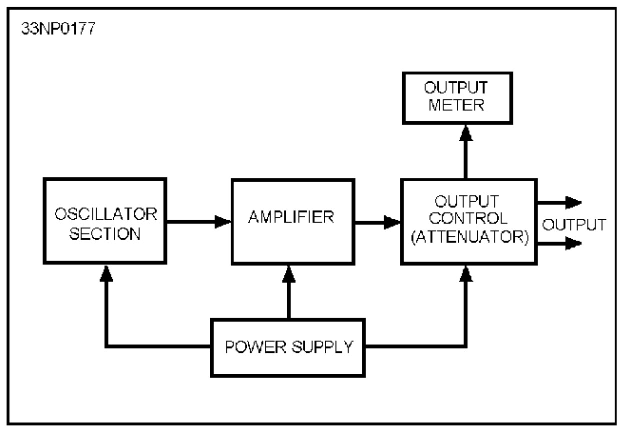

Figure 3A.—Af signal generator block diagram.

IN ANSWERING QUESTION 3-23, REFER TO FIGURE 3A.

3-23. What section of the signal generator regulates the output to the equipment under test?

1. The amplifier
2. The attenuator
3. The oscillator
4. The output meter

3-24. Typical rf signal generators use which of the following methods for modulation?

1. Internal modulation
2. External modulation
3. Both 1 and 2 above
4. Power supply modulation

3-25. The modulating circuit in an rf signal generator serves which of the following purposes?

1. It produces an fm signal that can be superimposed on the rf signal
2. It produces a video signal that can be superimposed on the rf signal
3. It produces an audio signal that can be superimposed on the rf signal
4. Both 2 and 3 above

3-26. The output level meter of a signal generator reads 0. 10 with the attenuator set to 080. 0. What is the actual output in microvolts?

1. 00.08
2. 00.80
3. 08.00
4. 80.00

3-27. Frequency counters serve which of the following purposes?

1. Measure voltage in a circuit
2. Measure frequencies in a circuit
3. Produce voltages to test a circuit
4. Produce frequencies to power a circuit

3-28. In which of the following ways is a logic probe useful to a technician?

1. It detects steady logic levels
2. It detects a train of logic levels
3. Both 1 and 2 above
4. It displays the shape of high-speed transients

3-29. In logic probes, which of the following devices is used as an indicator?

1. A dial
2. An LED
3. A scale
4. A pointer

3-30. The Tracker 2000 is used to isolate defective components on de-energized circuits only.

1. True
2. False

3-31. The VERT control adjustment controls what position of the signal on the CRT display?

1. Horizontal
2. Vertical
3. Trace rotation left
4. Trace rotation right

3-32. The axes of the CRT display on the Tracker 2000 are divided into what number of quadrants?

1. 1
2. 2
3. 3
4. 4

3-33. Quadrant 2 on the Tracker 2000 CRT is used to display what signal information?

1. Positive voltage negative current
2. Positive voltage and positive current
3. Negative voltage and negative current
4. Negative voltage and positive current

3-34. When you are adjusting the level control on the Tracker 2000, the peak of each pulse will be from 0 volts to what maximum voltage level?

1. 1
2. 5
3. 3
4. 9

3-35. The medium 1 range on the Tracker 2000 is designed to test resistance values between what (a) minimum and (b) maximum values?

1. (a) 5 ohms (b) 1 kilohm
2. (a) 50 ohms (b) 10 kilohms
3. (a) 500 ohms (b) 100 kilohms
4. (a) 50 kilohms (b) 10 megohms

3-36. What is the principal use of the oscilloscope?

1. To measure microwave energy
2. To visually examine waveforms
3. To measure in-line power supply currents
4. To locate sources of radio interference

3-37. Cathode-ray tubes used in oscilloscopes contain which of the following components?

1. An electron gun
2. A deflection system
3. A fluorescent screen
4. All of the above

3-38. In a basic oscilloscope, what is the purpose of the deflection system?

1. To filter harmonic frequencies
2. To deflect harmonic frequencies
3. To position the beam on the screen
4. To deflect synchronous side effects

3-39. If the electron beam is left in one position on the CRT for long periods, damage is likely to occur to what component(s)?

1. Illuminating coating
2. Deflection plates
3. Signal generator
4. Electron gun

3-40. Of the following factors, which one(s) control(s) the angle of deflection of the electron beam in the CRT?

1. Difference of potential between plates
2. Length of deflection field
3. Beam acceleration
4. All of the above

3-41. In an oscilloscope, which of the following waveform characteristics are represented by (a) vertical deflection and (b) horizontal deflection?

1. (a) Amplitude (b) frequency
2. (a) Power (b) amplitude
3. (a) Power (b) frequency
4. (a) Time (b) amplitude

3-42. In oscilloscopes using electrostatic CRTs, what type of signal is used to produce horizontal beam movement?

1. Dc
2. Sine wave
3. Square wave
4. Sawtooth wave

3-43. The length of time the phosphor coating on the CRT remains bright after the electron beam is removed depends on which of the following characteristics?

1. Persistence of the coating
2. Amplitude of the applied signal
3. Frequency of the applied signal
4. Synchronization frequency of the oscilloscope

3-44. An oscilloscope that can display two vertical input signals at the same time is said to be what type?

1. Two-function
2. Dual-trace
3. Single-function
4. Single-trace

3-45. The FOCUS control on the front of an oscilloscope is used to adjust what characteristic on the CRT display?

1. Beam size
2. Beam location
3. Trace position
4. Beam brilliance

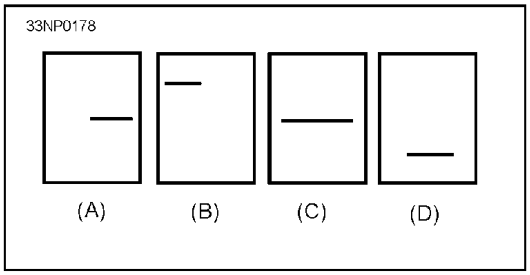

Figure 3B.—CRT traces.

IN ANSWERING QUESTIONS 3-46 THROUGH 3-48, REFER TO FIGURE 3B.

3-46. What trace in the figure should you correct by adjusting ONLY the HORIZONTAL POSITION control?

1. A
2. B
3. C
4. D

3-47. What trace in the figure should you correct by adjusting ONLY the VERTICAL POSITION control?

1. A
2. B
3. C
4. D

3-48. In the figure, what trace would be corrected by adjusting both the HORIZONTAL POSITION and VERTICAL POSITION controls?

1. A
2. B
3. C
4. D

3-49. What is the purpose of the deflection amplifiers in a cathode-ray oscilloscope?

1. To isolate the input signal from the vertical deflection plates
2. To increase the amplitude of the signal applied to the vertical deflection plates
3. To eliminate distortion of the CRT beam
4. To position the beam on the CRT

3-50. What control on the front panel of an oscilloscope limits the input signal amplitude and allows the oscilloscope to be used with a wide range of signals?

1. TIME/CM
2. TIME BASE
3. ATTENUATOR
4. TRIGGER

3-51. What is the purpose of a variable potentiometer mounted on the VOLTS/DIV control of an oscilloscope?

1. To provide definite step control of the input signal
2. To provide fine control of the input signal
3. To provide fine control of the output signal
4. To provide definite step control of the output signal

3-52. The time base of an oscilloscope is variable to enable the instrument to

1. measure low- and high-amplitude signal voltages
2. operate over a wide range of input frequencies
3. make accurate measurements of signal amplitudes
4. accurately position the presentation on the CRT

3-53. The triggered oscilloscope has which of the following advantages over a basic oscilloscope?

1. Better low-voltage input- handling capability
2. Lower distortion of input signal
3. Both 1 and 2 above
4. Improved presentation stability

3-54. The TRIGGER and LEVEL controls are used to synchronize the sweep generator with what signal?

1. Input
2. Output
3. Vertical deflection rate
4. Horizontal deflection rate

3-55. The setting of what control establishes the amplitude point of the input waveform at which the displayed sweep will begin?

1. TRIGGER LEVEL
2. TRIGGER SLOPE
3. AMPLITUDE
4. A delayed by B

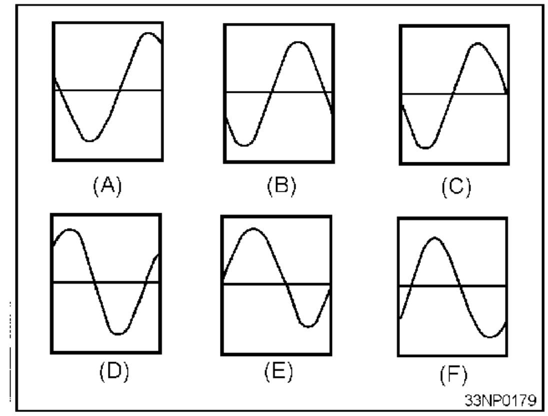

Figure 3C.—Oscilloscope displays.

IN ANSWERING QUESTIONS 3-56 THROUGH 3-60, REFER TO FIGURE 3C. SELECT THE OSCILLOSCOPE DISPLAY THAT CORRESPONDS TO THE SETTING OF THE TRIGGER LEVEL AND SLOPE CONTROLS IN THE QUESTIONS.

3-56. TRIGGER LEVEL set to zero; SLOPE set to negative.

1. A
2. C
3. E
4. F

3-57. TRIGGER LEVEL set to positive; SLOPE set to negative.

1. A
2. D
3. E
4. F

3-58. TRIGGER LEVEL set to negative; SLOPE set to positive.

1. B
2. C
3. D
4. F

3-59. TRIGGER LEVEL set to negative; SLOPE set to negative.

1. A
2. B
3. C
4. D

3-60. TRIGGER LEVEL set to positive; SLOPE set to positive.

1. A
2. C
3. D
4. F

3-61. Which of the following electrical quantities can be measured using an oscilloscope?

1. Current
2. Frequency
3. Inductance
4. Capacitance

3-62. What effect does sweep frequency that is higher than the incoming signal frequency have on the displayed signal?

1. It produces a jittery view of the incoming signal
2. It produces a multiple view of the incoming signal
3. It produces an exact view of the incoming signal
4. It produces less than a complete view of the incoming signal

3-63. A dual-trace oscilloscope differs from a dual-beam oscilloscope in that the dual-trace device uses (a) what number of electron beams and (b) what number of channels?

1. (a) 1 (b) 1
2. (a) 2 (b) 1
3. (a) 2 (b) 2
4. (a) 1 (b) 2

3-64. What two modes are used to obtain the dual trace on an oscilloscope?

1. Chop and beam
2. Chop and alternate
3. Slow sweep and beam
4. Alternate and slow sweep

3-65. Of the following oscilloscope switch settings, which ones will provide desirable (a) slow sweep speeds and (b) high sweep speeds?

1. (a) CHOP
   (b) ALTERNATE
2. (a) SLOW SWEEP
   (b) ALTERNATE
3. (a) BEAM SWITCH
   (b) SLOW SWEEP
4. (a) ALTERNATE
   (b) CHOP

3-66. In a dual-trace oscilloscope, the gate that controls both sweeps is controlled by a multivibrator that operates at which of the following maximum frequencies?

1. 50 kHz
2. 100 kHz
3. 500 kHz
4. 1,200 kHz

3-67. What is the basic internal configuration of the typical dual-trace oscilloscope?

1. One gun assembly with two vertical channels
2. Two gun assemblies with two horizontal channels
3. One gun assembly with two vertical and horizontal channels
4. Two gun assemblies with one vertical and horizontal channel

3-68. The horizontal sweep channels of the dual-trace oscilloscopes have which of the following time base circuit configurations?

1. One time base circuit
2. Two interdependent time base circuits
3. Two independently controlled time base circuits
4. Variations of all the above configurations

3-69. Which of the following types of probes are commonly available for use with the oscilloscope?

1. Current
2. One-to-one
3. Attenuation
4. All of the above

3-70. On the spectrum analyzer, what information can be found on the (a) x axis and (b) y axis?

1. (a) Voltage (b) current
2. (a) Frequency (b) amplitude
3. (a) Amplitude (b) frequency
4. (a) Current (b) voltage

3-71. The intensity knob on the spectrum analyzer controls what display function(s)?

1. Focus
2. Brightness of the CRT trace
3. Brightness of the readout display
4. Both 2 and 3 above

3-72. On the spectrum analyzer, the RF input jack is used to accept what maximum frequency input signals?

1. 21 GHz or below
2. 21 GHz or above
3. 31 GHz or below
4. 31 GHz or above

3-73. The POSITION control on the spectrum analyzer is used to adjust which of the following CRT display features?

1. Vertical position only
2. Horizontal position only
3. Vertical and horizontal position
4. Beam focus

PREFACE

By enrolling in this self-study course, you have demonstrated a desire to improve yourself and the Navy. Remember, however, this self-study course is only one part of the total Navy training program. Practical experience, schools, selected reading, and your desire to succeed are also necessary to successfully round out a fully meaningful training program.

COURSE OVERVIEW: To introduce the student to the subject of Radio-Frequency Communications Principles who needs such a background in accomplishing daily work and/or in preparing for further study.

THE COURSE: This self-study course is organized into subject matter areas, each containing learning objectives to help you determine what you should learn along with text and illustrations to help you understand the information. The subject matter reflects day-to-day requirements and experiences of personnel in the rating or skill area. It also reflects guidance provided by Enlisted Community Managers (ECMs) and other senior personnel, technical references, instructions, etc., and either the occupational or naval standards, which are listed in the *Manual of Navy Enlisted Manpower Personnel Classifications and Occupational Standards*, NAVPERS 18068.

THE QUESTIONS: The questions that appear in this course are designed to help you understand the material in the text.

VALUE: In completing this course, you will improve your military and professional knowledge. Importantly, it can also help you study for the Navy-wide advancement in rate examination. If you are studying and discover a reference in the text to another publication for further information, look it up.

Sailor’s Creed

“I am a United States Sailor.

I will support and defend the Constitution of the United States of America and I will obey the orders of those appointed over me.

I represent the fighting spirit of the Navy and those who have gone before me to defend freedom and democracy around the world.

I proudly serve my country’s Navy combat team with honor, courage and commitment.

I am committed to excellence and the fair treatment of all.”

TABLE OF CONTENTS

CREDITS

The figures listed below and included in this edition of NEETS, Module 17, *Radio-Frequency Communications Principles*, were provided by Martin Marietta DSCS III Program. Permission to use these illustrations is gratefully acknowledged.

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7*, Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

INSTRUCTIONS FOR TAKING THE COURSE

ASSIGNMENTS

The text pages that you are to study are listed at the beginning of each assignment. Study these pages carefully before attempting to answer the questions. Pay close attention to tables and illustrations and read the learning objectives. The learning objectives state what you should be able to do after studying the material. Answering the questions correctly helps you accomplish the objectives.

SELECTING YOUR ANSWERS

Read each question carefully, then select the BEST answer. You may refer freely to the text. The answers must be the result of your own work and decisions. You are prohibited from referring to or copying the answers of others and from giving answers to anyone else taking the course.

SUBMITTING YOUR ASSIGNMENTS

To have your assignments graded, you must be enrolled in the course with the Nonresident Training Course Administration Branch at the Naval Education and Training Professional Development and Technology Center (NETPDTC). Following enrollment, there are two ways of having your assignments graded: (1) use the Internet to submit your assignments as you complete them, or (2) send all the assignments at one time by mail to NETPDTC.

Grading on the Internet: Advantages to Internet grading are:

- you may submit your answers as soon as you complete an assignment, and
- you get your results faster; usually by the next working day (approximately 24 hours).

In addition to receiving grade results for each assignment, you will receive course completion confirmation once you have completed all the assignments. To submit your assignment answers via the Internet, go to:

https://courses.cnet.navy.mil

COMPLETION TIME

Courses must be completed within 12 months from the date of enrollment. This includes time required to resubmit failed assignments.

PASS/FAIL ASSIGNMENT PROCEDURES

If your overall course score is 3.2 or higher, you will pass the course and will not be required to resubmit assignments. Once your assignments have been graded you will receive course completion confirmation.

If you receive less than a 3.2 on any assignment and your overall course score is below 3.2, you will be given the opportunity to resubmit failed assignments. **You may resubmit failed assignments only once.** Internet students will receive notification when they have failed an assignment—they may then resubmit failed assignments on the web site. Internet students may view and print results for failed assignments from the web site. Students who submit by mail will receive a failing result letter and a new answer sheet for resubmission of each failed assignment.

COMPLETION CONFIRMATION

After successfully completing this course, you will receive a letter of completion.

STUDENT FEEDBACK QUESTIONS

We value your suggestions, questions, and criticisms on our courses. If you would like to communicate with us regarding this course, we encourage you, if possible, to use e-mail.

NAVAL RESERVE RETIREMENT CREDIT

If you are a member of the Naval Reserve, you may earn retirement points for successfully completing this course, if authorized under current directives governing retirement of Naval Reserve personnel. For Naval Reserve retirement, this course is evaluated at 7 points. (Refer to *Administrative Procedures for Naval Reservists on Inactive Duty,* BUPERSINST 1001.39, for more information about retirement points.)

THIS PAGE LEFT BLANK INTENTIONALLY.

CHAPTER 1

INTRODUCTION TO RADIO-FREQUENCY COMMUNICATIONS

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions are based on the objectives. By successfully completing the OCC/ECC, you indicate that you have met the objectives and have learned the information. The learning objectives are listed below.

Upon completion of this chapter, you will be able to:

1. Define electrical telecommunications.
2. Describe the use of radiotelegraph, radiotelephone, teletypewriter, and facsimile.
3. Define and describe the interrelationships of the system, set, group, unit, assembly, subassembly, part, and reference designations.
4. State the frequency ranges of the various frequency bands and describe the most common uses of those bands by the Navy.
5. Describe a strategic communications link.
6. Describe a tactical communications link.
7. Describe the five basic communications modes of operation.
8. Describe a switched communications network.
9. Describe the purpose of the two Navy-only networks.

INTRODUCTION TO NAVAL TELECOMMUNICATIONS

When the wireless (radiotelegraph) was invented, the Navy saw a possible use for it. It could be used for communications from shore stations to ships along the coast. In 1899, the first official naval radio message was sent from ship to shore. It only traveled a distance of 20 miles but that was a start. The next advance was in 1916 when the Navy first used radiotelephone between ships. Three years later the first airborne radio was used to communicate with a ground station. In the early years, communications was not the best because of poor tuning techniques. Receivers often did not pick up the signal. This problem was almost eliminated in 1931 when the first superheterodyne receivers were installed in the fleet. In 1944, another important event took place. The first successful radio teletypewriter transmissions between ships were completed. The first successful use of radiophoto (facsimile) occurred in 1945 with the transmission of the surrender document signing that ended World War II. Naval communications has grown tremendously in size and complexity since then.

The fleets of our modern Navy travel faster and are spread over greater areas of ocean than any seagoing force of the past. Commanders and their subordinates throughout the Department of the Navy use the facilities of naval communications as a primary method of communicating.

Naval communications relies on top performance from all of its assigned personnel. Reliable, secure, and timely transmission and receipt of information, based on wartime requirements, is the ultimate goal.

Previous modules have discussed electronic components or circuitry in individual units. In this chapter we will tie up some loose ends for you and discuss radio-frequency communications.

We will cover the considerations involved in receiving or transmitting a radio-frequency signal between two or more geographic locations. Let's start by defining telecommunications.

TELECOMMUNICATIONS refers to communications over a distance and includes any transmission, emission, or reception of signs, signals, writings, images, or sounds. Intelligence produced by visual means, oral means, wire, radio, or other electromagnetic systems are also included. Electrical, visual, and sound telecommunications are all used in the Navy. In this chapter we will talk only about electrical types of telecommunications.

ELECTRICAL

The types of electrical communications are radio and wire. Radio uses electromagnetic waves to transmit and receive intelligence. The waves are not guided by a physical path between sender and receiver. Wire uses conductors to carry these waves. Radio is the most important method the Navy has of communicating between widely separated forces. The transmission methods we will be discussing are radiotelegraph, radiotelephone, teletypewriter, and facsimile.

Radiotelegraph

Radiotelegraph transmissions are referred to as continuous wave (cw) telegraphy. Cw is a manual or automatic system of transmitting signals using a wave of radio-frequency (rf) energy. The radio operator separates a continuously transmitted wave into dots and dashes based on the Morse code. This is accomplished by opening and closing a telegraphic hand key.

Radiotelegraphy was the first means of radio communications that had military and commercial importance. Radiotelegraph still is used as a means of communication to, from, and among widely separated units of the Navy.

Relative slow speed of transmission and the requirement for experienced operators are the major disadvantages of radiotelegraph. The main advantage is reliability. A thinking person at both sending and receiving stations provides a capability of being understood not present in automated systems.

Radiotelephone

Radiotelephone is one of the most useful military communications methods. Because of its directness, convenience, and ease of operation, radiotelephone is used by ships, aircraft, and shore stations. It has many applications and is used for ship-to-shore, shore-to-ship, ship-to-ship, air-to-ship, ship-to-air, air-to-ground, and ground-to-air communications. Modern means of operation make it possible to communicate around the world by radiotelephone. One of the most important uses of radiotelephone is short-range tactical communications. This method permits tactical commanders to communicate directly with other ships. Little delay results while a message is prepared for transmission, and acknowledgments can be returned instantly. Radiotelephone equipment for tactical use usually is operated on frequencies that are high enough to have line-of-sight characteristics; that is, the waves do not follow the curvature of the earth. As you know, these characteristics limit the usual range of radiotelephone from 20 to 25 miles. This is important because it reduces the chances of the enemy intercepting the message. Radiotelephone procedures can be learned easily by persons with no other training in communications.

Radiotelephone has some disadvantages. You may find transmissions unreadable because of static, enemy interference, or high local noise level caused by shouts, gunfire, and bomb or shell bursts. Wave propagation characteristics of radiotelephone frequencies sometimes are unpredictable, and tactical transmissions may be heard from great distances. Most radiotelephone messages are in plain language, and if information is to be kept from the enemy, users must keep their messages short, stick to the proper procedures, and be careful of what they say.

Q1. What are the two types of electrical communications?

Q2. What is the main advantage of radiotelegraph communications?

Q3. Why is radiotelephone one of the most useful methods of military communications?

Q4. What are the disadvantages of radiotelephone communications?

Teletypewriter

Teletypewriter (tty) signals may be transmitted by either landline (wire), cable, or radio. The landline tty is used both by the military services and by commercial communication companies. The Navy uses radio teletypewriter (rtty) mainly for high-speed automatic communications across ocean areas. The tty unit is equipped with a keyboard similar to a typewriter. When the operator presses a key, a sequence of signals is transmitted. At receiving stations, the signals are fed into terminal equipment that translates the sequences of signals into letters, figures, and symbols and types the messages automatically.

The rtty mode of transmission and reception is rapidly becoming more efficient and reliable for communications between ships and from ship-to-shore. Ships copy what is known as "fleet broadcast" messages on rtty. The speed at which message traffic is transmitted on rtty circuits depends on the equipment in use. Normal speed of operation is 100 words per minute, but it may be faster or slower. You may find high-speed equipment, capable of printing a line or even a page at a time, in some communications centers. The use of rtty has brought about a considerable savings in manpower.

Facsimile

Facsimile (fax) is the process used to transmit photographs, charts, and other graphic information electronically. The image to be transmitted is scanned by a photoelectric cell. Electrical changes in the cell output, corresponding to the light and dark areas being scanned, are transmitted to the receiver. At the receiver, the signal operates a recorder that reproduces the picture. The fax signals may be transmitted either by landline or radio.

Facsimile transmissions suffer distortion from all of the common sources of interference experienced with ordinary radiotelegraph and radio teletypewriter. Certain characteristics of TIF transmission make it less susceptible to complete loss of intelligence. For example, picture quality will be downgraded by any noise bursts, since facsimile recording is a continuous recording of signals coming from a receiver. However, because the machine scans material at the rate of about 100 lines per inch, each line is only 1/100th of an inch high. So you can see, if a noise burst interfers with the signal, it will distort a line only 1/100th of an inch high, leaving the image still readable. Under similar circumstances on a conventional rtty circuit, such distortion could cause a portion of the page copy to be unreadable.

Facsimile transmission is not intended to be a replacement for teletypewriter and other general methods of transmission. It is an important communications supplement and provides a means of handling certain types of graphic and pictorial intelligence by swift communications methods. It is widely used by the Navy weather information services and ship and station weather centers to obtain the latest weather maps. Chances are the photo you saw in the newspaper was transmitted by facsimile.

Q5. What is the main use of a radio teletypewriter?

Q6. What is facsimile?

SYSTEM INTRODUCTION

Until recently, RADIO COMMUNICATIONS brought to mind either telegraphy (cw), voice (AM), or possibly radio teletypewriter (rtty) communications. Today, radio communications has become a highly sophisticated field of electronics. Even small Navy ships have the capability to "come up" on the commonly used ship-to-ship, ship-to-air, and ship-to-shore communications circuits. These circuit operations are accomplished through the use of compatible and flexible communications systems.

A communications system (as you will see later in this chapter) consists of two or more equipment sets (sets will be explained a little later). Communications systems follow the system subdivision shown in figure 1-1. Systems are arranged and interconnected to perform a circuit operation that cannot be performed by any single piece of equipment. Navy communications systems vary from the simple to the very complex, depending upon the circuit operations involved. Because a Navy ship must use every inch of available space, the communications equipment may be spread over several portions of the ship, for instance, receivers in one location, transmitters in another, and terminal equipment in another. The equipment must be installed in such a manner that it is flexible and can be used interchangeably with other installed communications equipment. Consequently, large numbers of sets which make up the shipboard communications system are installed and are capable of operating separately and simultaneously. Flexibility is provided through a complex arrangement of interconnections. These allow the physically separated equipment to be selectively switched (patched) by you into different circuit configurations.

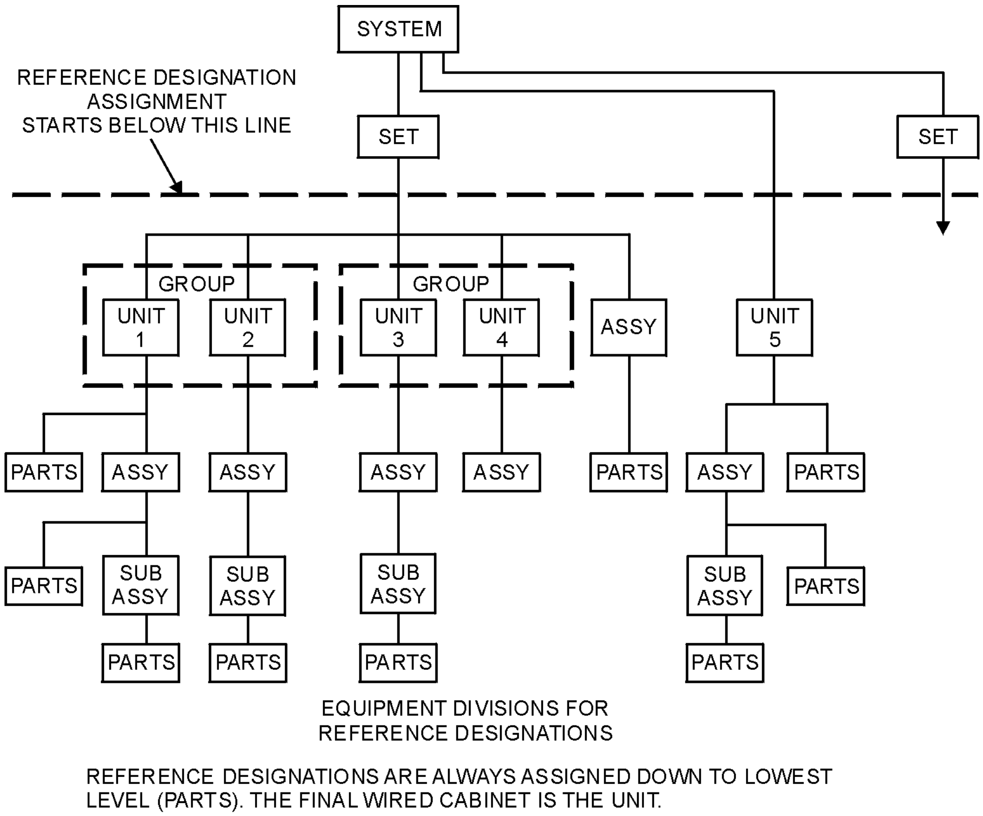

Figure 1-1.—System subdivision.

As naval electronics has grown in capability and complexity, an orderly plan of equipment designations has been adopted. The largest designator, *system*, describes equipment that work together for a specific function. For example, the radar system of a ship includes every item of electronics equipment used in or with a radar on board that ship. The smallest designator, *part*, describes one single piece, such as a bolt or a resistor.

System

A SYSTEM is a combination of *sets, units, assemblies, subassemblies*, and *parts* joined together to perform a specific operational function or several functions. Examples are communications systems, radar systems, or navigation systems. You will find the majority of troubleshooting done in the Navy is system oriented. Figure 1-2 is a pictorial view of a typical communications system containing the components necessary for transmission and reception of voice, telegraphy, and teletypewriter signals. Figure 1-3 is a block diagram of the same communications system with the arrows showing the direction of signal flow.

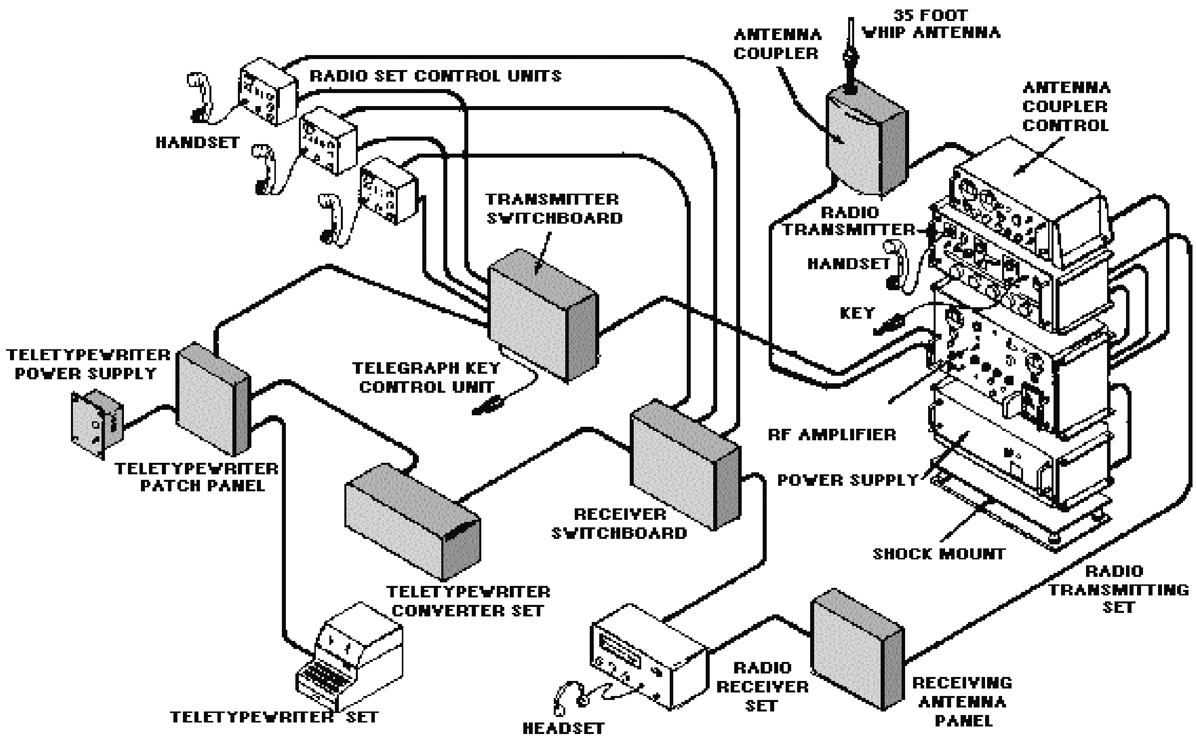

Figure 1-2.—Communications system pictorial view.

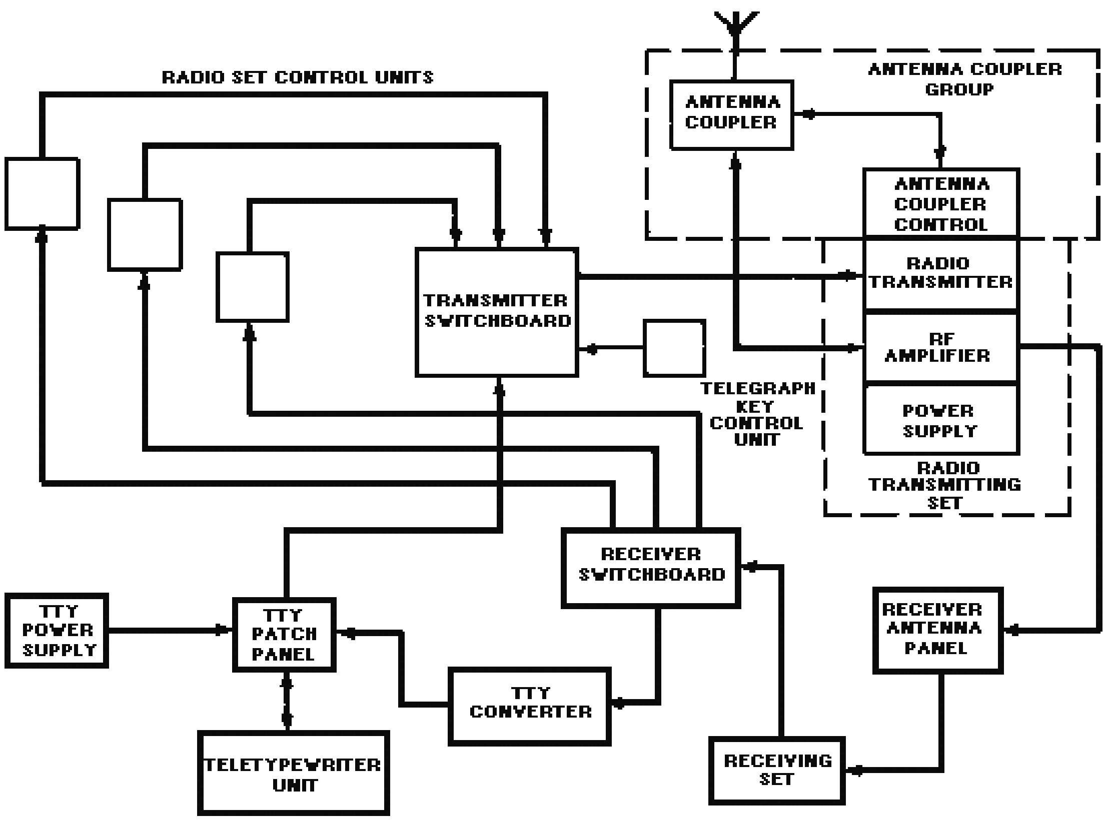

Figure 1-3.—Communications system block diagram.

Set

A SET consists of a unit or units and the assemblies, subassemblies, and parts connected or associated together to perform a specific function. A good example of this is a radio receiving set or a radio transmitting set.

Figure 1-4 is a block diagram of a radio transmitting set. It consists of a radio-frequency amplifier unit (1), a radio transmitter unit (2), a power supply unit (3), and an antenna coupler group.

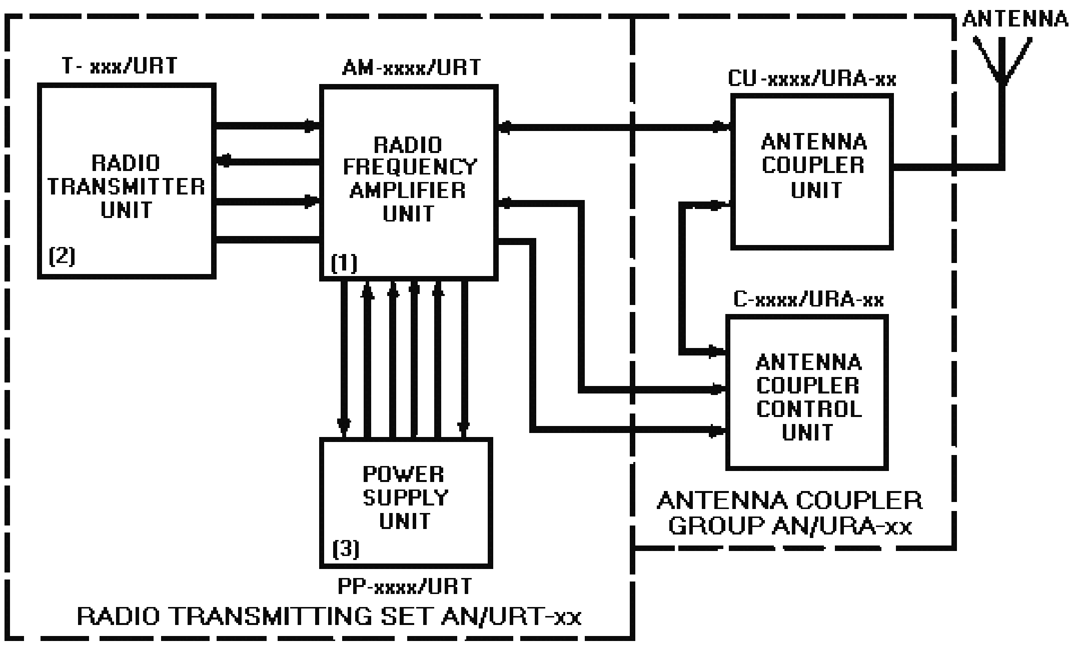

Figure 1-4.—Radio transmitting set.

Group

A GROUP is a collection of units, assemblies, subassemblies, and parts. It is a subdivision of a set or system, but it is not capable of performing a complete operational function. The coupler requires power and signals from the radiofrequency amplifier unit for operation. An example is the antenna coupler group in figure 1-4.

Unit

A UNIT is an assembly or any combination of parts, subassemblies, and assemblies mounted together. A unit is normally capable of independent operation in a variety of situations. An example of a unit might be a power supply.

Assembly

An ASSEMBLY is a number of parts or subassemblies, or any combination thereof, joined together to perform a specific function. Figure 1-5 shows a unit (2) with its six assemblies. The assembly (A6) contains six subassemblies.

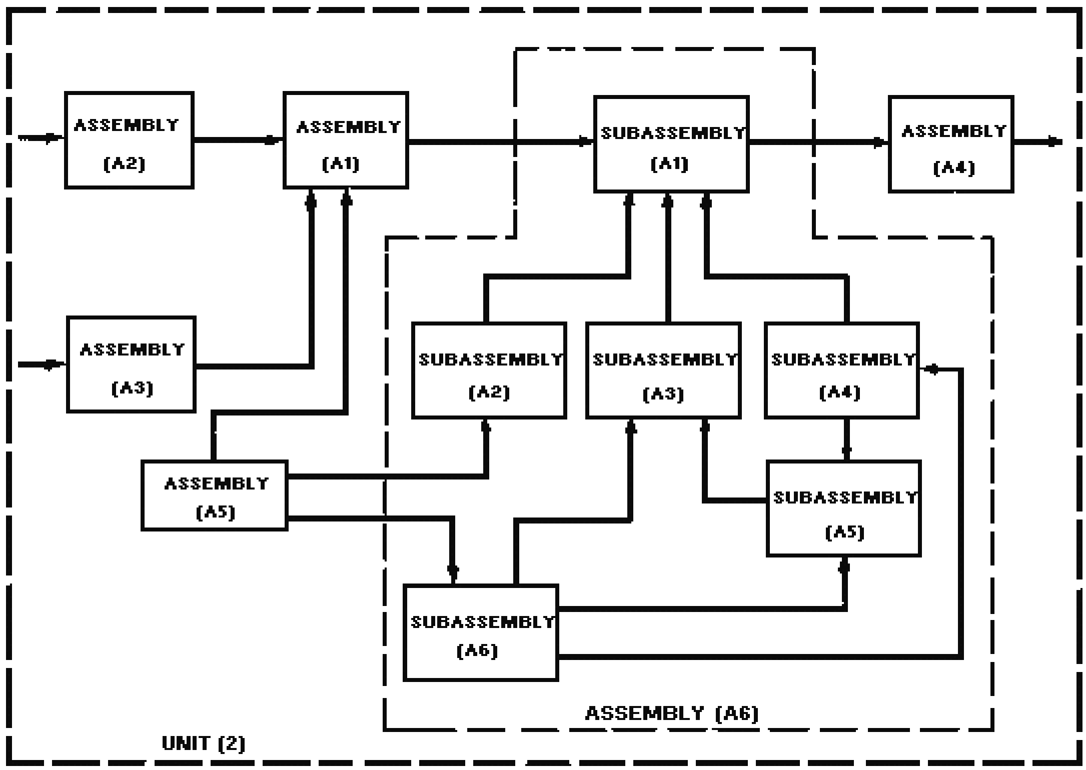

Figure 1-5.—Unit and assembly.

Subassembly

A SUBASSEMBLY consists of two or more parts that form a portion of an assembly or a unit. It is replaceable as a whole, but some of its parts are individually replaceable.

The distinction between an assembly and a subassembly is not always exact; an assembly in one application may be a subassembly in another when it forms a portion of an assembly. Figure 1-6 shows a printed circuit board subassembly and some of the parts which may be mounted on it.

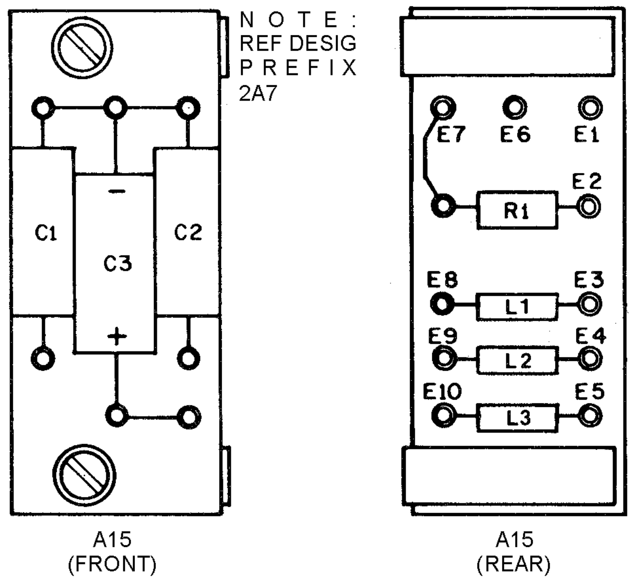

Figure 1-6.—Typical subassembly.

Part

A PART is one component or two or more components joined together. A part is not normally subject to disassembly without destruction. Resistors, capacitors, and transistors are examples of parts.

Reference Designations.

Reference designations consist of letters, numbers, or both and are used for identification purposes. Reference designations can be used in several different ways. One important way you will use them is as a cross-reference for locating supply stock numbers. When you know the reference designator, ordering the correct replacement for a failed component is easy. You will also use them frequently in corrective and preventive maintenance. Reference designators will help you to locate test points and adjustments; they will also help you to move back and forth between various technical manuals, schematics, tables, or other references.

Each set within a system is assigned an AN nomenclature. Each unit, assembly, subassembly, and part of a set has an assigned reference designation. Systems, sets, and groups have no reference designation. The unit is the highest level assigned a reference designator.

Each unit is assigned an identifying number. This number begins with the number 1 and runs consecutively for all units of a system or a set. Let's look back at the radio transmitting set AN/URT-xx with the unit numbers 1, 2, 3 on figure 1-4. You should note that these units may also have an AN nomenclature, such as T-xxx/URT. The T indicates the equipment is a transmitter. The xxx would be replaced by 3 digits that indicate the model number.

By examining the reference designator of a unit, you will be able to determine in which group, if any, the unit is contained. Let's look at a complete reference designator for a unit. A good example for us to break down is the reference designator 2A2A3C1 on figure 1-7.

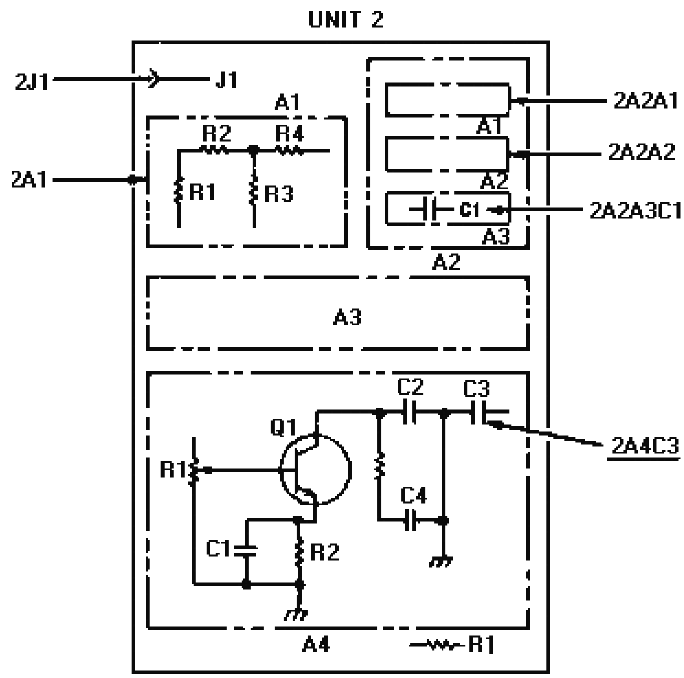

Figure 1-7.—Reference designations.

The first indicator, 2, is numeric and refers to unit 2. The next indicator, A2, is alphanumeric and refers to assembly A2. The next indicator, A3, is also alphanumeric and refers to subassembly A3. The last indicator, C1, like the two previous, is alphanumeric and refers to the part C1. We have just located capacitor C1 on subassembly A3, which is on assembly A2, which is in unit 2 of the equipment.

Reference designations may be expanded or reduced to as many levels as required to identify a particular part. Let's look at a couple of examples on our figure. The designator 2J1 identifies jack J1, which is mounted directly on unit 2. The designator 2A4C3 identifies capacitor C3, which is on assembly A4 in unit 2.

Partial reference designations are used to save space on diagrams. For example, refer back to figure 1-6. Partial reference designations are placed near the parts on subassembly A15, and a note indicates the reference designation prefix is added. Capacitor C3 on subassembly A15 has the complete reference designation 2A7A15C3.

Q7. A system is subdivided into what levels?

Q8. In the example 1A6CR3, what is the assembly designator?

NAVY FREQUENCY BAND USE

Rapid growth in the quantity and complexity of communications equipment and increased worldwide international requirements for radio frequencies have placed large demands upon the radio-frequency spectrum. These demands include military and civilian applications such as communications, location and ranging, identification, standard time and frequency transmission, and industrial, medical, and other scientific uses.

The allocation, assignment, and protection of all frequencies used by any component of the Navy are the responsibility of Commander Naval Telecommunications Command (COMNAVTELCOM). Table

1-1 shows the radio-frequency spectrum broken down into nine bands used by the military. Propagation of radio waves varies widely at different frequencies. Frequencies and equipment are chosen to meet the communications application desired. We will discuss the radio-frequency spectrum in the following paragraphs.

Table 1-1.—Radio-Frequency Spectrum

FREQUENCY	DESCRIPTION
30 GHZ - 300 GHz	extremely high frequency (EHF)
3 GHZ - 30 GHz	super high frequency (SHF)
300 MHZ - 3 GHz	ultra high frequency (UHF)
30 MHZ - 300 MHz	very high frequency (VHF)
3 MHZ - 30 MHz	high frequency (HF)
300 KHZ - 3 MHz	medium frequency (MF)
30 KHZ - 300 KHz	low frequency (LF)
3 KHZ - 30 KHz	very low frequency (VLF)
300 HZ - 3 KHz	voice frequency
Up to 300 Hz	extremely low frequency (ELF)

Extremely Low-Frequency Communications

The purpose of the EXTREMELY LOW-FREQUENCY (elf) communications system is to send short "phonetic letter spelled out" (PLSO) messages from operating authorities in the continental United States (CONUS) to submarines operating at normal mission speeds and depths. Elf has the ability to penetrate ocean depths to several hundred feet with little signal loss. This ability allows submarines to be operated well below the immediate surface and enhances submarine survivability by making detection more difficult.

This is a one-way communications system from the operating authority to submarines at sea. The large size of elf transmitters and antennas makes elf transmission from submarines impractical.

Very-Low-Frequency Communications

The communications commitments of the Navy now cover the face of the earth. New sea frontiers to the north have opened a four-million-square-mile, ice-covered ocean of strategic importance. Our Navy must maintain control of the operating forces in an ever expanding coverage area. This additional area requires changes in communications capacity, range, and reliability. Additional needs have been particularly great in the North Atlantic and the newly opened Arctic Ocean. High-frequency circuits are too unreliable in these areas because of local atmospheric disturbances.

VERY-LOW-FREQUENCY (vlf) transmissions provide a highly reliable path for communications in these northern latitudes as well as over and under all oceans and seas of the world. At present, practically all Navy vlf transmitters are used for fleet communications or navigation. The vlf transmission is normally considered a broadcast, that is, one-way transmission, no reply required. The vlf transmitter normally transmits single-channel rtty.

Vlf is currently used for communications to large numbers of satellites and as a backup to shortwave communications blacked out by nuclear activity. Our Navy depends on vlf for crucial communications during hostilities.

Secondary applications of the vlf range include worldwide transmission of standard frequency and time signals. Standard frequency and time signals with high accuracy over long distances have become increasingly important in many fields of science. It is essential for tracking space vehicles, worldwide clock synchronization and oscillator calibration, international comparisons of atomic frequency standards, radio navigational aids, astronomy, national standardizing laboratories, and communications systems.

A vlf broadcast of standard time and frequency signals has more than adequate precision for the operation of synchronous cryptographic devices, decoding devices, and single-sideband transmissions.

Low-Frequency Communications

The LOW-FREQUENCY (lf) band occupies only a very small part of the radio-frequency spectrum. This small band of frequencies has been used for communications since the advent of radio.

Low-frequency transmitting installations are characterized by their large physical size and by their high construction and maintenance costs. Another disadvantage is low-frequency signal reception being seriously hampered by atmospheric noise, particularly at low geographical latitudes. Over the years, propagation factors peculiar to the low-frequency band have resulted in their continued use for radio communications. Low-frequency waves are not so seriously affected during periods of ionospheric disturbance when communications at the high frequencies are disrupted. Because of this, the Navy has a particular interest in the application of low frequencies at northern latitudes.

The Navy's requirement to provide the best possible communications to the fleet requires operation on all frequency bands. Constant research is being done to improve existing capabilities and to use new systems and developments as they become operationally reliable.

In the past, the fleet broadcast system provided ships at sea with low-frequency communications via cw telegraph transmissions. As technology advanced, the system was converted to single-channel radio teletypewriter transmission. Today If communications is used to provide eight channels of frequency-division multiplex rtty traffic on each transmission of the fleet multichannel broadcast system.

Medium-Frequency Communications

The MEDIUM-FREQUENCY (mf) band of the radio-frequency spectrum includes the international distress frequencies (500 kilohertz and approximately 484 kilohertz). Some ships have mf equipment. If desired the distress frequencies may be monitored. When this is done the transmitter usually is kept in the standby position. Ashore, the mf receiver and transmitter equipment configuration is usually affiliated with search and rescue organizations, which are generally located near the coast.

Only the upper and lower ends of the mf band have naval use because of the commercial broadcast band (AM) extending from 535 to 1,605 kilohertz. Frequencies in the lower portion of the mf band (300 to 500 kilohertz) are used primarily for ground-wave transmission for moderately long distances over water and for moderate to short distances over land. Transmission in the upper mf band is generally limited to short-haul communications (400 miles or less).

High-Frequency Communications

The Navy began using HIGH FREQUENCIES for radio communications around World War I when only a few communications systems were operated on frequencies near 3 megahertz. When we look at the extensive present-day use of high frequencies for long-distance communications, the fact that those Navy systems were intended for very short-range communications of a few miles seems curious. The general belief at the time was that frequencies above 1.5 megahertz were useless for communications purposes.

One of the prominent features of high-frequency, long-distance communications is the variable nature of the propagation medium. (You studied this in NEETS, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas*). Successful transmission of hf signals over a long distance is dependent upon refraction of radio waves by layers of the ionosphere. The height and density of these layers is formed mainly by ultraviolet radiation from the sun. They vary significantly with the time of day, season of the year, and the eleven-year cycle of sunspot activity. Because of these variations, you must generally use more than a single frequency, sometimes up to four or five, to maintain communications on a circuit.

In spite of the difficulties we encounter with hf propagation, the economic and technical advantages of using high frequencies have led to rapid expansion of the use of the hf band. Because the number of users has increased, the hf spectrum is approaching saturation.

The hf band is shared by many domestic and foreign users, and only portions scattered throughout the band are allocated to the military services. Like other agencies, Navy requirements have grown; the capacity of the Navy's assigned portion of the hf spectrum has become severely taxed. The use of single-sideband equipment and the application of independent sideband techniques have increased the capacity, but not enough to catch up with the demand. Some predict that satellite communications will eventually relieve congestion in the hf band and that, for some types of service, it will replace hf for long-distance communications. We will present more information to you concerning satellite communications in chapter 3. Even with new technology the hf spectrum most likely will continue to be in high demand for some time.

Naval communications within the hf band can be grouped into four general types of services: point-to-point, ship-to-shore, ground-to-air, and fleet broadcast. All but the fleet broadcast are normally operated with two-way communications. Some of these services involve ships and aircraft that present special problems because of their physical characteristics and mobility. Generally, the less than optimum hf performance of this shipboard equipment is at least partially offset by powerful transmitters and sensitive receiving systems at the shore terminals.

POINT-TO-POINT.—Point-to-point systems are established to communicate over long-distance trunks or links between fixed terminals. A trunk is normally a message circuit between two points that are both switching centers or individual message distribution points. A link is a transmitter-receiver system connecting two locations.

Generally, enough real estate is acquired at the terminals to permit the use of large, high-gain antennas aimed at opposite terminals of each link. This increases the effective radiated power and the sensitivity of the receiving system; it also reduces susceptibility of a circuit to interference.

With the path length and direction fixed, other propagation factors are simplified and highly reliable communications can be achieved.

SHIP-TO-SHORE.—This application of the hf band is more difficult than point-to-point since the ship is moving and constantly changing its position. In ship-to-shore the path length and direction are variable. Aboard ship, limited space and other restrictions prohibit installation of large, efficient hf antennas. Because of the mobility of ships, shipboard antennas are designed to be as nearly omnidirectional as possible.

Our problems are not as severe at the shore terminal where we have sufficient space for efficient omnidirectional antennas or arrays designed for coverage of large areas of the earth. At shore stations, rotatable, high-gain antennas or fixed, point-to-point antennas are used. For example, a rhombic antenna ashore may work well for long-haul, ship-to-shore communications when the ship is within range of the antenna.

Several frequencies are usually assigned for each circuit. Therefore, a frequency can be selected that best matches the propagation path conditions between the shore terminal and the ship.

GROUND-TO-AIR.—The use of hf radio for ground-to-air communications is similar to ship-to-shore. The only exception is an aircraft moves more rapidly than a ship. All major circuit improvements must be made at the ground station. For example, higher powered transmitters, lower noise receivers, and more efficient antennas must be used on the ground.

FLEET BROADCASTS.—As the name implies, this service involves broadcast area coverage from shore-based transmitters to ships at sea. Messages to be sent to ships are delivered by various means to the proper broadcast station. They are then broadcast for shipboard reception. To overcome propagation problems, naval communicators send the messages on several frequencies at once. This is known as frequency-diversity transmission. This type of transmission allows the ship to choose the best frequency for reception. Space-diversity with physically separated receive antennas also helps to overcome this problem.

Very-High-Frequency and Above Communications

Frequencies above 30 megahertz are not normally refracted by the atmosphere and ground-wave range is minimal. This normally limits our use of this frequency spectrum to line of sight. The exception to this is increased range through the use of tropospheric scatter techniques. Some communications using vhf and above frequencies use a technique called forward propagation by tropospheric scatter (fpts). This method will be discussed in more detail in chapter 5.

Certain atmospheric and ionospheric conditions can also cause the normal line-of-sight range to be extended. Frequencies at the lower end of this band are capable of overcoming the shielding effects of hills and structures to some degree; but as the frequency is increased, the problem becomes more pronounced. Reception is notably free from atmospheric and man-made static. (The VERY-HIGH-FREQUENCY (vhf) and ULTRAHIGH-FREQUENCY (uhf) bands are known as line-of-sight transmission bands.) Because this is line-of-sight communications, the transmitting antenna is in a direct line with the receiving antenna and not over the horizon. The line-of-sight characteristic makes the vhf band ideal for amphibious operations (beach landing from sea craft) and the uhf well suited for tactical voice transmissions (maneuvering of ships traveling together). The SUPERHIGH-FREQUENCY (shf) band is used for radar and satellite communications, whereas the EXTREMELY HIGH-FREQUENCY (ehf) band is used only in the experimental stage.

Q9. he majority of vlf transmitters are used for what purpose?

Q10. Today the Navy uses lf communications as a segment of what operational system?

Q11. Why does the Navy only use the upper and lower ends of the mf band?

Q12. What are the four general types of communications services in the hf band?

Q13. A message transmitted on several frequencies at the same time is an example of what type of transmission?

Q14. Physically separating receive antennas is an example of what technique?

Q15. When using frequencies above 30 megahertz, you are normally limited to using what range?

COMMUNICATIONS FUNDAMENTALS

Now that we have learned the Navy's fundamental use of the various frequency bands, we should look at the types of communications links and their modes of operation. The Navy uses many modes of operation; the type used is based upon the function of the circuit or network. These modes (or functions) are combined to form a communications link. We will also discuss some of the actual networks the Navy uses on a daily basis.

COMMUNICATIONS LINKS

A complex of links forms a major communications system. The naval communications system is broken down into strategic and tactical groups.

Strategic

Strategic communications are generally world-wide in nature. They are operated on a common-user (Navy, Army, Department of Defense, and so on) or special-purpose basis. A strategic system may be confined within a specified area or limited to a specific type of traffic, but the configuration is designed so that combined operations with other strategic systems are possible. As an example, we will look at the automatic voice network, automatic digital network, and the defense special security communications system later in this chapter.

Tactical

Tactical communications are usually limited to a specific area of operations and are used to direct or report the movement of specific forces. Some tactical networks are used only for operational traffic; others may be used for operational and administrative traffic. For instance, the task force, task-group, and air-control networks are ordinarily used for operational traffic. Ship-to-shore networks and broadcast networks serve both types of traffic.

Modes of Operation

Communications links have numerous modes of operation. In our discussion, a mode of operation is identified as a link or path between two or more points that is capable of providing one or more channels for the transmission of intelligence. Let's take a look at the five most common modes of operation.

SIMPLEX.—The simplex (splx) mode uses a single channel or frequency to exchange information between two or more terminals. Communications is in one direction only.

HALF DUPLEX.—The half-duplex (hdx) mode has one-way flow of information between terminals. Technical arrangements often permit transmission in either direction, but not simultaneously. This term must be qualified to show s/o (send only), r/o (receive only), or s/r (send or receive).

SEMIDUPLEX.—The semiduplex (sdx) uses an arrangement of equipment where one terminal is simplex configured and the other uses two channels or frequencies in full duplex. A clarifying example is a ship in a simplex mode terminated full duplex with a shore station. The ship may send or receive but not do both at the same time.

FULL DUPLEX.—The full-duplex (fdx) mode is a method of operation in which telecommunications between stations takes place simultaneously in both directions using two separate frequencies. In other words, a ship may send and receive different messages at the same time. The term "full duplex" is synonymous with "duplex."

BROADCAST.—Broadcast (bc) is the type of operation in which one station transmits information on one or more channels directed to more than one station and/or unit. The broadcast system has no provision for receipt or reply; however, special arrangements may require the receiving station to reply or receipt for the message at a later time by other means. Broadcasts are the primary means of delivering messages to the fleet. Since Navy units copying broadcasts are not required to receipt for messages received, they can maintain radio silence while still receiving essential messages.

Message traffic is normally sent to the fleet by three methods: broadcast, intercept, and receipt. The first two are "do not answer" methods; the third, as its name implies, requires a receipt from the addressee (addee) for each message. Broadcast and intercept methods allow the fleet to preserve radio silence, which is a great advantage from the standpoint of security. By the intercept method, a shore radio station transmits messages to another shore station that repeats them back. Ships intercept and copy all of this message traffic.

Broadcast is preferable to intercept chiefly because it is faster. It is the method by which nearly all fleet traffic is handled. It uses radiotelegraph, radiotelephone, radio teletypewriter, and facsimile.

There is some similarity between civilian and naval broadcasts. Just as commercial stations in the broadcast band transmit programs to radio receivers in the homes in their communities, Navy communications stations broadcast messages to fleet units in their particular geographic areas. The resemblance between Navy and commercial stations ceases there. Information broadcast by naval communications stations is contained in chronologically numbered messages addressed to the ships. The messages are copied by the fleet units, which check the serial numbers to ensure they have a complete file. This checks and balances system ensures the ship has not missed any of the broadcast message traffic.

Fleet broadcasts follow regular schedules. Messages are placed on the schedules in order of precedence. If a message of higher precedence is given to a transmitter station while a lower precedence message is being transmitted, the latter message may be interrupted to transmit the message of higher precedence. All ships copy all messages appearing on the broadcast schedule they are guarding.

Messages are normally transmitted on several frequencies to make sure they are received. This gives the receiving station the choice of frequency selection when considering time of day and atmospheric conditions for best reception.

Q16. The naval communications system is made up of what two groups of communications?

Q17. What are the five most prominent communications modes of operation?

SWITCHED NETWORKS

The defense communications system (DCS) is composed of all worldwide, long-haul, government-owned and leased point-to-point circuits, trunks, terminals, switching centers, control facilities, and tributaries of military departments and other defense activities. In essence the DCS combines into a single system all the elements that make up the naval communications system and the Army and Air Force equivalent.

The switched networks discussed in this section, automatic voice network, automatic secure voice communications, automatic digital network, and the defense special security communications system, are part of the DCS and are managed by the Defense Communications Agency (DCA). You should not confuse these DCS networks with the HICOM (high-command communications network) and NORATS (Navy operational radio and telephone switchboard) networks. We will discuss both of these Navy-only networks later in this chapter.

Automatic Voice Network (AUTOVON)

The DCS AUTOVON offers rapid, direct interconnection of DOD and certain other government installations through worldwide telephone exchanges. AUTOVON is a worldwide, general-purpose direct dialing telephone system. The goal of the AUTOVON system is to complete connections between two points anywhere in the world in about two seconds and to complete regular connections with push-button speed.

The AUTOVON system is made up of several installations comparable in function to commercial telephone exchanges. An installation is referred to as an AUTOVON switch, or simply switch. Within individual areas we have local command, control, and administrative voice communications systems. These systems connect into the worldwide AUTOVON through manually operated telephone switchboards or automatic dial exchanges by using direct in and out dialing.

Normal AUTOVON service allows your station to call other stations on a worldwide basis for day-to-day communications by using the telephone.

Automatic Secure Voice Communications (AUTOSEVOCOM)

Another close relative to the AUTOVON system is the AUTOSEVOCOM a worldwide, switched telephone network. It provides authorized users with a means for exchanging classified information over communications security (COMSEC) circuitry or over other approved circuitry. The system consists of both manual and automated networks within a single system.

For subscribers to the AUTOSEVOCOM network, telephone directories containing subscriber listings, general instructions for placing calls, and trouble-reporting procedures are provided.

Automatic Digital Network (AUTODIN)

The DCS AUTODIN is a fully automatic, digital system. The system converts word messages to digital form for transmission.

AUTODIN is used to furnish instantaneous, error-free, and secure communications around the world to several thousand directly connected subscriber terminals. Daily capacity of the system is about five-million average-length messages.

AUTODIN switching centers are interconnected through a network of high-frequency radio channels, submarine cables, microwave and tropospheric channels, and a variety of wire lines.

The whole concept of AUTODIN is to reduce manual handling of messages to a minimum by the use of automated equipment. This system has reduced message delivery times and delay anywhere in the world to a matter of seconds rather than minutes or hours.

Defense Special Security Communications System (DSSCS)

The defense special security communications system (DSSCS) was established for the purpose of integrating the critical intelligence communications (CRITICOMM) and the special intelligence communications (SPINTCOMM) networks into a single automated communications network. In effect, the integration of DSSCS subscribers into AUTODIN provides two separate systems within AUTODIN-one system for special intelligence (SI) message traffic and the other for the AUTODIN regular message traffic.

NAVY-ONLY NETWORKS

Some networks are used by the Navy only. As mentioned previously, these are the high command communications network (HICOM) and the Navy operational radio and telephone switchboard (NORATS) networks. Let's look at some of their functions and purposes.

High Command Communications Network (HICOM)

The HICOM network provides a voice link between the Chief of Naval Operations (CNO) and all subordinate commands ashore, afloat, and airborne. CNO is the master control station and each fleet commander in chief has an area network control station. All naval communications stations are members.

In cases where a fleet unit is suffering communications difficulties with normal channels, HICOM is used on a not-to-interfere basis to restore communications. All naval communications stations are required to guard HICOM for their respective area networks and use this system.

Navy Operational Radio and Telephone Switchboard (NORATS)

The NORATS meets our need for a connection between Navy tactical voice systems of the operating forces and the various fixed telephone services ashore. This system extends tactical voice to shore-based operational commands. NORATS provides a connecting point in the fleet center of each communication station. This point allows us to connect or patch all ship-to-shore voice circuits and designated local shore telephone systems and extensions. A combined HICOM/NORATS console exists at many naval communications stations.

Q18. What four switched networks are part of the defense communications system?

Q19. What two elements support only designated Navy requirements?

SUMMARY

Now that you have completed this chapter, a short review of what you have learned is in order. The following summary will refresh your memory of radio-frequency communications terms.

TELECOMMUNICATIONS refers to transmission, emission, or reception of signs, signals, writings, images, or sounds. This is done by visual, oral, wire, radio, or other electromagnetic means.

RADIO COMMUNICATIONS is the term describing teletypewriter, voice, telegraphic, and facsimile communications.

SYSTEM is a combination of sets, units, assemblies, subassemblies, and parts joined together to form a specific operational function or several functions.

SET is a unit or units and the assemblies, subassemblies, and parts connected or associated together to perform a specific function.

GROUP is a collection of units, assemblies, subassemblies, and parts. It is a subdivision of a set or system but is not capable of performing a complete operational function.

UNIT is an assembly or any combination of parts, subassemblies, and assemblies mounted together. Normally capable of independent operation.

ASSEMBLY is a number of parts or subassemblies, or any combination thereof, joined together to perform a specific function.

SUBASSEMBLY consists of two or more parts that form a portion of an assembly or a unit.

PART is one component or two or more components joined together. It is not normally subject to disassembly without destruction.

EXTREMELY LOW FREQUENCY is the band of frequencies up to 300 hertz.

VERY LOW FREQUENCY is the band of frequencies from 3 kilohertz to 30 kilohertz.

LOW FREQUENCY is the band of frequencies from 30 kilohertz to 300 kilohertz.

MEDIUM FREQUENCY is the band of frequencies from 300 kilohertz to 3 megahertz.

HIGH FREQUENCY is the band of frequencies from 3 megahertz to 30 megahertz.

VERY HIGH FREQUENCY is the band of frequencies from 30 megahertz to 300 megahertz.

ULTRAHIGH FREQUENCY is the band of frequencies from 300 megahertz to 3 gigahertz.

SUPERHIGH FREQUENCY is the band of frequencies from 3 gigahertz to 30 gigahertz.

EXTREMELY HIGH FREQUENCY is the band of frequencies from 30 gigahertz to 300 gigahertz.

ANSWERS TO QUESTIONS Q1. THROUGH Q19.

A1. Radio and wire.

A2. Reliability.

A3. It is direct, convenient and easy to use.

A4. Static, enemy interference or a high local noise level.

A5. High speed automatic communications across ocean areas.

A6. The process used to transmit photographs, charts and other graphic information electronically.

A7. Set, group, unit, assembly, subassembly, and part.

A8. A6.

A9. Fleet communications or navigation.

A10. Fleet Multichannel Broadcast System.

A11. Due to the commercial broadcast (AM) band.

A12. Point-to-point, ship-to-shore, ground-to-air, and fleet broadcast.

A13. Frequency-diversity.

A14. Space-diversity.

A15. Line of sight.

A16. Strategic and tactical.

A17. Simplex, half-duplex, semiduplex, duplex, and broadcast.

A18. AUTOVON, AUTOSEVOCOM, AUTODIN, and DSSCS.

A19. HICOM and NORATS.

CHAPTER 2

INTRODUCTION TO COMMUNICATIONS THEORY

LEARNING OBJECTIVES

Upon completion of this chapter you will be able to:

1. Describe the four basic types of transmitters.
2. Describe the two basic types of single-sideband circuits.
3. Describe the three basic types of teletypewriter circuits.
4. List the four primary functions of a basic receiver.
5. Describe the four primary functions of a basic receiver.
6. State the four characteristics of a basic receiver.
7. Evaluate the four characteristics of a basic receiver.
8. Describe the fundamental heterodyning process.
9. Describe the basic difference between an AM and an fm receiver.
10. Describe single-sideband suppressed carrier communications.
11. State the purpose of carrier reinsertion and how it is used in single-sideband communications.
12. Describe the basic theory and functions of receiver control circuits.
13. Describe the basic frequency synthesis process.
14. Describe the basic audio reproduction process.

INTRODUCTION

In the previous chapter you learned the fundamentals of U.S. naval telecommunications and communications. Now, let's look at the equipment and systems that are used to communicate in the Navy. The fundamental equipment used to communicate are the transmitter and receiver.

Transmitters and receivers must each perform two basic functions. The transmitter must generate a radio frequency signal of sufficient power at the desired frequency. It must have some means of varying (or modulating) the basic frequency so that it can carry an intelligible signal. The receiver must select the desired frequency you want to receive and reject all unwanted frequencies. In addition, receivers must be able to amplify the weak incoming signal to overcome the losses the signal suffers in its journey through space.

Representative transmitters and their fundamental features are described for you in this module.

TRANSMITTER FUNDAMENTALS

Basic communication transmitters include continuous wave (cw), amplitude modulated (AM), frequency modulated (fm), and single sideband (ssb) types. A basic description of each of these transmitters is given in this chapter.

CONTINUOUS WAVE TRANSMITTER

The continuous wave is used principally for radiotelegraphy; that is, for the transmission of short or long pulses of rf energy to form the dots and dashes of the Morse code characters. This type of transmission is sometimes referred to as interrupted continuous wave. Cw transmission was the first type of radio communication used, and it is still used extensively for long-range communications. Two of the advantages of cw transmission are a narrow bandwidth, which requires less output power, and a degree of intelligibility that is high even under severe noise conditions. (For example, when the receiver is in the vicinity of rotating machinery or thunderstorms.)

A cw transmitter requires four essential components. These are a *generator*, *amplifier*, *keyer*, and *antenna*. We have to generate rf oscillations and have a means of amplifying these oscillations. We also need a method of turning the rf output on and off (keying) in accordance with the intelligence to be transmitted and an antenna to radiate the keyed output of the transmitter.

Let's take a look at the block diagram of a cw transmitter and its power supply in figure 2-1. The oscillator generates the rf carrier at a preset frequency and maintains it within close tolerances. The oscillator may be a self-excited type, such as an electron-coupled oscillator, or a quartz crystal type, which uses a crystal cut to vibrate at a certain frequency when electrically excited. In both types, voltage and current delivered by the oscillator are weak. The oscillator outputs must be amplified many times to be radiated any distance.

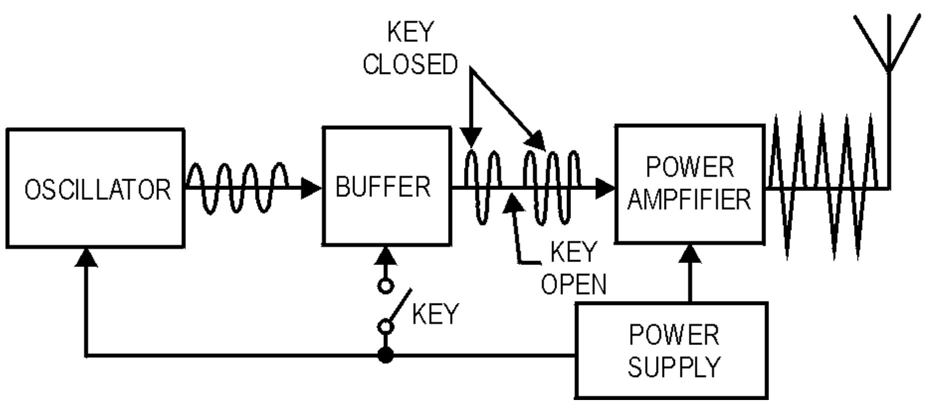

Figure 2-1.—Cw transmitter block diagram.

The buffer stage or first intermediate power amplifier stage (referred to as the ipa) is a voltage amplifier that increases the amplitude of the oscillator signal to a level that drives the power amplifier (pa). You will find the signal delivered by the buffer varies with the type of transmitter and may be hundreds or thousands of volts.

The buffer serves two other purposes. One is to isolate the oscillator from the amplifier stages. Without a buffer, changes in the amplifier caused by keying or variations in source voltage would vary the load of the oscillator and cause it to change frequency. It may also be used as a frequency multiplier, which is explained later in this text.

As you can see in the figure, a key is used to turn the buffer on and off. When the key is closed, the rf carrier passes through the buffer stage; when the key is open (buffer is turned off), the rf carrier is prevented from getting through.

The final stage of a transmitter is the power amplifier (referred to as the pa). In chapter 3 of NEETS, Module 1, *Introduction to Matter, Energy, and Direct Current*, you learned that power is the product of current and voltage (P = IE). In the power amplifier a large amount of rf current and voltage is made available for radiation by the antenna.

The power amplifier of a high-power transmitter may require far more driving power than can be supplied by an oscillator and its buffer stage. One or more low-power intermediate amplifiers are used between the buffer and the final amplifier that feeds the antenna. The main difference between many low- and high-power transmitters is in the number of intermediate power-amplifier stages used.

Figure 2-2 is a block diagram of the input and output powers for each stage of a typical medium-power transmitter. You should be able to see that the power output of a transmitter can be increased by adding amplifier stages capable of delivering the power required. In our example, the .5 watt output of the buffer is amplified in the first intermediate amplifier by a factor of 10, (this is a times 10 [× 10] amplifier) giving us an input of 5 watts to the second intermediate amplifier. You can see in this example the second intermediate amplifier multiplies the 5 watt input to it by a factor of 5 (× 5) and gives us a 25 watt input to our power (final) amplifier. The final amplifier multiplies its input by a factor of 20 (× 20) and gives us 500 watts of power out to the antenna.

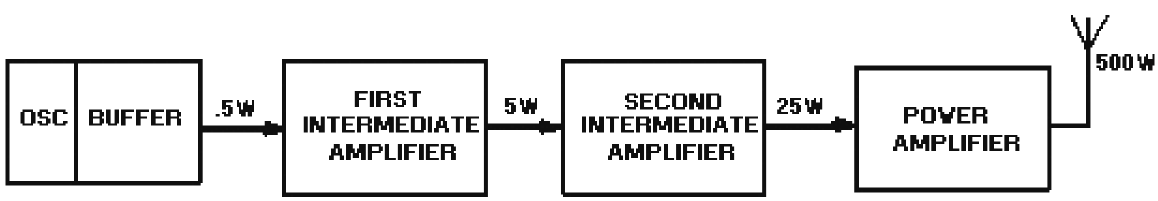

Figure 2-2.—Intermediate amplifiers increase transmitter power.

Q1. What are the four basic transmitter types?

Q2. What is the function of the oscillator in a cw transmitter?

Q3. What is the final stage of a transmitter?

AMPLITUDE MODULATED TRANSMITTER

In AM transmitters, the instantaneous amplitude of the rf output signal is varied in proportion to the modulating signal. The modulating signal may consist of many frequencies of various amplitudes and phases, such as the signals making up your own speech pattern.

Figure 2-3 gives you an idea of what the block diagram of a simple AM transmitter looks like. The oscillator, buffer amplifier, and power amplifier serve the same purpose as those in the cw transmitter. The microphone converts the audio frequency (af) input (a person’s voice) into corresponding electrical energy. The driver amplifies the audio, and the modulator further amplifies the audio signal to the amplitude necessary to fully modulate the carrier. The output of the modulator is applied to the power amplifier. The pa combines the rf carrier and the modulating signal in the power amplifier to produce the amplitude-modulated signal output for transmission. In the absence of a modulating signal, a continuous rf carrier is radiated by the antenna.

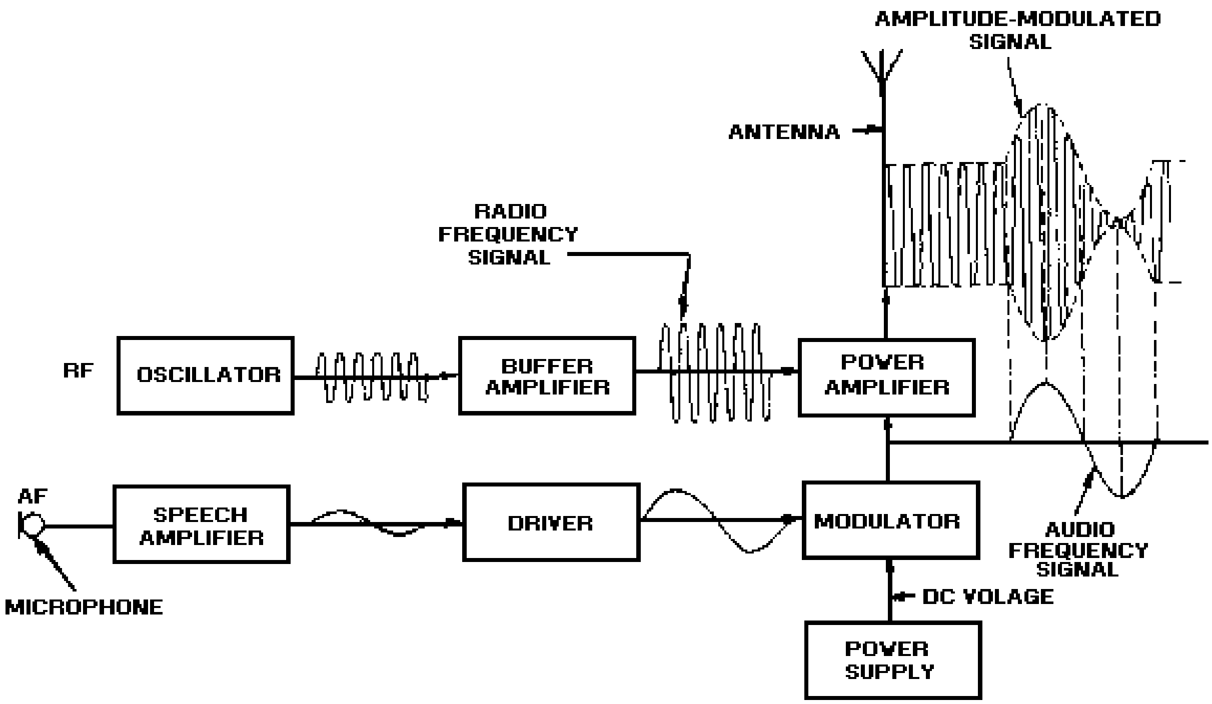

Figure 2-3.—AM radiotelephone transmitter block diagram.

FREQUENCY MODULATED TRANSMITTER

In frequency modulation (fm) the modulating signal combines with the carrier to cause the frequency of the resultant wave to vary with the instantaneous amplitude of the modulating signal.

Figure 2-4 shows you the block diagram of a frequency-modulated transmitter. The modulating signal applied to a varicap causes the reactance to vary. The varicap is connected across the tank circuit of the oscillator. With no modulation, the oscillator generates a steady center frequency. With modulation applied, the varicap causes the frequency of the oscillator to vary around the center frequency in accordance with the modulating signal. The oscillator output is then fed to a frequency multiplier to increase the frequency and then to a power amplifier to increase the amplitude to the desired level for transmission.

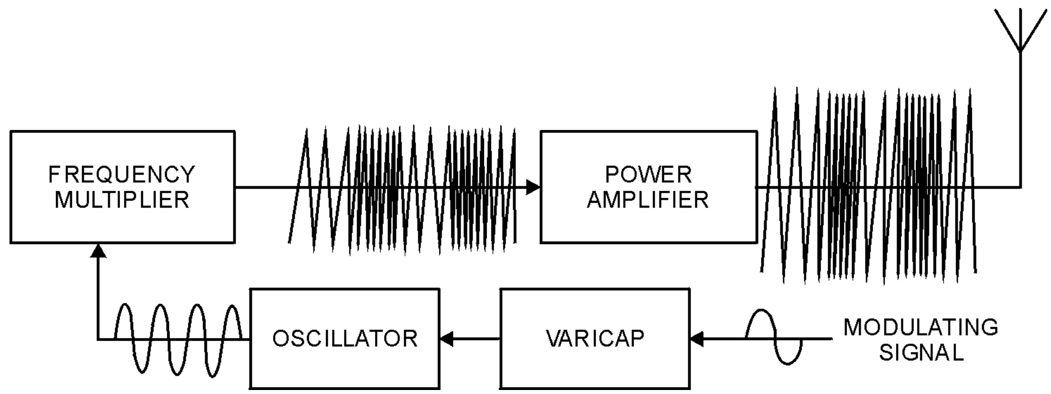

Figure 2-4.—Fm transmitter block diagram.

Harmonics

True harmonics are always exact multiples of the basic or fundamental frequency generated by an oscillator and are created in amplifiers and their associated circuits. Even harmonics are 2, 4, 6, and so on, times the fundamental; odd harmonics are 3, 5, 7, and so on, times the fundamental. If an oscillator has a fundamental frequency of 2,500 kilohertz, the harmonically related frequencies are

5,000………………	second harmonic
7,500………………	third harmonic
10,000………………	fourth harmonic
12,500………………	fifth harmonic

You should note that the basic frequency and the first harmonic are one and the same.

The series ascends indefinitely until the intensity is too weak to be detected. In general, the energy in frequencies above the third harmonic is too weak to be significant.

In some electronics books, and later in this chapter, you will find the term SUBHARMONIC used. It refers to a sine wave quantity (for example, an oscillator output) that has a frequency that is a submultiple of the frequency of some other sine wave quantity it helped make. For example, a wave that is half the fundamental frequency of another wave is called the second subharmonic of that wave; one with a third of the fundamental frequency is called a third subharmonic; and so forth.

Q4. What purpose does a microphone perform in an AM transmitter?

Q5. In an fm transmitter, when does an oscillator generate only a steady frequency?

Q6. What is a harmonic?

Q7. If the fundamental frequency is 200 megahertz, what is the third harmonic?

Frequency Multiplication

Designing and building a stable crystal oscillator is difficult. As operating frequencies increase, the crystal must be ground so thin that it often cracks while vibrating. You will find that you can get around this problem by operating the oscillators in most transmitters at comparatively low frequencies, sometimes as low as 1/100 (.01) of the output frequency. You raise the oscillator frequency to the required output frequency by passing it through one or more frequency multipliers. Frequency multipliers are special power amplifiers that multiply the input frequency. Stages that multiply the frequency by 2 are called doublers; those that multiply by 3 are triplers; and those multiplying by 4 are quadruplers.

You will find the main difference between low-frequency and high-frequency transmitters is the number of frequency-multiplying stages used. Figure 2-5 shows the block diagram of the frequency-multiplying stages of a typical Navy uhf/vhf transmitter. The oscillator in this transmitter is tunable from 18 megahertz to 32 megahertz. You have multiplier stages that increase the oscillator frequency by a factor of 12 through successive multiplications of 2, 2, and 3.

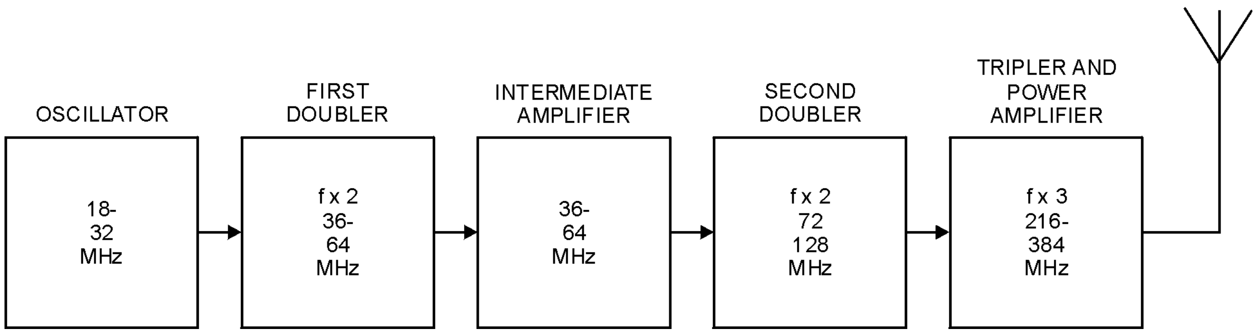

Figure 2-5.—Frequency multiplying stages of a typical vhf/uhf transmitter.

Figure 2-6 is a block diagram of an fm transmitter showing waveforms found at various test points. In high-power applications you often find one or more intermediate amplifiers added between the second doubler and the final power amplifier.

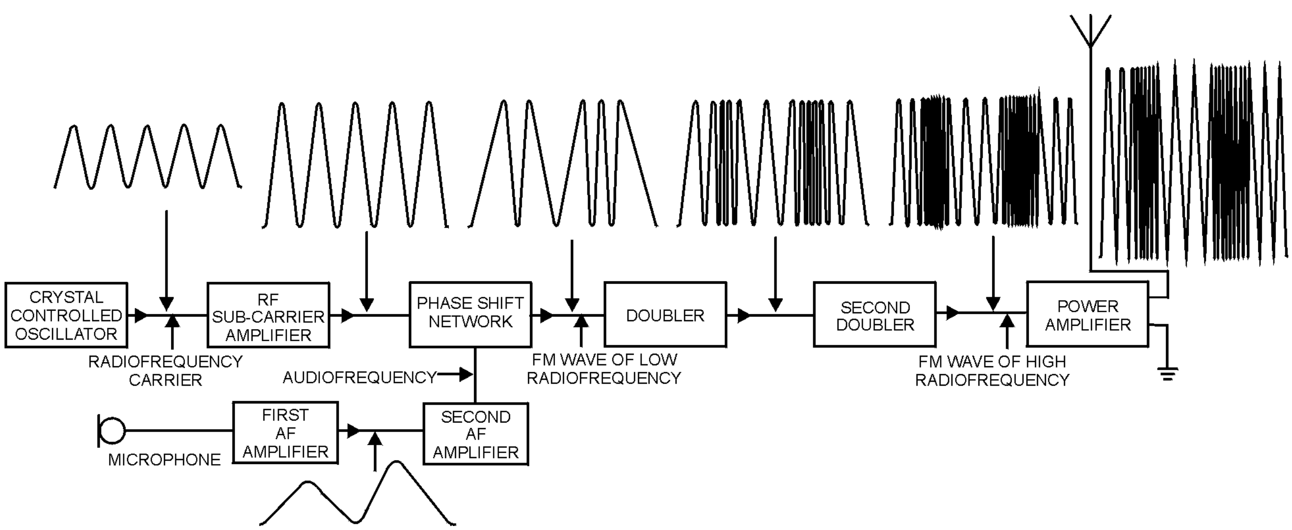

Figure 2-6.—Block diagram of an fm transmitter and waveforms.

SINGLE-SIDEBAND TRANSMITTER

You should remember the properties of modulation envelopes from your study of NEETS, Module 12, *Modulation Principles*. A carrier that has been modulated by voice or music is accompanied by two identical sidebands, each carrying the same intelligence. In amplitude-modulated (AM) transmitters, the carrier and both sidebands are transmitted. In a single-sideband transmitter (ssb), only one of the sidebands, the upper or the lower, is transmitted while the remaining sideband and the carrier are suppressed. SUPPRESSION is the elimination of the undesired portions of the signal.

Figure 2-7 is the block diagram of a single-sideband transmitter. You can see the audio amplifier increases the amplitude of the incoming signal to a level adequate to operate the ssb generator. Usually the audio amplifier is just a voltage amplifier.

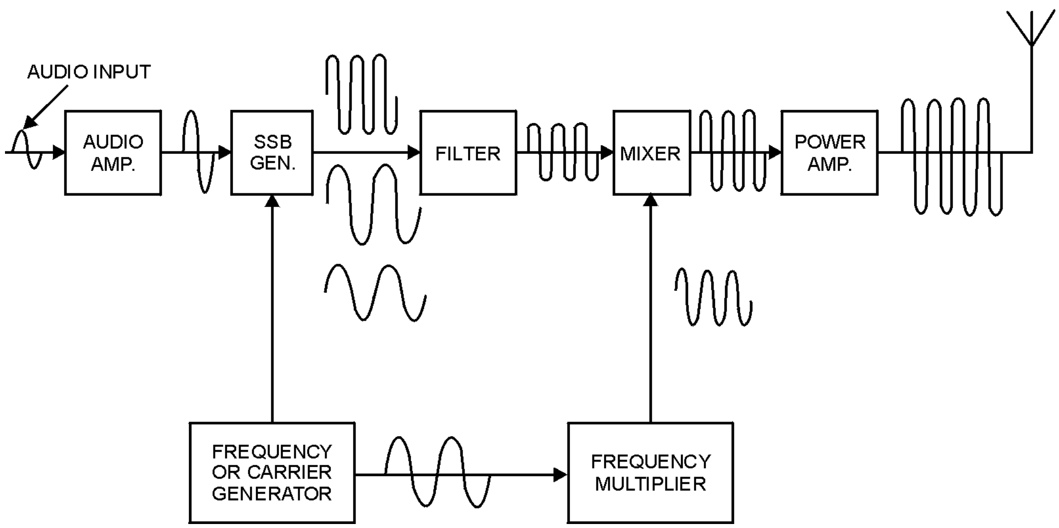

Figure 2-7.—Ssb transmitter block diagram.

The ssb generator (modulator) combines its audio input and its carrier input to produce the two sidebands. The two sidebands are then fed to a filter that selects the desired sideband and suppresses the other one. By eliminating the carrier and one of the sidebands, intelligence is transmitted at a savings in power and frequency bandwidth.

In most cases ssb generators operate at very low frequencies when compared with the normally transmitted frequencies. For that reason, we must convert (or translate) the filter output to the desired frequency. This is the purpose of the mixer stage. A second output is obtained from the frequency generator and fed to a frequency multiplier to obtain a higher carrier frequency for the mixer stage. The output from the mixer is fed to a linear power amplifier to build up the level of the signal for transmission.

Suppressed Carrier

In ssb the carrier is suppressed (or eliminated) at the transmitter, and the sideband frequencies produced by the carrier are reduced to a minimum. You will probably find this reduction (or elimination) is the most difficult aspect in the understanding of ssb. In a single-sideband suppressed carrier, no carrier is present in the transmitted signal. It is eliminated after modulation is accomplished and is reinserted at the receiver during the demodulation process. All rf energy appearing at the transmitter output is concentrated in the sideband energy as "talk power."

After the carrier is eliminated, the upper and lower sidebands remain. If one of the two sidebands is filtered out before it reaches the power amplifier stage of the transmitter, the same intelligence can be transmitted on the remaining sideband. All power is then transmitted in one sideband, instead of being divided between the carrier and both sidebands, as it is in conventional AM. This provision gives you an increase in power for the wanted sideband. You should note in figure 2-8 that the bandwidth required for the ssb suppressed carrier, view B, is approximately half that needed for conventional AM, view A. This enables us to place more signals in a smaller portion of the frequency spectrum and permits a narrower receiver bandpass.

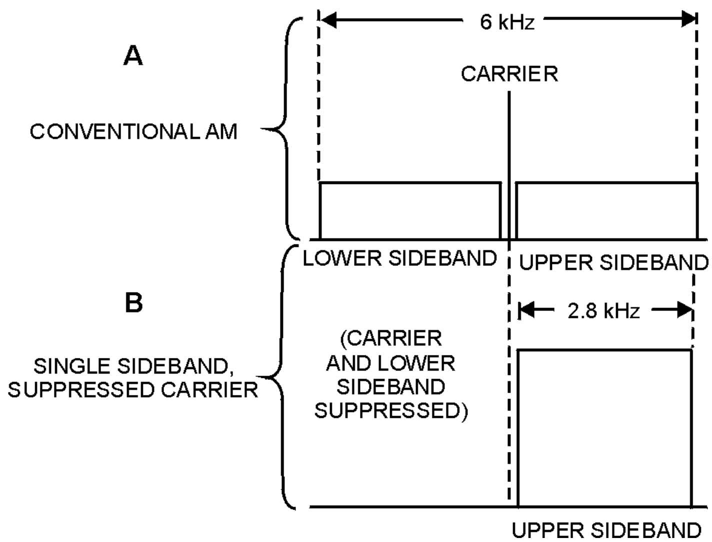

Figure 2-8.—Comparison of bandwidths of conventional AM and ssb voice channels.

Applications

Single-sideband transmission is the most common communications mode used today. Some of the ssb applications used in naval communications are described for you in the following paragraphs.

SSB VOICE CIRCUITS.—The high command (HICOM) network uses ssb as a means of communications between fleet commanders; and fleet commanders use it for communications between their subordinates and adjacent commands.

Ssb is generally used whenever special voice communications circuits are necessary between shore activities or between ships and shore activities because it is less susceptible to atmospheric interference than amplitude modulation.

SSB TELETYPEWRITER CIRCUITS.—With few exceptions, you will find ssb used on all long-haul (great distance) teletypewriter circuits, which includes ship-to-shore. Most of these systems are covered circuits; that is, an electronic cryptographic device on both ends of the circuit automatically encrypts and decrypts message traffic. These devices are used on point-to-point, ship-to-shore, ship-to-ship, and broadcast circuits.

Point-to-Point.—Most point-to-point, long-haul circuits between naval communications stations quickly use up the available frequency spectrum that ssb provides. Independent sideband (isb) transmission is normally used to compensate for the deficiency. Isb is used extensively in naval communications to expand our traffic capabilities. You will find there is a similarity between ssb and isb. Isb uses outputs from two sideband generators; it suppresses both carriers and then filters out an upper sideband from one and a lower sideband from the other. We then combine the two remaining sidebands and transmit an envelope with upper and lower sidebands that contain different intelligence. Isb can be used with MULTIPLEXING (a method for simultaneous transmission of two or more signals over a common carrier wave) to transmit a lot of intelligence on one circuit. Independent sideband and multiplexing will be discussed in more detail in chapter 3.

Ship-to-Shore.—Many ships handle enough message traffic to justify ship-to-shore teletypewriter circuits. Depending on traffic load, these circuits may contain from one to four (minimum) teletypewriter circuits on one sideband circuit. If the traffic load warrants more than one teletypewriter circuit, we usually use time division multiplex or frequency division multiplex (mux) equipment. This equipment is capable of handling many incoming and outgoing circuits. One circuit normally is used as an ORDERWIRE CIRCUIT for operator-to-operator service messages and for making frequency changes when necessary. The remaining circuits are available for handling official message traffic.

Q8. Why are frequency multipliers used?

Q9. What are two advantages of ssb transmission?

Q10. What is the purpose of an order-wire circuit?

Ship-to-Ship.—Ship-to-ship ssb teletypewriter circuits are in wide use today. Their main application is with task force or task group networks or with several ships in company. By using this type of network, ships can send their outgoing messages to another ship that relays traffic ashore. You can see this procedure saves manpower and circuit time, prevents individual ships from overcrowding ship-to-shore circuits, and conserves the frequency spectrum. Depending on the number and types of ships in company, the guard can be shifted to other ships from time to time. A major advantage of these circuits is that electronic cryptographic devices can be used to send classified messages without need for manual encryption. These circuits are used for incoming as well as outgoing traffic, and they can use either hf or uhf communications equipment.

RECEIVER FUNDAMENTALS

An AM receiver processes amplitude-modulated signals received by its antenna. It delivers an output that is a reproduction of the signal that originally modulated the rf carrier at the transmitter. The signal can then be applied to some reproducing device, such as a loudspeaker, or to a terminal device, such as a teletypewriter. Actual AM receivers vary widely in complexity. Some are very simple; others contain a large number of complex circuits.

FUNCTIONS

Whatever its degree of sophistication, a receiver must perform certain basic functions to be useful. These functions, in order of their performance, are *reception, selection, detection,* and *reproduction*.

Reception

Reception occurs when a transmitted electromagnetic wave passes through the receiver antenna and induces a voltage in the antenna.

Selection

Selection is the ability of the receiver to select a particular frequency of a station from all other station frequencies appearing at the antenna of the receiver.

Detection

Detection is the action of separating the low (audio) frequency intelligence from the high (radio) frequency carrier. A detector circuit is used to accomplish this action.

Reproduction

Reproduction is the action of converting the electrical signals to sound waves, which can then be interpreted by your ear as speech, music, and the like. An example of this might be the stereo speakers in your car.

RECEIVER CHARACTERISTICS

Sensitivity, *noise*, *selectivity*, and *fidelity* are important receiver characteristics. These characteristics will be useful to you when performing receiver tests. They can help you to determine whether a receiver is working or not or in comparing one receiver to another.

Sensitivity

The ability of a receiver to reproduce weak signals is a function of the sensitivity of a receiver. The weaker a signal that can be applied to a receiver and still produce a certain value of signal output, the better the sensitivity rating. Sensitivity of a receiver is measured under standardized conditions. It is expressed in terms of the signal voltage, usually in the microvolts that must be applied to the antenna input terminals to give an established level of the output. The output may be an ac or dc voltage measured at the detector output or a power measurement (measured in decibels or watts) at the loudspeaker or headphone terminals.

Noise

All receivers generate a certain amount of noise, which you must take into account when measuring sensitivity. Receiver noise may originate from the atmosphere (lightning) or from internal components (transistors, tubes). Noise is the limiting factor of sensitivity. You will find sensitivity is the value of input carrier voltage (in microvolts) that must be applied from the signal generator to the receiver input to develop a specified output power.

Selectivity

Selectivity is the degree of distinction made by the receiver between the desired signal and unwanted signals. You will find the better the ability of the receiver to reject unwanted signals, the better its selectivity. The degree of selection is determined by the sharpness of resonance to which the frequency-determining circuits have been engineered and tuned. You usually measure selectivity by taking a series of sensitivity readings. As you take the readings, you step the input signal along a band of frequencies above and below the circuit resonance of the receiver; for example, 100 kilohertz below to 100 kilohertz above the tuned frequency. As you approach the tuned frequency, the input level required to maintain a given output level will fall. As you pass the tuned frequency, the required input level will rise. Input voltage levels are then compared with frequency. They can be plotted on paper or you might view them on an oscilloscope. They would appear in the form of a response curve. The steepness of the response curve at the tuned frequency indicates the selectivity of the receiver.

Fidelity

The fidelity of a receiver is its ability to accurately reproduce, in its output, the signal that appears at its input. You will usually find the broader the band passed by frequency selection circuits, the greater your fidelity. You may measure fidelity by modulating an input frequency with a series of audio frequencies; you then plot the output measurements at each step against the audio input frequencies. The resulting curve will show the limits of reproduction.

You should remember that good selectivity requires that a receiver pass a narrow frequency band. Good fidelity requires that the receiver pass a broader band to amplify the outermost frequencies of the sidebands. Receivers you find in general use are a compromise between good selectivity and high fidelity.

Q11. What four basic functions must a receiver perform?

Q12. What are the four basic receiver characteristics?

SUPERHETERODYNE RECEIVER

The superheterodyne is the type receiver most familiar to you. You probably see one daily in your home in the form of an AM and/or fm radio. We will discuss the basic workings of both AM and fm types and their differences.

Amplitude Modulation Receiver

Figure 2-9 shows a block diagram with waveforms of a typical AM superheterodyne receiver developed to overcome the disadvantages of earlier type receivers. Let's assume you are tuning the receiver. When doing this you are actually changing the frequency to which the rf amplifier is tuned. The rf carrier comes in from the antenna and is applied to the rf amplifier. The output of the amplifier is an amplified carrier and is sent to the mixer. The mixer also receives an input from the local oscillator. These two signals are beat together to obtain the IF through the process of heterodyning. (Heterodyning will be further discussed later in this chapter and was covered in NEETS, Module 12, *Modulation Principles.*) At this time you should note the dotted lines connecting the local oscillator, rf amplifier, and the mixer. This is used on block diagrams and schematics to indicate GANGED TUNING. Ganged tuning is the process used to tune two or more circuits with a single control. In our example, when you change the frequency of the receiver all three stages change by the same amount. There is a fixed difference in frequency between the local oscillator and the rf amplifier at all times. This difference in frequency is the IF. This fixed difference and ganged tuning ensures a constant IF over the frequency range of the receiver.

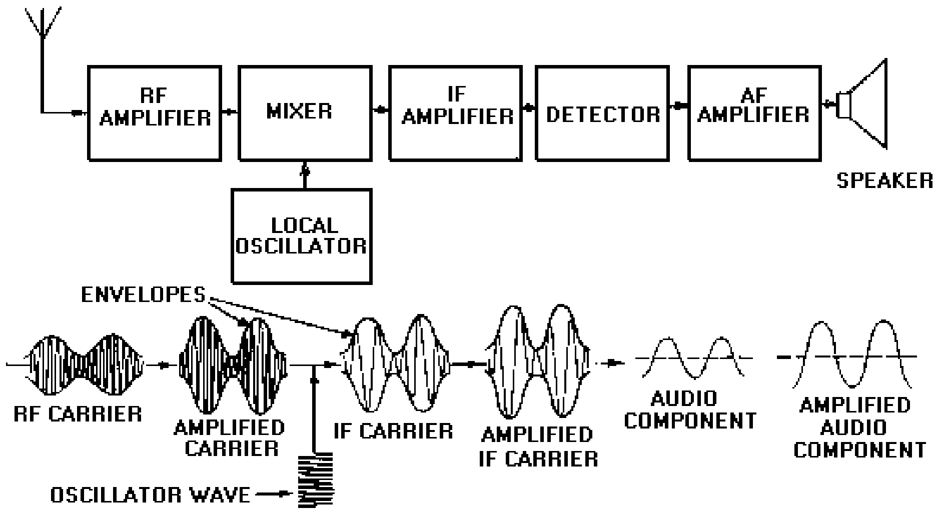

Figure 2-9.—AM superheterodyne receiver and waveforms.

The IF carrier is applied to the IF amplifier. The amplified IF carrier is then sent to the detector. The output of the detector is the audio component of the input signal. This audio component is then passed through an audio frequency amplifier. The amplified audio component is sent to a speaker for reproduction. This allows you to hear the signal.

You should note that a superheterodyne receiver may have more than one frequency-converting stage and as many amplifiers as needed to obtain the desired power output. (Additional amplifiers are not shown.)

HETERODYNING.—As you know the intermediate frequency is developed by a process called heterodyning. This action takes place in the mixer stage (sometimes called a converter or first detector). Heterodyning is the combining of the incoming signal with the local oscillator signal. When heterodyning the incoming signal and the local oscillator signal in the mixer stage, four frequencies are produced. They are the two basic input frequencies and the sum and the difference of those two frequencies. The amplifier that follows (IF amplifier) will be tuned to the difference frequency. This difference frequency is known as the intermediate frequency (IF). A typical value of IF for an AM communications receiver is 455 kilohertz. The difference frequency is a lower frequency than either the rf input or oscillator frequencies. This lower frequency gives slightly better gain but does increase the chances of image frequency interference. Image frequencies will be discussed later in this chapter.

DETECTION.—Once the IF stages have amplified the intermediate frequency to a sufficient level, it is fed to the detector. When the mixer is referred to as the first detector, this stage would be called the second detector. The detector extracts the modulating audio signal. The detector stage consists of a rectifying device and filter, which respond only to the amplitude variations of the IF signal. This develops an output voltage varying at an audio-frequency rate. The output from the detector is further amplified in the audio amplifier and is used to drive a speaker or earphones.

Frequency Modulated Receiver

The function of a frequency-modulated receiver is the same as that of an AM superheterodyne receiver. You will find some important differences in component construction and circuit design caused by differences in the modulating technique. Figure 2-10 is a block diagram showing waveforms of a typical fm superheterodyne receiver. Comparison of block diagrams in figures 2-9 and 2-10 shows that in both AM and fm receivers, the amplitude of the incoming signal is increased in the rf stages. The mixer combines the incoming rf with the local oscillator signal to produce the intermediate frequency, which is then amplified by one or more IF amplifier stages. You should note that the fm receiver has a wide-band IF amplifier. The bandwidth for any type of modulation must be wide enough to receive and pass all the side-frequency components of the modulated signal without distortion. The IF amplifier in an fm receiver must have a broader bandpass than an AM receiver.

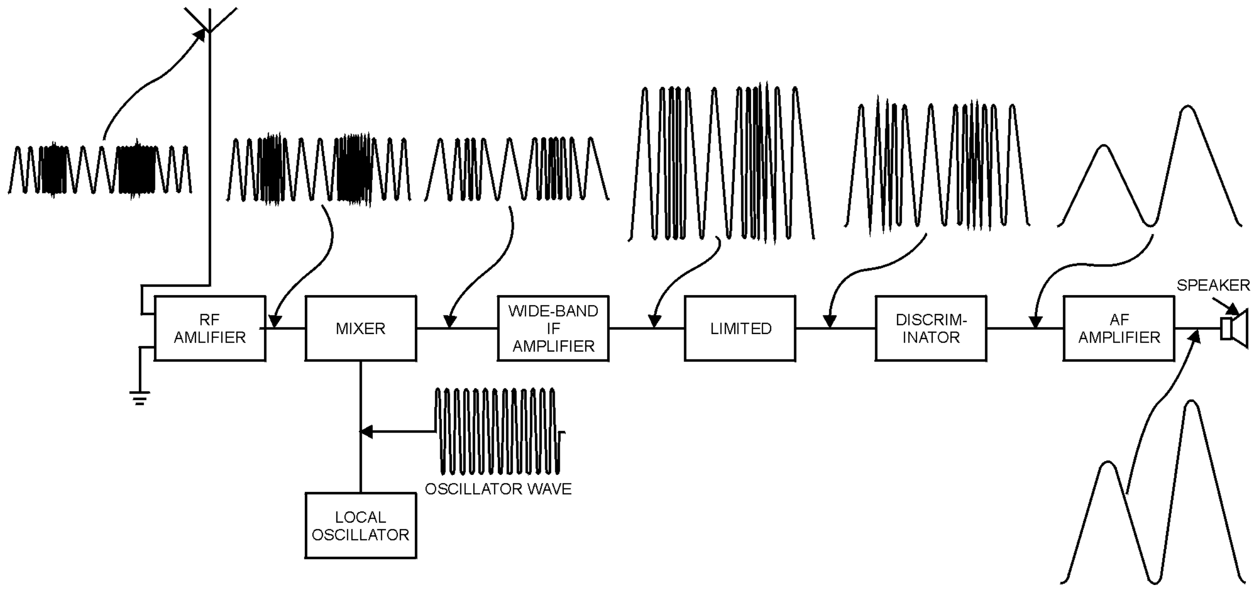

Figure 2-10.—Block diagram of an fm receiver and waveforms.

Sidebands created by fm differ from the AM system. You should recall that the AM system consists of a single set of side frequencies for each radio-frequency signal modulated. An fm signal inherently occupies a wider bandwidth than AM because the number of extra sidebands that occur in an fm transmission is directly related to the amplitude and frequency of the audio signal.

You should observe that only two fundamental sections of the fm receiver are electrically different from the AM receiver. These are the discriminator (detector) and the limiter.

Beyond the IF stage, the two receivers have a marked difference. AM demodulation involves the detection of variations in the amplitude of the signal; fm demodulation is the process of detecting variations in the frequency of the signal. In fm receivers a DISCRIMINATOR is a circuit designed to respond to frequency shift variations. A discriminator is preceded by a LIMITER circuit, which limits all signals to the same amplitude level to minimize noise interference. The audio frequency component is then extracted by the discriminator, amplified in the af amplifier, and used to drive the speaker.

ADVANTAGES.—In normal reception, fm signals are almost totally absent of static while AM signals are subject to cracking noises and whistles. Fm followed AM in development and has the advantage of operating at a higher frequency where a greater amount of frequencies are available. Fm signals provide much more realistic sound reproduction because of an increase in the number of sidebands. This increase in the number of sidebands allows more of the original audio signal to be transmitted and, therefore, a greater range of frequencies for you to hear.

As you can see, fm requires a wide bandpass to transmit signals. Each transmitting station must be assigned a wide band in the fm frequency spectrum. During fm transmissions, the number of significant sidebands that must be transmitted to obtain the desired fidelity is related to the deviation (change in carrier' frequency) divided by the highest audio frequency to be used. At this point you may want to review chapter 2 of NEETS, Module 12, *Modulation Principles*. For example, if the deviation is 40 kilohertz and the highest audio frequency is 10 kilohertz, the modulation index is figured as shown below:

$$\frac{40 \text{ kilohertz}}{10 \text{ kilohertz}} = 4$$

In this example, a modulation index of 4 equates to 14 significant sidebands. Because the audio frequency is 10 kilohertz and there are 14 side-bands, the bandwidth must accommodate a 140-kilohertz signal. You can see this is considerably wider than the 10-to-15-kilohertz bandpass used in AM transmitting.

FREQUENCY CONVERSION.—Frequency conversion is accomplished by using the heterodyne principle of beating two frequencies together to get an intermediate frequency. So far, you have only become familiar with single conversion; however, some receivers use double or triple conversion. These methods are sometimes referred to as double or triple heterodyning. Receivers using double or triple conversion are very selective and suppress IMAGE SIGNALS to yield sharp signal discrimination. (Image signals are undesired, modulated carrier signals that differ by twice the intermediate frequency from the frequency to which the superheterodyne receiver is tuned.) Double and triple conversion receivers also have better adjacent channel selectivity than can be realized in single conversion sets.

In military communications receivers you may sacrifice fidelity to improve selectivity. This is permitted because intelligence (voice, teletypewriter) can be carried on a fairly narrow band of frequencies. Entertainment receivers, on the other hand, must reproduce a wider band of frequencies to achieve their high-fidelity objective.

Q13. What frequency conversion principle is used to develop the IF?

Q14. What is the function of the detector?

Q15. What is the major disadvantage of an fm signal as compared to an AM signal?

SINGLE-SIDEBAND

You know from studying the single-sideband transmitter material in this chapter you may transmit only one sideband of an AM signal and retain the information transmitted. Now you will see how a single-sideband signal is received.

Advantages

Figure 2-11 illustrates the transmitted signal for both AM and ssb. Ssb communications has several advantages. When you eliminate the carrier and one sideband, all of the transmitted power is concentrated in the other sideband. Also, an ssb signal occupies a smaller portion of the frequency spectrum in comparison to the AM signal. This gives us two advantages, narrower receiver bandpass and the ability to place more signals in a small portion of the frequency spectrum.

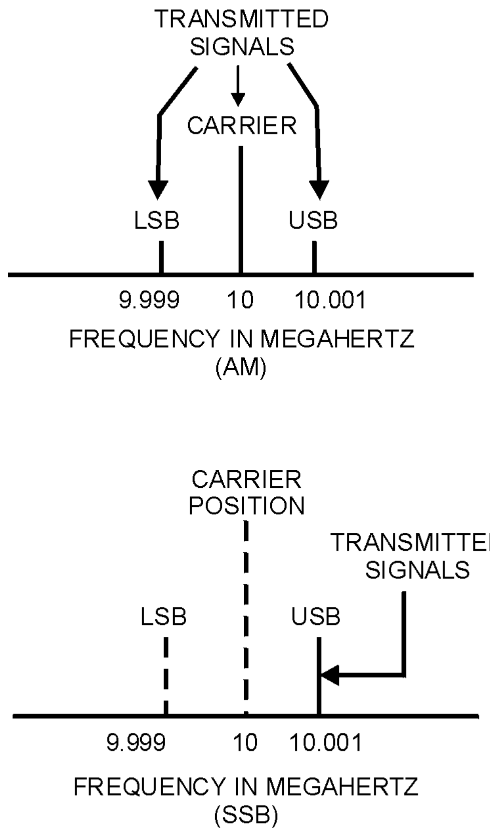

Figure 2-11.—Comparison of AM and ssb transmitted signals.

Ssb communications systems have some drawbacks. The process of producing an ssb signal is somewhat more complicated than simple amplitude modulation, and frequency stability is much more critical in ssb communication. While we don't have the annoyance of heterodyning from adjacent signals, a weak ssb signal is sometimes completely masked or hidden from the receiving station by a stronger signal. Also, a carrier of proper frequency and amplitude must be reinserted at the receiver because of the direct relationship between the carrier and sidebands.

Figure 2-12 is a block diagram of a basic ssb receiver. It is not significantly different from a conventional superheterodyne AM receiver. However, a special type of detector and a carrier reinsertion oscillator must be used. The carrier reinsertion oscillator must furnish a carrier to the detector circuit. The carrier must be at a frequency which corresponds almost exactly to the position of the carrier used in producing the original signal.

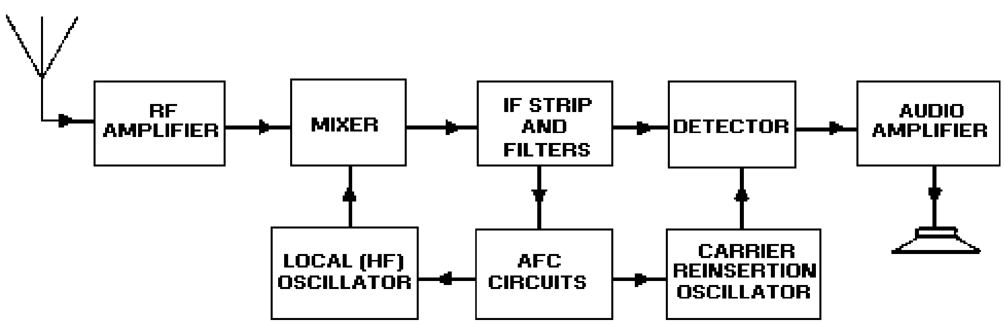

Figure 2-12.—Basic ssb receiver.

Rf amplifier sections of ssb receivers serve several purposes. Ssb signals may exist in a small portion of the frequency spectrum; therefore, filters are used to supply the selectivity necessary to adequately receive only one of them. These filters help you to reject noise and other interference.

Ssb receiver oscillators must be extremely stable. In some types of ssb data transmission, a frequency stability of ±2 hertz is required. For simple voice communications, a deviation of ±50 hertz may be tolerable.

These receivers often employ additional circuits that enhance frequency stability, improve image rejection, and provide automatic gain control (agc). However, the circuits contained in this block diagram are in all single-sideband receivers.

Carrier Reinsertion

The need for frequency stability in ssb operations is extremely critical. Even a small deviation from the correct value in local oscillator frequency will cause the IF produced by the mixer to be displaced from its correct value. In AM reception this is not too damaging, since the carrier and sidebands are all present and will all be displaced an equal amount. Therefore, the relative positions of carrier and sidebands will be retained. However, in ssb reception there is no carrier, and only one sideband is present in the incoming signal.

The carrier reinsertion oscillator frequency is set to the IF frequency that would have resulted had the carrier been present. For example, assume that a transmitter with a suppressed carrier frequency of 3 megahertz is radiating an upper sideband signal. Also assume that the intelligence consists of a 1-kilohertz tone. The transmitted sideband frequency will be 3,001 kilohertz. If the receiver has a 500-kilohertz IF, the correct local oscillator frequency is 3,500 kilohertz. The output of the mixer to the IF stages will be the difference frequency, 499 kilohertz. Therefore, the carrier reinsertion oscillator frequency will be 500 kilohertz, which will maintain the frequency relationship of the carrier to the sideband at 1 kilohertz.

Recall that 1 kilohertz is the modulating signal. If the local oscillator frequency should drift to 3,500.5 kilohertz, the IF output of the mixer will become 499.5 kilohertz. The carrier reinsertion oscillator, however, will still be operating at 500 kilohertz. This will result in an incorrect audio output of 500 hertz rather than the correct original 1-kilohertz tone. Suppose the intelligence transmitted was a complex signal, such as speech. You would then find the signal unintelligible because of the displacement of the side frequencies caused by the local oscillator deviation. The local oscillator and carrier reinsertion oscillator must be extremely stable.

Q16. What two components give a ssb receiver its advantages over an AM superheterodyne receiver?

RECEIVER CONTROL CIRCUITS

This section deals with circuits that control receiver functions. We will explain how some of the basic manual and automatic receiver control functions work.

Manual Gain Control (mgc)

You learned previously that high sensitivity is one of the desirable characteristics of a good receiver. In some cases high sensitivity may be undesirable. For example, let's suppose the signals received from a nearby station are strong enough to overload the rf sections of your receiver. This may cause the audio output to become distorted to the point of complete loss of intelligibility. To overcome this problem, you can use manual gain control of the rf section. By using the manual gain control, you can adjust the receiver for maximum sensitivity and amplify weak input signals. When you receive a strong input signal, the rf gain may be reduced to prevent overloading. A typical manual gain control circuit for a receiver is illustrated in figure 2-13. Let's go through the basic circuitry.

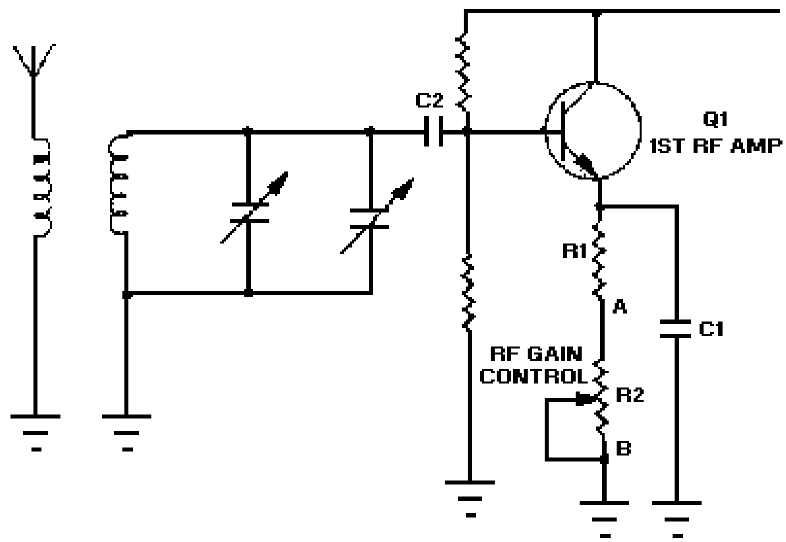

Figure 2-13.—Typical rf gain control.

C1 is an emitter bypass capacitor. Resistors R1 and R2 develop emitter bias for the amplifier. C2 provides dc isolation between the tank and the base of transistor Q1. You should recall from your studies of NEETS, Module 7, *Introduction to Solid-State Devices and Power Supplies*, and Module 8, *Introduction to Amplifiers*, that amplifier gain may be varied by changing bias. Potentiometer R2, the rf gain control, is nothing more than a manual bias adjustment. When the wiper arm of R2 is set at point B, minimum forward bias is applied to the transistor. This causes the amplifier to operate closer to cutoff and reduces gain. When you move the control toward point A, the opposite occurs. R1 limits the maximum conduction of Q1 when R2 is short circuited. You may run into an alternate biasing method when the transistor is operated near saturation. In that case, a large change in gain would again be a function of bias.

Manual Volume Control (mvc)

Figure 2-14 shows the circuitry for a common method of controlling volume in a superheterodyne receiver. C1 and R1 form an input signal coupling circuit and are also the means of controlling the level applied to the audio amplifier. R1, R2, and R3 develop forward bias and set the operating point for the transistor amplifier. R4 is the collector load resistor for Q1, and C3 is the output coupling capacitor. Potentiometer R1 in the circuit shown causes the input impedance of the stage to remain fairly constant. The signal from the preceding stage is felt across R1. By adjusting R1, you can change the input level to Q1 and vary the output amplitude.

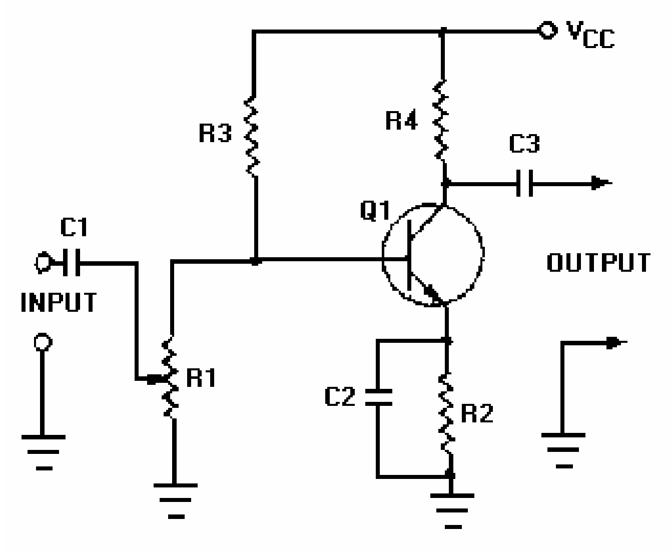

Figure 2-14.—Typical manual gain/volume control.

Automatic Gain/Volume Control (agc/avc)

Output volume variations of a receiver often result from variations in the input signal strength. Changes in input signal strength occur when we change stations or when we experience fading because of changing atmospheric conditions. The function of an AUTOMATIC GAIN CONTROL, also referred to as an AUTOMATIC VOLUME CONTROL, is to limit unwanted variations in the output of the receiver caused by variations in strength of the received signal input. A receiver without agc would require continuous manual readjustment to compensate for received signal changes so that it could maintain a constant output level.

Signals from stations operating at the same power level may not reach the receiver antenna with the same power. This is because of differences in transmission distances, carrier frequencies, atmospheric conditions, and obstructions between the transmitter and receiver antennas.

You might draw the conclusion that an agc network is not necessary when the receiver is operating on a single station. However, this is not true; atmospheric conditions may cause the signal strength to vary (fade in and out), or the antenna may receive components of the signal which have traveled along different paths. For example, one component may travel directly from the antenna, and another may have been reflected from a distant object. The two signals will sometimes be in phase and at other times be out of phase, thus tending to reinforce or cancel each other. The result is a variation in signal strength at the receiver antenna. This variation in signal strength is often referred to as FADING. The effect of fading in the output signal voltage of an rf stage is best demonstrated by the following example: An rf amplifier connected to a receiving antenna has a voltage gain of 100. If the antenna receives an input signal of 10 microvolts, the output voltage is computed as follows:

$$100 \times 10 \text{ microvolts} = 1{,}000 \text{ microvolts}$$

$$\text{or}$$

$$1 \text{ millivolt.}$$

With the output voltage equal to 1 millivolt, and if fading is to be avoided, the output voltage must remain at 1 millivolt. However, if a reflected signal is received that is approximately one-half the strength (5 microvolts) of the original and is in phase with the original signal, the total input signal to the receiving antenna will increase to 15 microvolts. To maintain the desired 1 millivolt of output signal, you must somehow reduce the gain of the rf amplifier. With an input of 15 microvolts and a desired output of 1 millivolt (1,000 microvolts), the gain of the amplifier must be reduced to:

$$\frac{1{,}000 \times 10^{-6} \text{ volts}}{15 \times 10^{-6} \text{ volts}} = 66.7$$

When the 10-microvolt original signal and the 5-microvolt reflected signal are out of phase with each other, the signal strength at the receiving antenna will decrease to 5 microvolts. If we want to maintain our original 1,000-microvolt output signal, the voltage gain of the amplifier must be increased as follows:

$$\frac{1{,}000 \times 10^{-6} \text{ volts}}{5 \times 10^{-6} \text{ volts}} = 200$$

A variation of amplifier gain, similar to the example, is necessary if we are going to compensate for input signal strength variations. The required amplifier gain variations can be accomplished automatically by the addition of an agc circuit within the receiver. Let's take a look at the methods and circuits used to produce agc and the manner in which agc (avc) controls receiver gain.

CIRCUITRY.—Figure 2-15 is a block diagram representing agc feedback to preceding stages. The detector circuit has a dc component in the output that is directly proportional to the average amplitude of the modulated carrier. The agc circuitry uses this dc component by filtering the detector output to remove the audio and IF components and by applying a portion of the dc component to the preceding stages. This agc voltage controls the amplification of any or all of the stages preceding the detector stage. Solid-state receivers may use either positive or negative voltage for agc. The type of transistors used and the elements to which the control voltage is applied determine which type we will have.

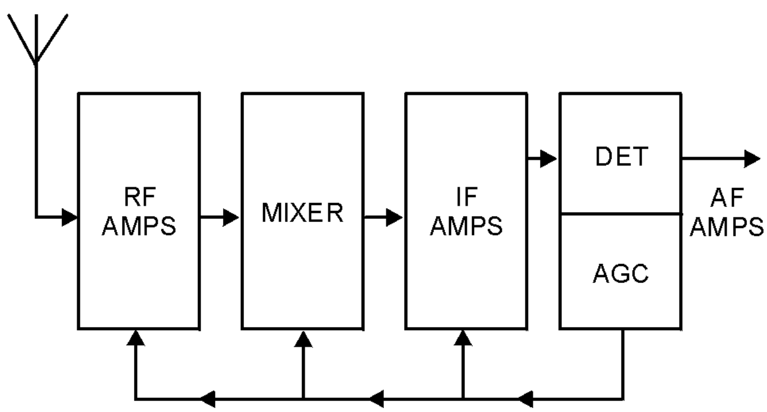

Figure 2-15.—Block diagram showing agc application.

The circuit shown in figure 2-16 produces a positive agc voltage. Transformer T1, diode CR1, capacitor C1, and resistor R1 comprise a series diode detector. The agc network is made up of R2 and C2. With normal detector operation and the positive (+) potential shown at the input, CR1 conducts. Conduction of the diode will cause a charging current (shown by the dashed line) to flow through agc capacitor C2 and agc resistor R2. This charging current develops a voltage across C2. When the potential across T1 reverses, the diode will be reverse biased and will not conduct. When this happens, the charging current ceases and C2 begins to discharge. The discharge path for C2 is shown by the solid arrows. The discharge path time constant of C2, R1, and R2 is chosen to be longer than the period (1/f) of the lowest audio frequency present in the output of the detector. Because of the longer time constant, C2 will not discharge much between peaks of the modulating signal, and the voltage across C2 will be essentially a dc voltage. This voltage is proportional to the average signal amplitude. Now, if the signal strength varies, C2 will either increase or decrease its charge, depending on whether the signal increases or decreases. Since the charge on the agc capacitor responds only to changes in the average signal level, instantaneous variations in the signal will not affect the agc voltage.
