You should remember that, depending on transistor types, the receiver may require either a positive or a negative agc voltage. A negative agc voltage could be easily obtained by reversing CR1. Once the values for R2 and C2 have been selected, the voltage divider action of the components is fixed, and the circuit operates automatically without further adjustment. If the average amplitude of the signal increases, the charge on C2 will also increase. If the signal amplitude decreases so does the charge on C2.

The agc voltages in a receiver provide controlled degenerative feedback. By adjusting the operating point of an amplifier, you can control the gain. Under no-signal conditions, bias of the rf and IF amplifiers is developed by standard means, such as self bias. With an applied signal, an agc voltage is developed, which in conjunction with normal biasing methods develops the operating bias for the amplifiers.

TRANSISTOR AMPLIFIER GAIN.—You have seen how a dc voltage that is obtained at the output of the agc network is proportional to, and will reflect, the average variations of the average signal level. Now all we have to do is use this agc voltage to control the amplification of one or more of the preceding amplifiers. Figure 2-17 illustrates a common-emitter amplifier with agc applied to the base element. A change in the agc voltage will change the operating point of the transistor and the dc emitter current. In this circuit, R1 and R4 form a voltage divider and establish no-signal (forward) bias on the base. Since a pnp transistor is used, the base has a negative potential. The agc voltage from the detector is positive with respect to ground and is fed to the base through dropping resistor R2. You will find when the dc output of the detector increases (because of an increase in the average signal level) the agc voltage will become more positive. This increased positive potential is applied to the base of Q1, which decreases the forward bias of Q1 and decreases the gain of the amplifier. Agc, in this application, works with controlled degenerative feedback. Use of an npn transistor, in the same configuration, would require the agc voltage to possess a negative potential.

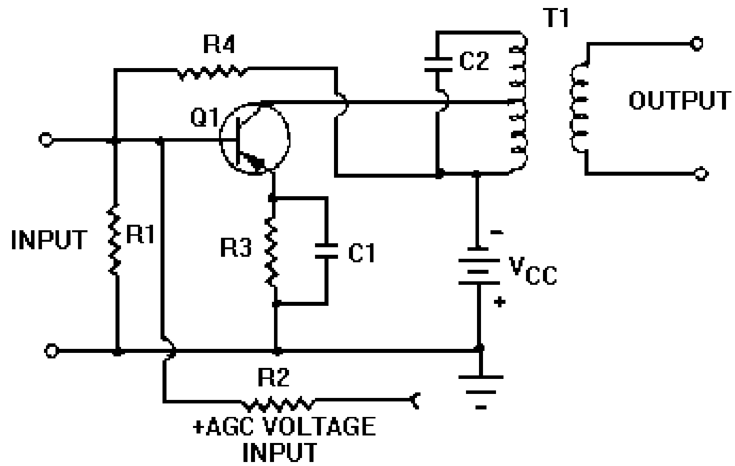

Figure 2-17.—Common emitter amplifier with agc.

FORWARD AND REVERSE AGC.—When we use an agc voltage to cause degeneration by driving the amplifiers toward cutoff, it is referred to as REVERSE agc. Figure 2-18 shows the type of agc circuitry normally used with this method. A second method that uses agc is an application called FORWARD agc. In the case of forward agc, you'll find the amplifier is driven toward the saturation region of its characteristic curve. (Sometimes referred to as an energy diagram.)

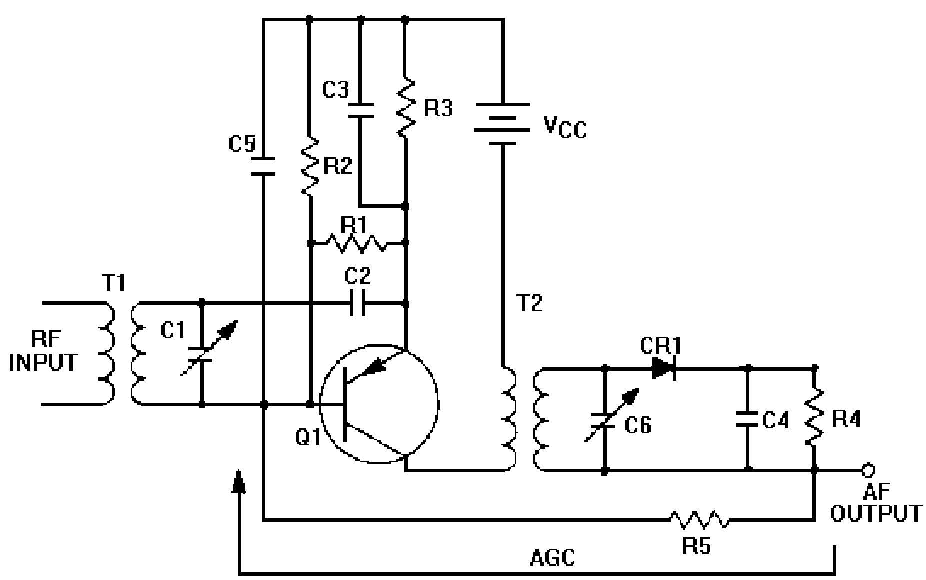

Figure 2-18.—Reverse agc.

Let’s look at our example. Assume the agc voltage is negative. Under this condition, Q1 is self biased; under no-signal conditions, it is operating well up on its characteristic curve. When a signal is applied, negative agc voltage is developed in the detector circuit and fed back to Q1, which increases forward bias. Any increase in signal level causes an increase in agc voltage. An increase in agc voltage increases conduction, which in turn drives the transistor to or near saturation. As the transistor approaches saturation, its gain is correspondingly reduced.

On the other hand, if the input signal level decreases, the negative agc voltage decreases. The forward bias is then reduced, and the transistor operates on a lower portion of its characteristic curve where gain is higher.

Forward agc provides you with better signal-handling capabilities; however, reverse agc is simpler to use, causes less loading of the tuned circuits, and produces smaller variations in input and output capacitance.

Q17. What does manual gain control do to strong and weak signals, respectively?

Q18. What is the purpose of agc/avc in a receiver?

Delayed Automatic Gain Control

The disadvantage of automatic gain control, attenuating even the weak signal, is overcome by the use of delayed automatic gain control (dagc). Let's take a look at the typical dagc circuitry in figure 2-19. This type of system develops no agc feedback until an established received signal strength is attained. For signals weaker than this value, no agc is developed. For sufficiently strong signals, the delayed agc circuit operates essentially the same as ordinary agc.

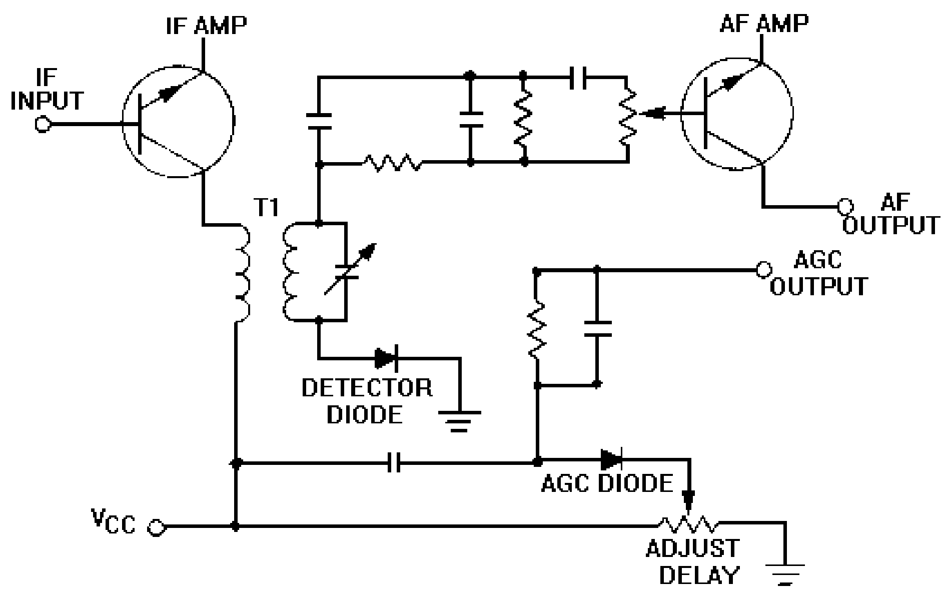

Figure 2-19.—Delayed agc action.

Our circuit uses two separate diodes; one is the detector diode and the other the agc diode. The agc diode is connected to the primary of the last IF transformer and the detector diode to its secondary. A positive bias is applied to the cathode of the agc diode. This keeps it from conducting until a prearranged signal level has been reached. The adjust delay control allows manual control of the agc diode bias. Manual control allows you to select the signal level at which agc is applied. If mostly weak stations are to be received, the setting should be high (no agc until the signal level is high). However, you should set it as low as possible to prevent overloading of the last IF amplifier by stronger signals.

Finally, you must have two diodes to obtain delayed agc. If only one diode were used, the agc would be developed from the detector diode, and there would be no delayed action. Or, if a signal diode were biased to provide the delaying action desired, no signal would pass to the audio amplifier until the bias was exceeded by the input signal.

Beat-Frequency Oscillator

The beat-frequency oscillator (bfo) is necessary when you want to receive cw signals. Cw signals are not modulated with an audio component, you remember, so we must provide one. The action of the rf amplifier, mixer, local oscillator, and IF amplifier is the same for both cw and AM; but the cw signal reaches the detector as a single frequency signal with no sideband components. To produce an af output, you must heterodyne (beat) any cw signal with an rf signal of the proper frequency. This separate signal is obtained from an oscillator known as a beat-frequency oscillator.

Figure 2-20 is a block diagram of a superheterodyne receiver capable of receiving and demodulating a cw signal. The bfo heterodynes at the detector and produces an af output. The detector (second detector) is used primarily because the mixer (first detector) is normally used as the source of agc.

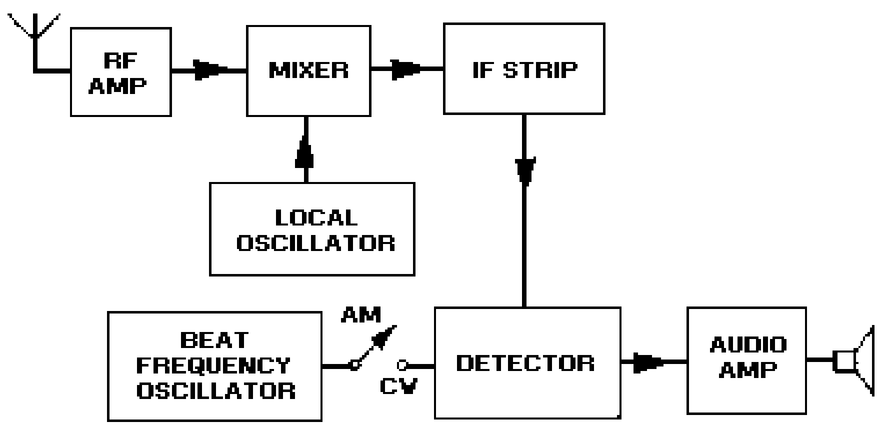

Figure 2-20.—Placement of the beat frequency oscillator.

If the intermediate frequency is 455 kilohertz and the bfo is tuned to 456 kilohertz or 454 kilohertz, the difference frequency of 1 kilohertz is heard in the output. Generally, you will tune the bfo from the front panel of a receiver. When you vary the bfo control, you are varying the output frequency of the bfo and will hear changes in the tone of the output audio signal.

Squelch

The sensitivity of a receiver is maximum when no signal is being received. This condition occurs, for example, when a receiver is being tuned between stations. At this time background noise is picked up by the antenna, and you will hear noise greatly amplified. This noise is highly annoying and occurs because receiver gain is maximum without a signal. You can often overcome this problem by using a circuit called a SQUELCH, NOISE SILENCER, NOISE SUPPRESSOR, or NOISE LIMITER. All of these noise type circuits just clip the peaks of the noise spikes. *Squelch* will actually eliminate noise. Figure 2-21 is a typical circuit of this type. The circuit cuts off receiver output when no input signal is being received. It accomplishes this by blocking either the detector or audio amplifier when no signal is present. Let's take a look at the theory involved in this process.

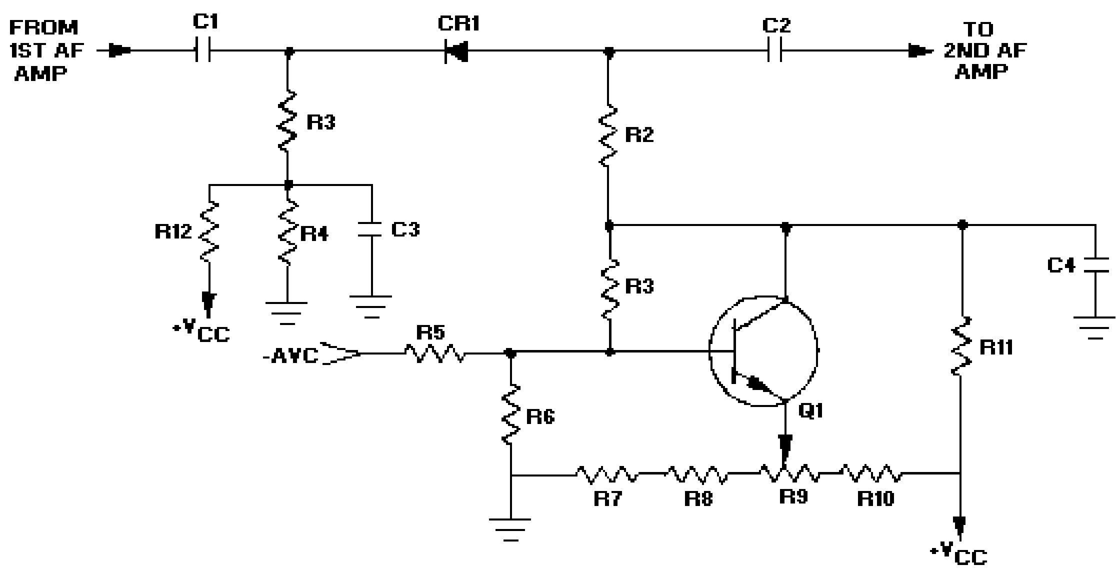

Figure 2-21.—Squelch circuit.

The squelch diode CR1 connects the output of the first af stage to the input of the second. Amplifier Q1 serves as the control transistor for the circuit. The anode and cathode voltages of CR1 are normally biased positive with respect to ground.

With no input signal, R9 is adjusted until Q1 draws enough collector current to reduce its collector voltage and the anode voltage of CR1 to a value below the voltage on the cathode of CR1. At this point the anode voltage of the squelch diode is negative with respect to its cathode, and conduction ceases. Audio output is now reduced to zero and the receiver is silent.

The base of Q1 is connected to the automatic volume control (avc) line. Anytime a signal enters the receiver, a negative avc voltage is applied to the base of Q1. This reduces the collector current and increases the collector voltage, which in turn increases the anode voltage of CR1 until the anode becomes positive with respect to the cathode. Once again diode CR1 will conduct, and the signal will be passed to the second af amplifier. Diode CR1 is effectively a switch controlled by the avc voltage.

Q19. What is a disadvantage of agc?

Q20. What is the main difference between agc and dagc?

Q21. What is the function of the bfo?

Q22. What is the purpose of a squelch circuit?

Audio Tone

The tone of the sound reproduced in the audio section of a receiver depends on several factors. The frequency response of the audio amplifiers determines the degree of amplification provided to different frequencies in the sound spectrum. The size and quality of any loudspeaker used will determine its response to various frequencies. Response of the human ear is the final judge of tonal quality, and that varies with the individual.

Because of these variables, some form of tone control is sometimes used in Navy receivers. Treble tones are defined as the audio frequencies above approximately 3,000 hertz and bass tones are those below approximately 300 hertz. Although several methods of tone control can be used, we are only going to mention the attenuation method. With this method, a decrease in the intensity of one tone can produce an apparent increase in the intensity of another tone. As an example, let's look at tones of 400 and 4,000 hertz produced by a speaker with the same intensity. If we reduce the intensity of the 4,000-hertz tone, the 400-hertz tone will appear to be louder, even though its intensity has not actually changed. You should see from this example that bass emphasis can be accomplished by attenuating treble tones.

The simplest type of tone control is illustrated in figure 2-22. Fixed capacitor C1 parallels the primary winding of the output transformer, effectively shunting the higher frequencies to ground. The size of C1 determines the lowest frequency to be affected. When you select the BASS position of the tone control, C1 is connected and improves bass response by de-emphasizing the treble tones. You can often use this circuit to improve the output of a small speaker with poor treble response.

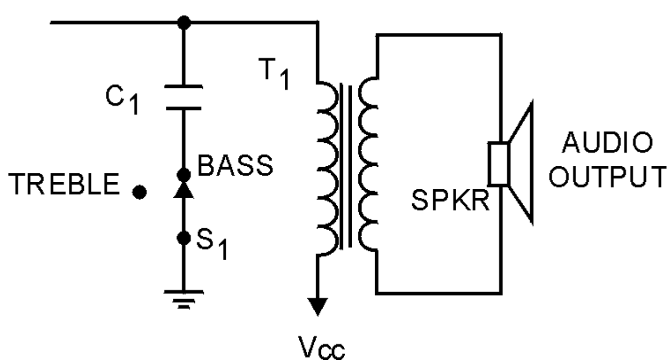

Figure 2-22.—Fixed capacitor tone control.

A continuously variable tone control is illustrated in figure 2-23. Tone control R1 and bypass capacitor C1 act as a variable RC filter. With the wiper arm of R1 in the upper (BASS) position, C1 bypasses the higher frequencies to ground and provides better bass response. When the wiper arm of R1 is in the lower (TREBLE) position, the resistance of R1 is placed in series with C1, which reduces the shunting effect of C1 to high frequencies and improves the treble response. This method gives you the advantage of smooth, continuous tone control at all points between maximum bass and maximum treble response.

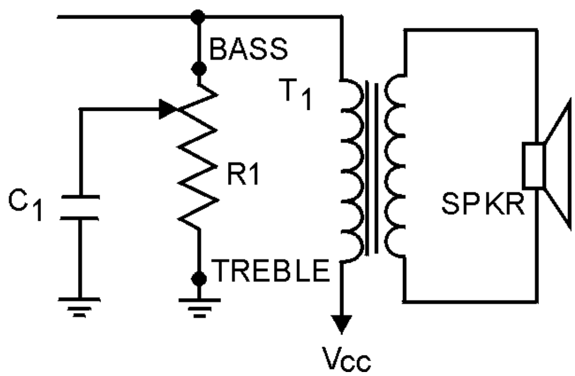

Figure 2-23.—Variable tone control using an RC filter.

A switch-type, variable tone control is illustrated in figure 2-24. With this method we use a three-position switch to provide fixed degrees of tone control. When tone control S1 is in the BASS position, capacitor C1 bypasses the high frequencies and provides bass emphasis. With S1 in the normal (NORM) position, C2 acts as the bypass, and a moderate amount of high-frequency attenuation is accomplished. This position provides balanced bass and treble response. When S1 is in the TREBLE position, C3 acts as the bypass and provides minimum high-frequency attenuation and maximum treble emphasis. As a rule of thumb, you can figure the capacitance of C2 is approximately five times the value of C3, and C1 is approximately ten times the value of C3. For example with C3 at .001 microfarads, C2 would be .005 microfarads, and C1 would be .01 microfarads.

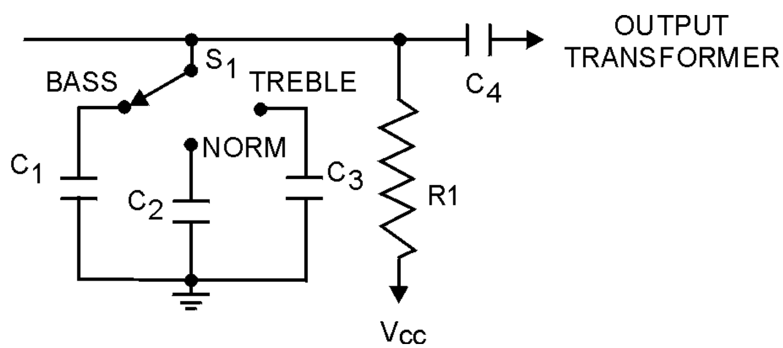

Figure 2-24.—Switch tone control.

Crystal Filters

A quartz crystal, used as a selective filter in the IF section of a communications receiver, is one of the most effective methods of achieving maximum selectivity. It is especially useful when the channel is crowded and considerable noise (both external and internal) is present.

One possible circuit arrangement is shown in figure 2-25. Let's look at the theory involved in understanding this circuit. You can see a crystal in one leg of the bridge circuit. The secondary of the input transformer (T1) is balanced to ground through the center tap connection. The crystal acts as a high Q series resonant circuit. It allows signals within the immediate vicinity of resonance to pass through the crystal to the output coil (L3). The desired signal appears between the center tap of L3 and ground.

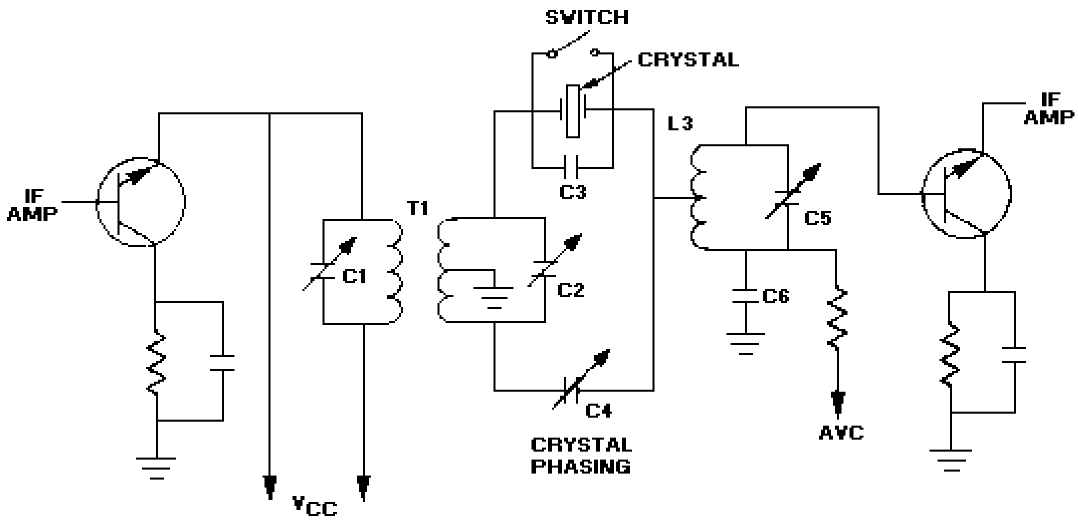

Figure 2-25.—Crystal filter used in the IF section of a superheterodyne receiver.

The capacitance that exists between the crystal holder plates (C3) may bypass unwanted signals around the crystal; therefore, some method must be provided to balance out this capacitance. You accomplish circuit balancing by applying out-of-phase voltages to neutralize any undesired signal voltages. The tap on L3 permits proper impedance matching and is the balanced input to the next stage.

Q23. What does a tone control circuit in a receiver do to the audio signal?

Q24. What is the function of a crystal filter in a receiver?

Automatic Frequency Control

Afc circuits are used in situations where you must accurately control the frequency of an oscillator by some external signal. Basically, this type circuit does two things: It senses the difference between the actual oscillator frequency and the frequency that is desired and produces a control voltage proportional to the difference; it also uses the control voltage to change the oscillator to the desired frequency. Afc circuits are used to control the frequency of sinusoidal oscillators and nonsinusoidal oscillators. Only sinusoidal afc circuits will be covered here. Afc circuits are used in radio receivers, fm transmitters, and frequency synthesizers to maintain frequency stability. Figure 2-26 is a block diagram illustrating afc operation in a receiver. Let's run through the applicable parts of this block diagram.

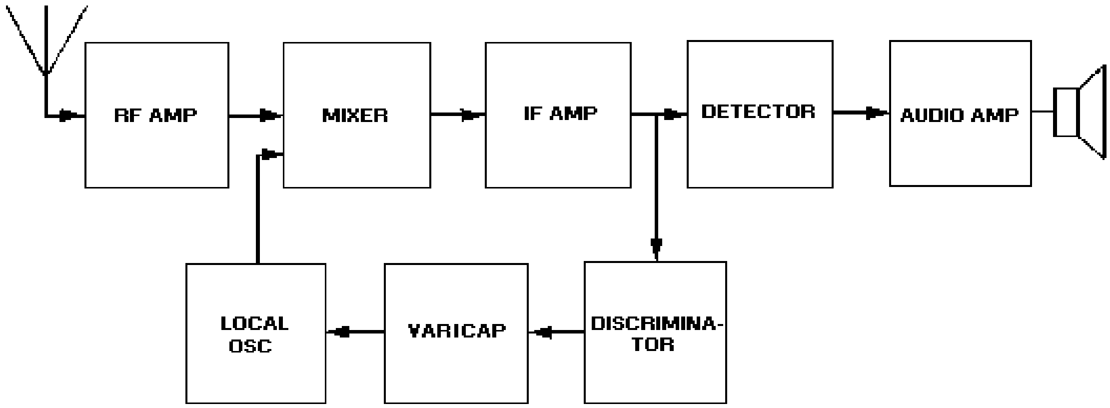

Figure 2-26.—Block diagram of receiver showing automatic frequency control.

The frequency discriminator controls the varicap in this receiver. A varicap is used to keep the IF stable. You may want to review varicap theory in chapter 3 of NEETS, Module 7, *Introduction to Solid-State Devices and Power Supplies* at this point. The varicap application here produces an apparent reactance, which is included in the oscillator frequency control circuitry. For example, let's assume the IF is 455 kilohertz and the local oscillator (lo) is tracking below the incoming station. When the lo output decreases slightly in frequency, the IF will rise. This causes the output of the discriminator to increase the capacitive reactance of the varicap, which increases the oscillator frequency to the desired value. Now let's assume the lo output increases. The IF will then decrease. This causes the discriminator output to decrease the capacitive reactance of the varicap. This will cause the oscillator frequency to decrease.

Figure 2-27 shows another widely used type of afc and its circuitry. This type is commonly referred to as a BALANCED-PHASE DETECTOR or PHASE-DISCRIMINATOR. This circuit uses fixed capacitors and the varying conductance of the diodes to achieve a variable reactance. As you have seen in the block diagram, an afc circuit requires two sections, a frequency detector and a variable reactance. Our detector output is a dc control voltage proportional to the amount of frequency change. This dc voltage is applied directly to the oscillator. The phase inverter input signals are discriminated IF outputs fed to the two diodes 180 degrees out of phase.

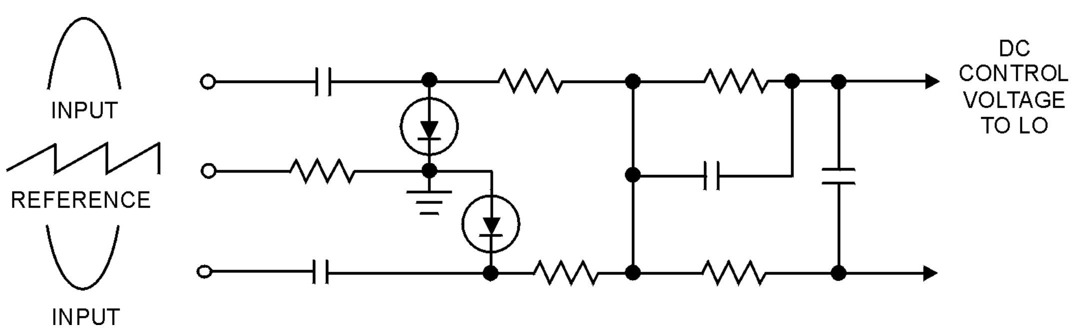

Figure 2-27.—Automatic frequency control (phase discriminator).

A reference voltage is also applied to both diodes. The diodes are biased to conduct only during the peak portions of the input signals. Any change in oscillator frequency will alter the phase relationship between the sawtooth reference voltage and the incoming signals. If this happens, one diode will conduct more than the other and produce a control signal. This system remains unbalanced at all times because any change in frequency is instantaneously corrected. The network between the diodes and oscillator is essentially a low-pass filter. This filter prevents discriminator pulses from reaching the oscillator.

FREQUENCY SYNTHESIS

In present day communications systems, long term accuracy of one part in a million is required from many of the frequency generators (local oscillators) used in communications equipment. Variable frequency oscillators cannot practically achieve this high degree of stability. Therefore, a system known as FREQUENCY SYNTHESIS has been developed to meet the stringent demands for stability. This system uses circuitry that produces a signal frequency through a heterodyning and frequency selection process. This signal is not harmonically related to any of the signals used in the heterodyning process. It is also not related to the selected crystal frequency. This makes the signal unique.

Figure 2-28 is a multiple crystal, frequency synthesizer that produces desired output frequencies by mixing frequencies from several crystal oscillators. Each oscillator uses ten or more crystals to control its operating frequency. This provides for a large number of output frequency combinations. Figure 2-29 is a practical frequency synthesizer in which the harmonics and subharmonics of a single standard oscillator are combined to provide a wide multichoice of output signals. Each of these signals is harmonically related to a subharmonic of the standard oscillator. You will find the primary difficulty encountered in the frequency synthesizers is the presence of spurious signals generated in the "combining mixers." Extensive filtering and extremely careful selection of operating frequencies are required for even the simplest circuits. Spurious frequency problems increase and channel spacing decreases as the range of operating frequencies increases.

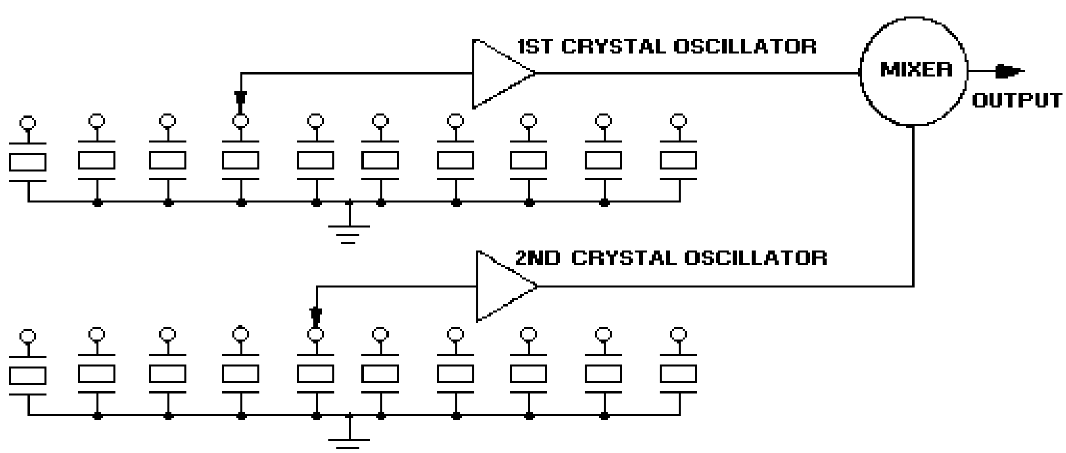

Figure 2-28.—Multiple crystal frequency synthesizer.

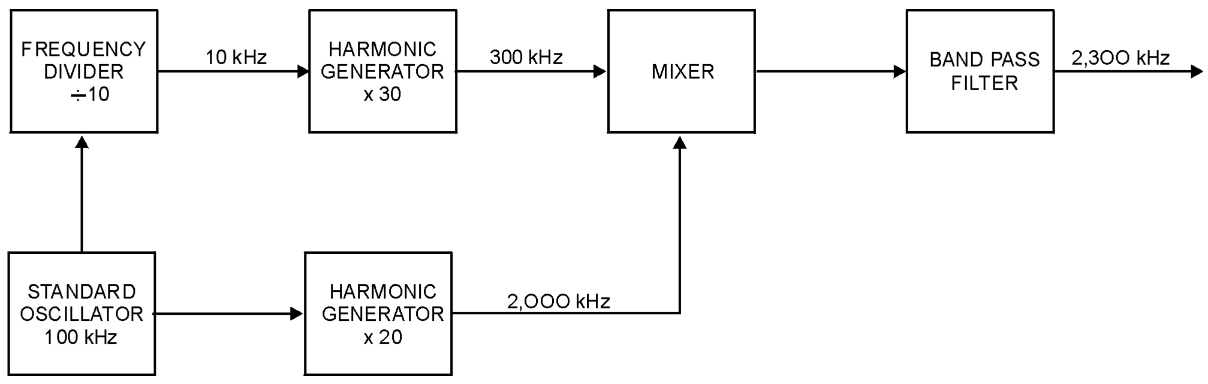

Figure 2-29.—Simple crystal frequency synthesizer.

Q25. What is the primary function of an afc circuit?

Q26. What is frequency synthesis?

AUDIO REPRODUCTION DEVICES

The purpose of audio reproduction devices, such as loudspeakers and headphones, is to convert electrical audio signals to sound power. Figure 2-30 shows you a diagram of a loudspeaker called the PERMANENT MAGNET SPEAKER. This speaker consists of a permanent magnet mounted on soft iron pole pieces, a voice coil that acts as an electromagnet, and a loudspeaker cone connected to the voice coil. The audio signal has been previously amplified (in terms of both voltage and power) and is applied to the voice coil. The voice coil is mounted on the center portion of the soft iron pole pieces in an air gap so that it is mechanically free to move. It is also connected to the loudspeaker cone; as it moves, the cone will also move. When audio currents flow through the voice coil, the coil moves back and forth proportionally to the applied ac current. As the cone (diaphragm) is attached to the voice coil, it also moves in accordance with the signal currents; in so doing, it periodically compresses and rarefies the air, which produces sound waves.

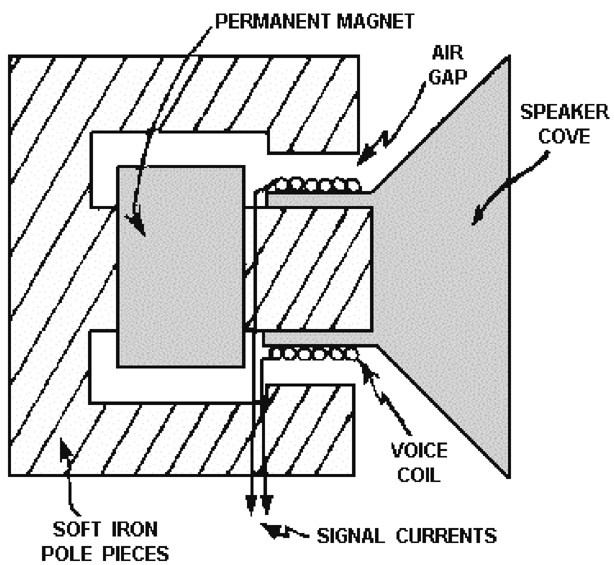

Figure 2-30.—Permanent magnet speaker.

Most speakers of the above type receive their input by means of transformer coupling. This is necessary because of the normal, low impedance of the voice coil. You will find the standard impedance values for this type speaker are 4, 8, 16, and 32 ohms. Other impedance values may be obtained, but those listed are the most common.

While permanent magnet speakers perform reasonably well in the audio range, they have limitations. Most Navy speakers reproduce low audio frequencies quite well, mid-band frequencies fairly well, and high frequencies quite poorly. Let's see why. When the speaker is constructed, only a limited number of turns may be built into the voice coil. This gives us a fixed inductance. At low frequencies, the inductive reactance of the voice coil is relatively low, and large audio currents flow. This provides a strong magnetic field around the voice coil and a strong interaction with the field of the permanent magnet. Low frequency response is excellent. At midband frequencies, inductive reactance increases and less current flows in the voice coil. This produces less magnetic field and less interaction. Midband response is still acceptable in a properly designed speaker. At high audio frequencies inductive reactance is quite high, and little current flows in the voice coil. This results in a greatly reduced voice coil field and little interaction with the permanent magnetic field. Also at high frequencies the interwinding capacitance of the voice coil tends to shunt some of the high audio frequencies, which further reduces the high frequency response.

Frequency response of most permanent magnet speakers falls off at the higher audio frequencies. This problem is normally overcome either by the use of an expensive, specially designed speaker, or through the use of two speakers, one of which is designed to operate well at the higher audio frequencies (tweeter) and one at the lower frequencies (woofer).

As shown in figure 2-31, an electromagnet may be used in place of a permanent magnet to form an electromagnetic dynamic speaker. When we do this, sufficient dc power must be available to energize the field electromagnet. The operation otherwise is much the same as that of the permanent magnet type. This type of speaker is seldom used in Navy equipment.

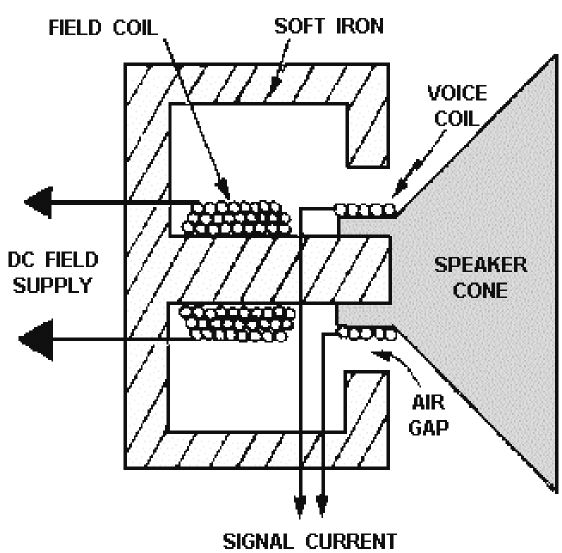

Figure 2-31.—Electromagnetic speaker.

Figure 2-32 shows a diagram of typical headphones used with Navy equipment. The device consists of a permanent magnet and two small electromagnets through which the signal currents pass. A soft iron diaphragm is used to convert the electrical effects of the device into sound power. When no signal currents are present, the permanent magnet exerts a steady pull on the soft iron diaphragm. Signal current flowing through the coils mounted on the soft iron pole pieces develops a magnetomotive force that either adds to or subtracts from the field of the permanent magnet. The diaphragm thus moves in or out according to the resultant field. Sound waves are then reproduced that have an amplitude and frequency (within the mechanical capability of the reproducer) similar to the amplitude and frequency of the signal currents.

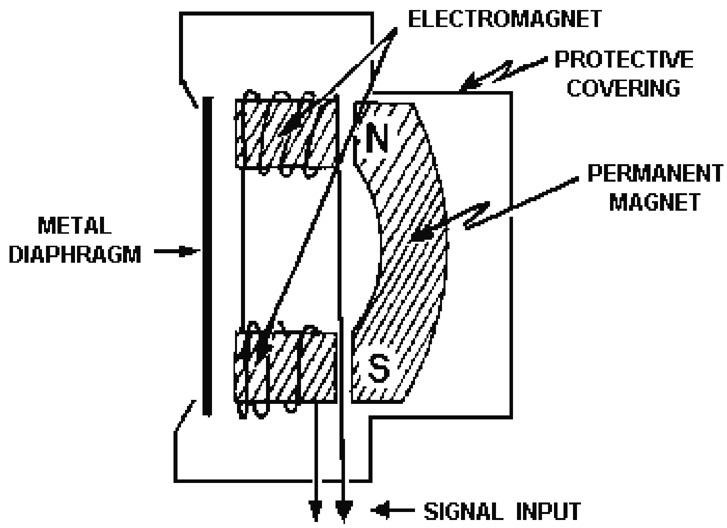

Figure 2-32.—Headphone.

As compared to permanent magnet speakers, standard headphones are considered to be high-impedance devices. Headphone electromagnets are normally wound with many turns of small wire, which provide the larger impedance. Because of the physically small size and inflexibility of the metal diaphragm, the headphones often give poor response to the lower audio frequencies. In the voice range of audio, most standard issue headphones are adequate.

SUMMARY

In this chapter you learned transmitter and receiver fundamentals. We also discussed modes of operation and special controls circuits. Let's review some of these areas.

A **HARMONIC** is an exact multiple of the fundamental frequency. Even harmonics are 2, 4, and so on, times the fundamental. Odd are 3, 5, and so on, times the fundamental frequency.

A **SUBHARMONIC** is an exact submultiple of the fundamental frequency. Even subharmonics are one-half, one-quarter, and so on. Odd subharmonics are one-third, one-fifth, and so on, of the fundamental frequency.

SUPPRESSION is the process of eliminating an undesired portion of a signal.

MULTIPLEXING is a method for simultaneous transmission of two or more signals over a common carrier wave.

An **ORDER-WIRE CIRCUIT** is a circuit between operators used for operations control and coordination.

RECEPTION is when an electromagnetic wave passes through a receiver antenna and induces a voltage in that antenna.

DETECTION is the separation of low-frequency (audio) intelligence from the high (radio) frequency carrier.

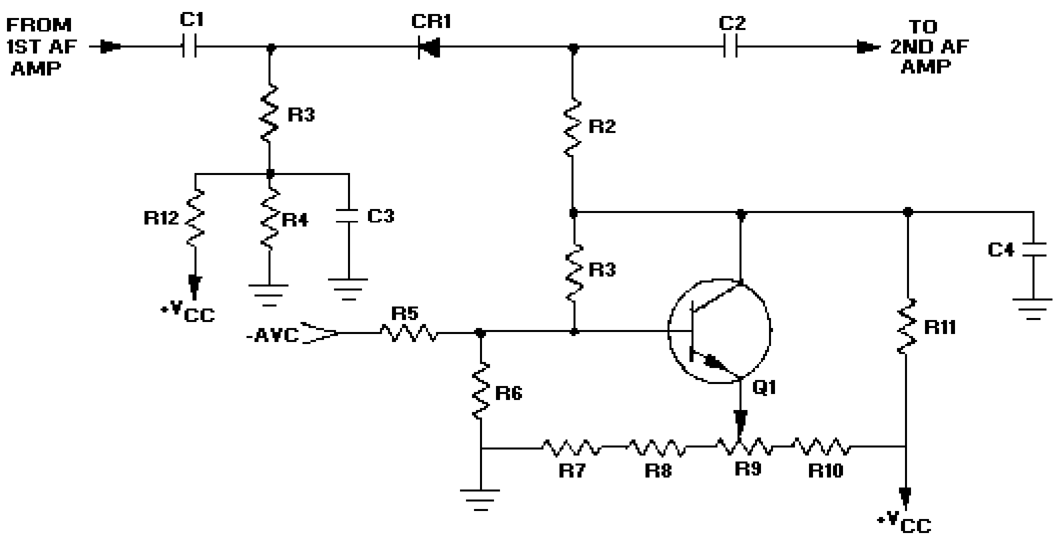
REPRODUCTION is the process of converting electrical signals to sound waves. This sound is speech, music, and so on.

SENSITIVITY of a receiver is the ability to reproduce weak signals. The greater the receiver sensitivity, the weaker the signal that will be reproduced.

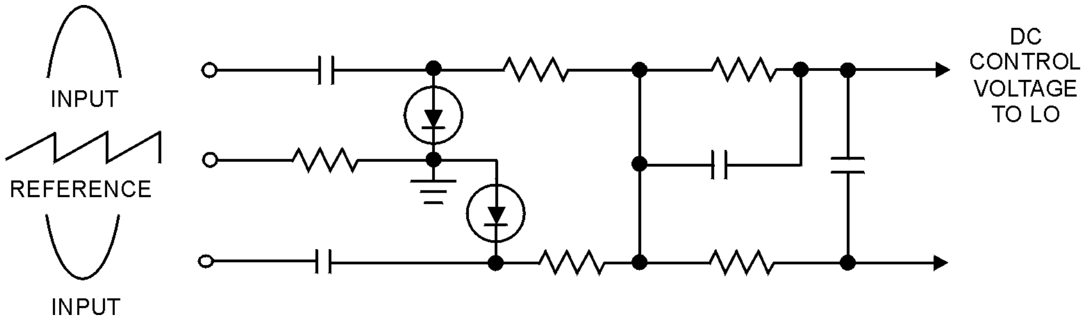
Receiver **SELECTIVITY** is the ability to select the desired signal and reject unwanted signals.

NOISE SILENCER, NOISE SUPPRESSOR, or **NOISE LIMITER**, are circuits that clip the peaks of the noise spikes in a receiver.

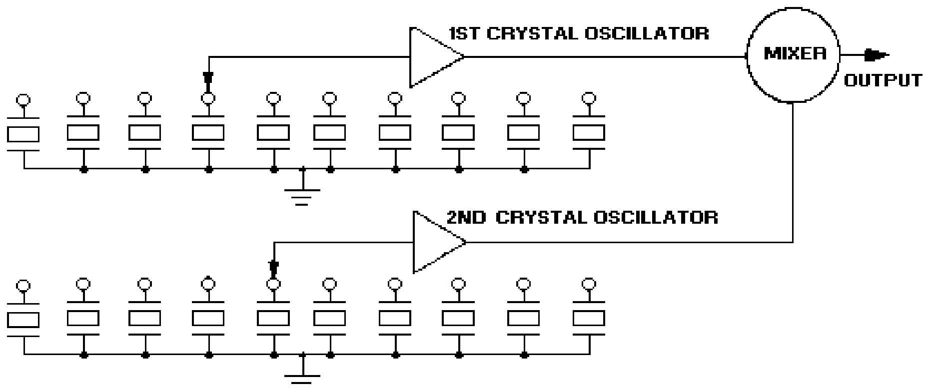
SQUELCH is a circuit that cuts off the output of a receiver when there is no input.



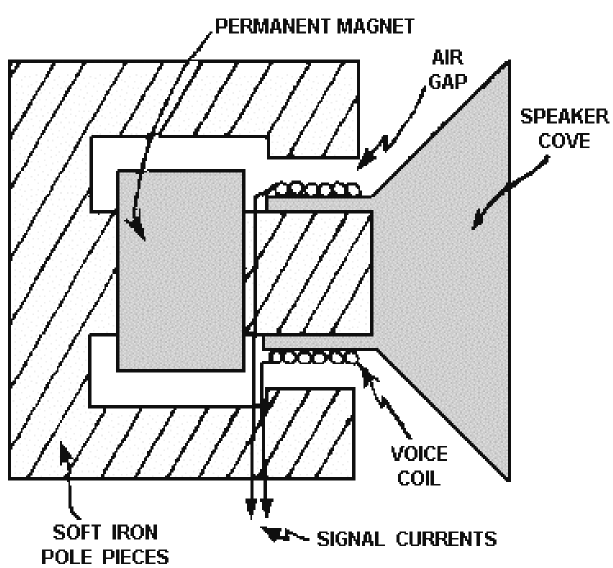
A **BALANCED-PHASE DETECTOR** or **PHASE-DISCRIMINATOR** is a circuit that controls the oscillator frequency (afc).



FREQUENCY SYNTHESIS is a signal-producing process through heterodyning and frequency selection.



A **PERMANENT MAGNET SPEAKER** is one with a permanent magnet mounted on soft iron pole pieces.



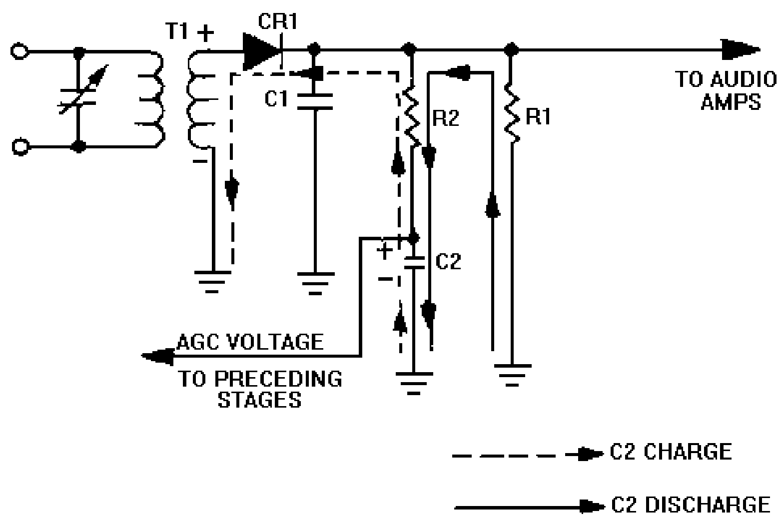
The **FIDELITY** of a receiver is the ability to accurately reproduce at its output the signal at its input.

GANGED TUNING is the process used to tune two or more circuits with a single control.

HETERODYNING is the mixing of the incoming signal with the local oscillator frequency. This produces the two fundamentals and the sum and difference frequencies.

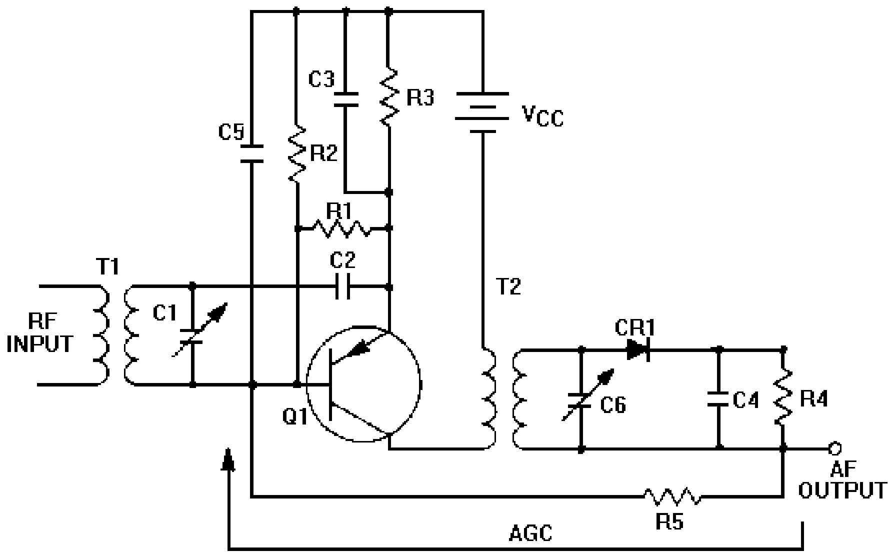
An **IMAGE FREQUENCY** is an undesired frequency capable of producing the desired frequency through heterodyning.

AUTOMATIC VOLUME/GAIN CONTROL is a circuit used to limit variations in the output signal strength of a receiver.



FADING is the variations in signal strength at the antenna of a receiver.

REVERSE AGC is when an amplifier is driven toward cutoff.



FORWARD AGC is when an amplifier is driven toward saturation.

A **BEAT-FREQUENCY OSCILLATOR** is an additional oscillator used in a receiver when the receiver is receiving a cw signal and provides an audible tone.

ANSWERS TO QUESTIONS Q1. THROUGH Q26.

A1. Am, fm, cw, ssb.

A2. It generates an rf carrier at a given frequency within required limits.

A3. Power amplifier.

A4. It converts audio (sound) into electrical energy.

A5. When no modulation is present.

A6. It is an exact multiple of the basic or fundamental frequency.

A7. 600 megahertz.

A8. To obtain higher carrier frequencies.

A9. It saves power and frequency bandwidth.

A10. For operator-to-operator service messages and frequency changes.

A11. Reception, selection, detection, and reproduction.

A12. Sensitivity, noise, selectivity, and fidelity.

A13. Heterodyning.

A14. To extract the modulating audio signal.

A15. Wide bandpass.

A16. A special type of detector and a carrier reinsertion oscillator.

A17. Attenuates the strong and amplifies the weak.

A18. To limit unwanted variations in the output.

A19. Weak signals produce bias, which could result in no usable receiver output.

A20. Dagc does not attenuate weak signals.

A21. It is heterodyned with the rf to produce an audio frequency.

A22. It eliminates noise when no signal is being received.

A23. It controls the amount of bass and treble response.

A24. It is used to achieve maximum selectivity.

A25. It is used to accurately control the frequency of the oscillator.

A26. The process of selecting and/or heterodyning frequencies to produce a signal frequency.

CHAPTER 3

FUNDAMENTAL SYSTEMS EQUIPMENT

LEARNING OBJECTIVES

Upon completion of this chapter you will be able to:

1. State the function of a radio communications handset, a radio set control, and a transfer switchboard.
2. Describe the functions and interrelationships of a radio transmitter.
3. Describe the functions of receive and transmit multicouplers.
4. Describe the differences between the codes used for manual telegraphy and teletypewriter transmissions.
5. Describe the two basic modes of teletypewriter operation.
6. Describe the two types of teletypewriter dc circuits.
7. State the two types of radio teletypewriter shift systems and describe their basic differences.
8. Describe the functions and interrelationships of radio-frequency-carrier shift send and receive systems.
9. Describe the signal flow in an audio-frequency-tone shift system.
10. State the function of the tone terminal set in an audio-frequency-tone shift system.
11. Describe the basic multiplexing process.
12. Describe the three operations performed by a facsimile system.
13. Describe the functions and interrelationships of facsimile equipment.
14. Describe the countermeasures that can be used to eliminate compromising emanations.

EQUIPMENT PURPOSES

A communications system is a collection of equipment used together to do a specific job. You may see this equipment used to send or receive voice communications, or both, or to send, receive, or send and receive teletypewriter information.

Figure 3-1 is a basic block diagram of a voice system. You can see how this equipment is interconnected to form a basic communications system. We are going to look at several of the equipment blocks in detail.

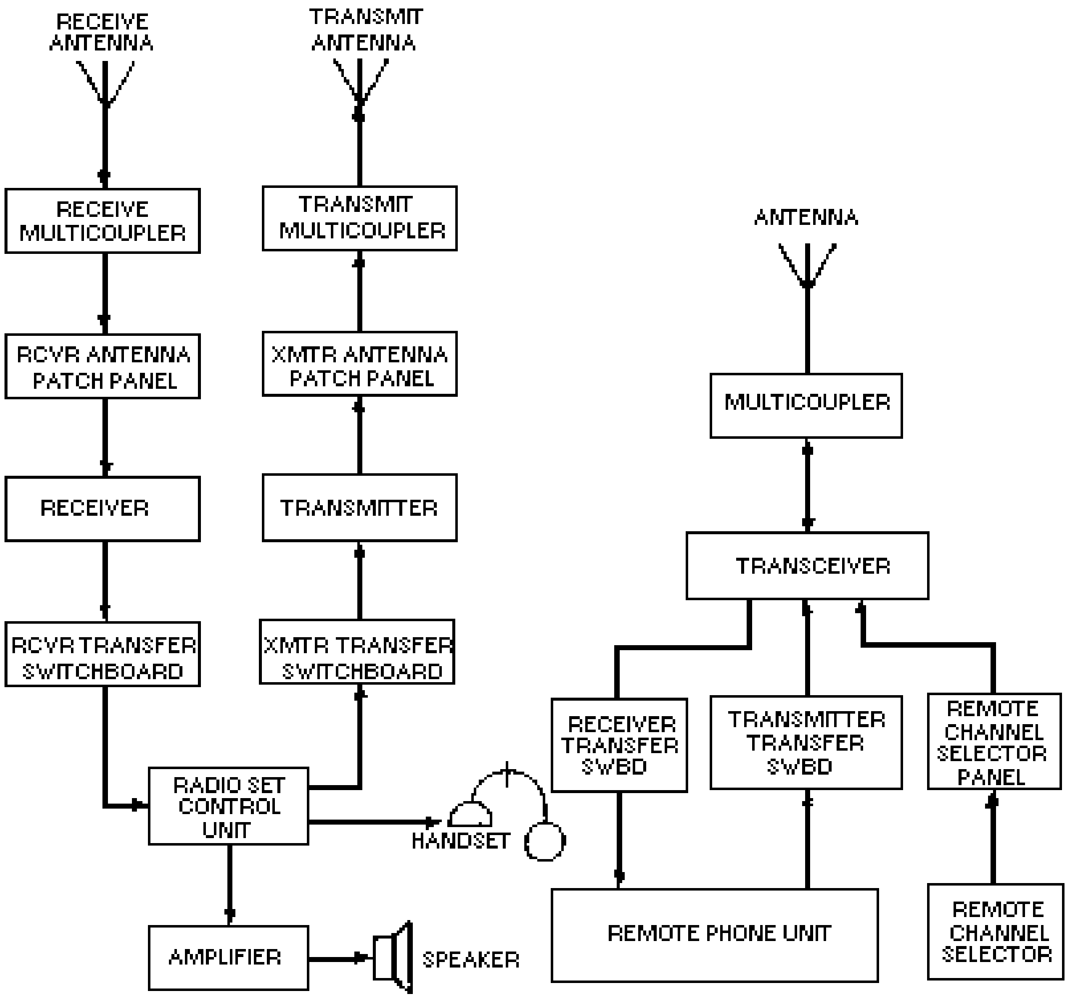


Figure 3-1.—Voice system.

HANDSET

The handset converts acoustical energy (your voice) to electrical energy for use in modulating a radio transmitter. It also converts electrical energy to acoustical energy for reproduction of a received signal. When the push-to-talk button is depressed on the handset, the dc keying circuit to the transmitter is closed, placing the transmitter on the air.

Handsets are normally connected to a radio set control unit.

RADIO SET CONTROL UNIT

The radio set control unit shown in figure 3-2 provides a capability to remotely control some radiophone transmitter functions and the receiver output. Some of the controls are used for turning the transmitter on and off. Others are used for voice modulating the transmission (or keying when cw operation is desired). You can even control the audio output level of the receiver and silence the receiver when transmitting.

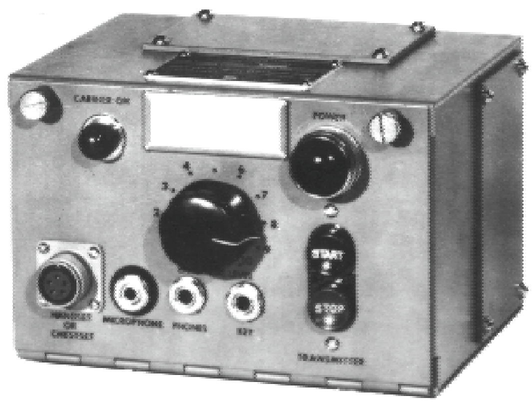

Figure 3-2.—Radio set control unit.

Under standard operating conditions up to four of these units can be used in parallel with a single transmitter and receiver group to provide additional operating positions. This setup is often found aboard ship where a transmitter and/or receiver is controlled and operated from several locations such as the bridge or the combat information center.

TRANSFER SWITCHBOARDS

A transmitter transfer switchboard provides the capability to transfer remote control station functions and signals to transmitters. Figure 3-3 is a representative transfer switchboard that provides the capability for selectively transferring any one, or all, of ten remote control station functions and signals to any one of six transmitters. The cabinet has ten rotary switches arranged in two vertical rows of five each. Each switch has eight positions. The circuitry is arranged so that you cannot parallel transmitter control circuits; that is, you cannot connect more than one transmitter to any remote control location.

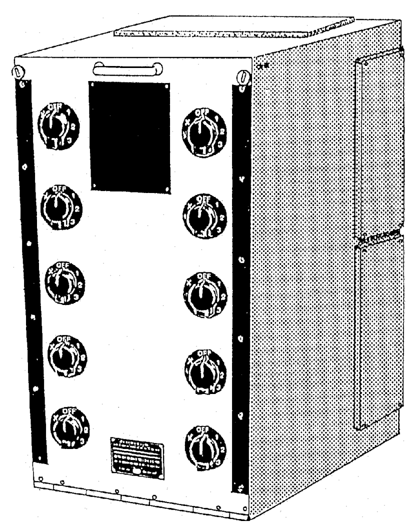

Figure 3-3.—Transmitter transfer switchboard.

Each switch operating knob corresponds to a remote control station. Each switch position (1 through 6) corresponds to a transmitter. One switch position, X, provides for transfer of all circuits to additional transmitter transfer switchboards when more than six transmitters are installed in the system. When the rotary switch is placed in the OFF position the remote control station is removed from the system.

Let's look at an example of one transfer switchboard application. When remote control station number two is to have control of transmitter number three, the switch knob designated number two is rotated until its pointer indicates position three on its dial plate.

The receiver transfer switchboard permits the operator to transfer the audio output from a receiver to a remote control station audio circuit. A representative receiver transfer switchboard is shown in figure 3-4. This switchboard contains ten seven-position switches. Each switch is connected to a remote control station, and each switch position (one through five) is connected to a receiver.

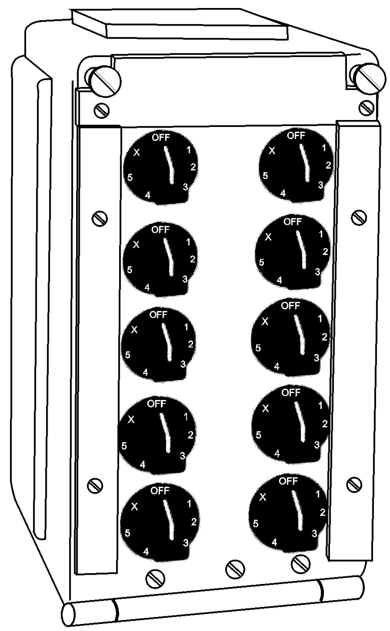

Figure 3-4.—Receiver transfer switchboard.

The X position on each switch allows transfer of circuits to additional switchboards just like with the transmitter transfer switchboard.

Q1. What are the basic functions of a handset?

Q2. What capability does a transmitter transfer switchboard provide?

Q3. What function does a receiver transfer switchboard perform?

TRANSMITTERS

You learned earlier that transmitters may be simple with low power (milliwatts) capabilities. These may be used to send voice messages a short distance. You may also use highly sophisticated units that use thousands (even millions) of watts of power to send many channels of data (for example voice, teletypewriter, television, telemetry) simultaneously over long distances. Let's look at a complete transmitter set.

Radio Transmitting Set

The applications, configurations, and components you will become familiar with here are typical of most general purpose transmitter systems used in the Navy. A specific transmitter is used only for ease of illustration and example.

We will be discussing a 1,000 watt, single-sideband radio transmitting set that is available to the Navy in any one of four setups. The normal configuration has a transmitter capable of voice, continuous wave, and radio teletypewriter transmissions in the 2- to 30-megahertz frequency range. Exact spacing and number of channels available within the frequency spectrum, modes of operation, and frequency range depend on the model of equipment and how it is configured for use. Stack or rack mounting is used in a ship or shore permanent installation with accessory equipment (for example an rf amplifier, coupler control unit, or power supply) to form a complete communications system. One of three different three-phase primary power sources can be used (depending on whether the transmitter is land, air, or shore based) to provide operating power to the set. Combinations available are 115 volts, 400 hertz; or 208/440 volts, 60 hertz.

General Description

Figure 3-5 shows the major units of this set. They are the radio transmitter, the radio frequency amplifier, the power supply, and the electrical equipment shock mount base. An antenna coupler group (consisting of a coupler and coupler control unit) is normally used to match the impedance of the system to a 50-ohm transmission line. If you want to operate with any 50-ohm antenna system, terminating connections are available.

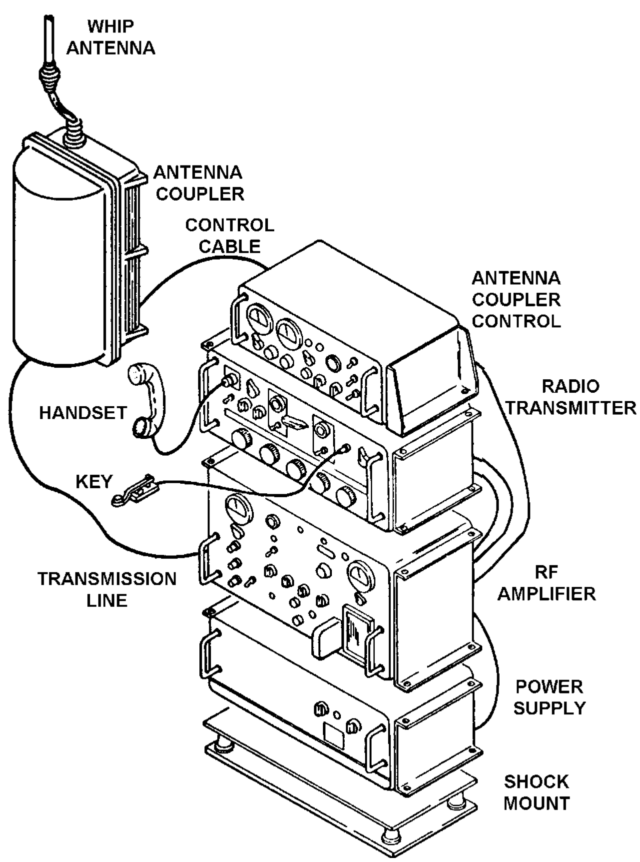

Figure 3-5.—Radio transmitting set.

The transmitter unit provides an upper sideband (usb), lower sideband (lsb), independent sideband (isb), cw, fsk, or compatible AM signal. The output of the transmitter has enough power to drive the radio frequency amplifier.

Depending on the model, the transmitter tunes across the frequency range in 100- or 500-hertz increments. Digital circuitry is used to accomplish this process. Transmitter outputs are also applied to the rf amplifier to automatically tune it to the correct frequency. We will go through a detailed breakdown of the transmitter unit later in this chapter.

RADIO FREQUENCY AMPLIFIER.—The rf amplifier unit is a two-stage linear power amplifier that produces an output of 1,000 watts with a nominal input of 100 milliwatts. Nineteen frequency bands are used to cover the operating frequency range. The operating band is automatically selected by digital coding generated by the transmitter. The code controls two motor-driven band switch assemblies. Automatic control circuits protect the unit against overload and compensate for variations in system gain, mode of operation, and loading.

All low voltages required for operation (except two of the relay control voltages) are internally produced. The high voltages required in the amplifier stages are produced by the associated power supply (when using 60 hertz primary power) or the optional internally mounted power supply (when using 400 hertz primary power).

Let's take a look at figure 3-6 to see all the operating controls and indicators located on the front panel. Some controls are used only for initial setup and are protected by a hinged access cover. All connections are made at the rear of the case. The amplifiers and the associated interstage broadband transformer assemblies are cooled by forced ventilation. Cooling air is drawn through a filter on the front panel and exhausted through a port on the rear of the case. You should always take particular care to clean or replace any filter in electronic equipment as a regular part of your preventive maintenance program.

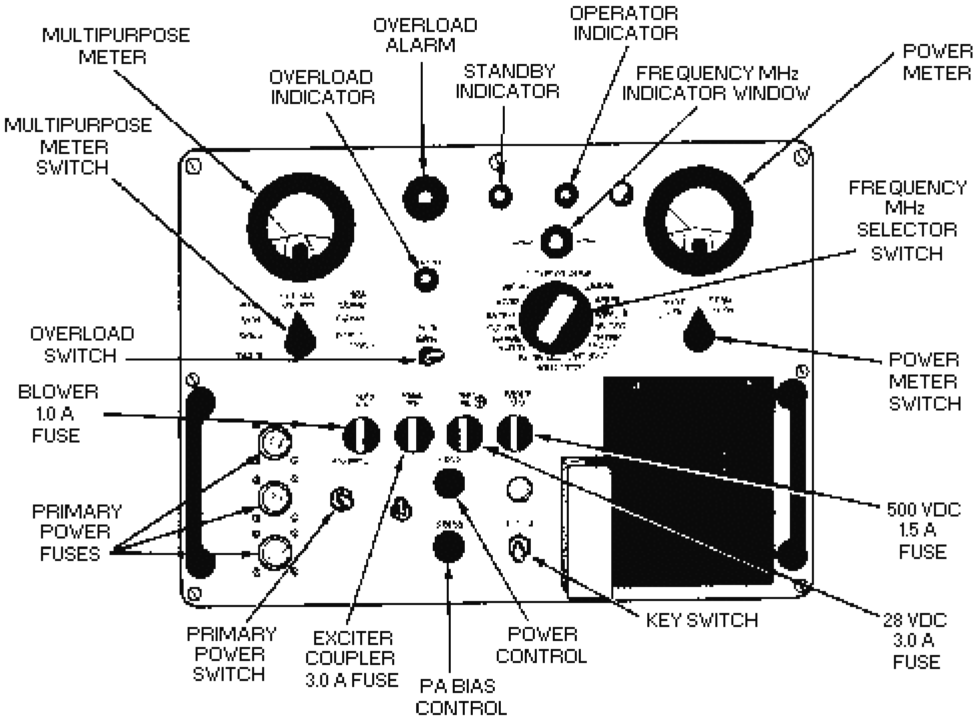

Figure 3-6.—Rf amplifier unit.

POWER SUPPLIES.—One power supply produces operating voltages for the amplifier when operating from a 60-hertz power source. All components of the power supply, except the power transformers, are mounted on a chassis and panel assembly that is hinge-mounted to a metal case. The power transformers are constructed as part of the case and there are no operating controls.

The other power supply produces operating voltages for the rf amplifier when a 400-hertz, three-phase, 115-volt primary power source is used.

ANTENNA COUPLER GROUP.—The antenna coupler group is an automatic antenna tuning system. However, the equipment design includes provisions for manual or semiautomatic tuning. This makes the system adaptable for use with other radio transmitters. The manual tuning capability is useful when a failure occurs in the automatic tuning circuitry. Tuning can also be accomplished without the use of rf power (SILENT TUNING). This method is useful in installations where radio silence must be maintained except for brief transmission periods.

The antenna coupler matches the impedance of a 15-, 25-, 28-, or 35-foot whip antenna to a 50-ohm transmission line at any frequency in the 2- to 30-megahertz range. Control signals from the associated antenna coupler control unit automatically tune the matching network in less than five seconds. During manual and silent operation, tuning is accomplished by the operator with the controls mounted on the antenna coupler control unit. A low power (not to exceed 250 watts) cw signal is required for tuning. Once tuned, the coupler is capable of handling 1,000 watts peak envelope power (pep).

The coupler is enclosed in an aluminum, airtight, pressurized case. Six mounting feet enable the unit to be attached to the mast of a ship at the base of a whip antenna. The coupler is pressurized with dry nitrogen to aid internal heat transfer and to prevent corona and arcing. All components of the coupler are secured to a chassis that is mounted to the case so that an air duct exists between the chassis plate and the case. An internal fan circulates the nitrogen over and through the heat-producing elements and then through the air duct. While passing through the air duct, the nitrogen loses its heat to the bottom of the case. This heat is then transferred by convection through fins on the bottom of the case and by conduction through the mounting feet.

Figure 3-7 shows the antenna coupler control unit. This unit provides the power and control signals required to tune the coupler. Control signals are either automatically produced by the coupler control when a tune cycle is initiated or manually produced with the front panel controls.

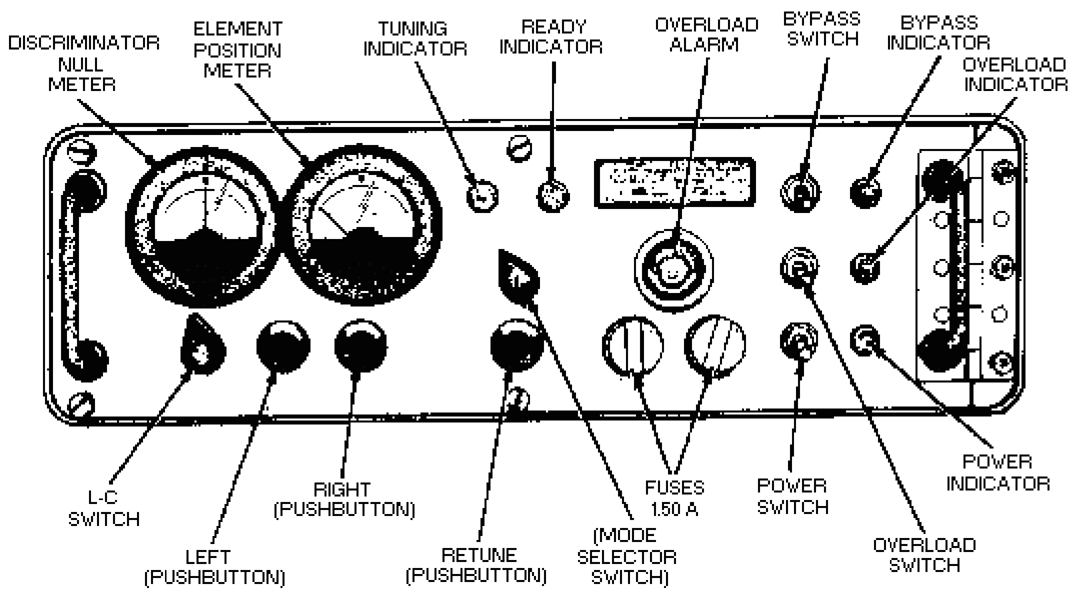

Figure 3-7.—Antenna coupler control unit.

All dc operating voltages are produced from a 115-volt, 48- to 63- or 350- to 450-hertz, single-phase primary power source. Meter and protection circuits are used to give you complete control of the coupler from the remotely positioned coupler control unit.

Q4. If the rf amplifier discussed has an 80 milliwatt input, what would be the maximum output?

Q5. What are the tuning modes for the coupler group discussed?

Q6. What is the purpose of an antenna coupler?

Q7. Why is the coupler pressurized with nitrogen?

RADIO TRANSMITTER.—Figure 3-8 shows the front panel of the radio transmitter unit. The radio transmitter accepts audio or coded intelligence and uses it to modulate one of 280,000 possible operating radio frequencies in the 2.0- to 29.999-megahertz frequency range. Tuning is accomplished digitally by means of five control knobs and a switch located on the front panel. The transmitter has a normal rf output level of at least 100 milliwatts and is designed to be used with an associated rf power amplifier.

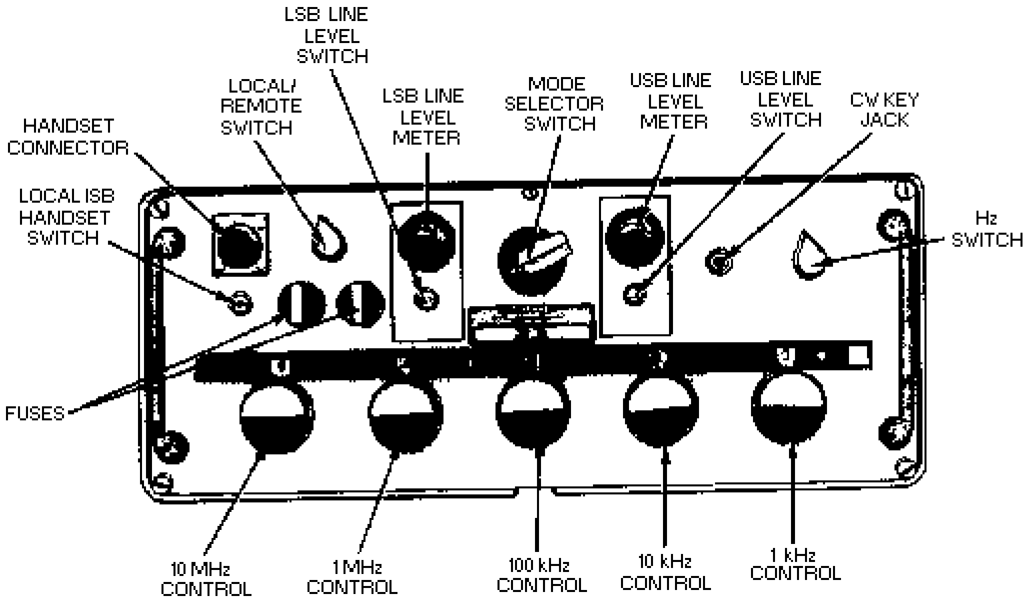

Figure 3-8.—Radio transmitter unit.

When the AM and ssb transmit modes of operation are used, the output from a handset is applied to the transmitter. The voice signals are amplified and used to modulate a 500-kilohertz local carrier that produces a 500-kilohertz IF. The resulting double sideband signal is filtered in the AM mode, amplified, and converted by a triple-conversion process to the desired rf operating frequency. The rf signal is amplified to a nominal 100 milliwatt level. In cw operation, the 500-kilohertz local carrier is inserted directly into the IF amplifiers. The signal is further processed in the same manner as the voice signals in the AM or ssb modes of operation. In fsk operation, the loop current is converted to audio frequencies representing marks and spaces. These audio signals are applied to the audio circuits of the transmitter. Thereafter, these signals are processed in the same manner as the voice signals in AM or ssb modes of operation. A typical radio transmitting set block diagram is shown in figure 3-9.

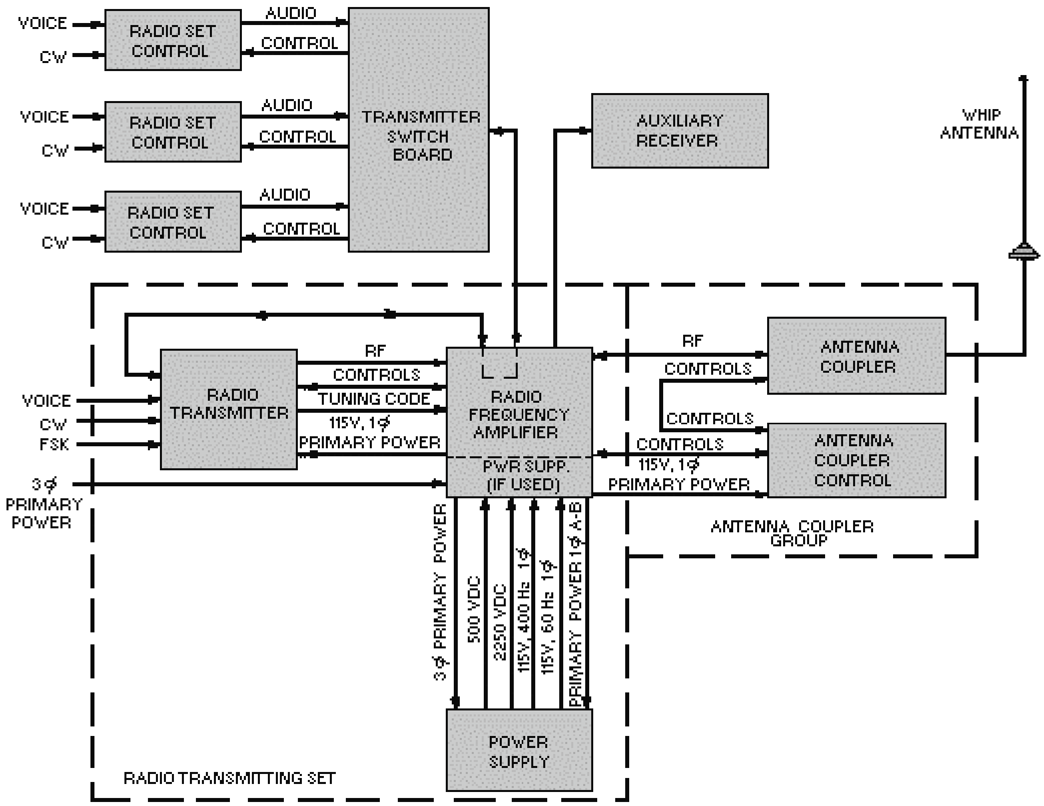

Figure 3-9.—Typical radio transmitting set block diagram.

RECEIVERS

The receiver we will discuss is a triple-conversion superheterodyne, tunable from 2 to 30 megahertz. Triple conversion uses three IF frequencies to give better adjacent-channel selectivity and greater image-frequency suppression. Figure 3-10 shows the front panel of this receiver where tuning is done digitally by five controls and a switch. A display window directly above each control provides a digital readout of the frequency setting. The displayed frequency can be changed in 1-kilohertz increments. The front panel switch allows the operating frequency to be changed in 100- or 500-hertz increments depending on the model. This will provide you with 280,000 discrete frequencies locked to a very accurate frequency standard. You can continuously tune each 1,000-hertz increment by selecting the VERNIER position of the hertz switch. When using the vernier, the full accuracy of the frequency standard is sacrificed. The receiver demodulates and provides audio outputs for the lsb, usb, isb, AM, cw, and fsk types of received signals.

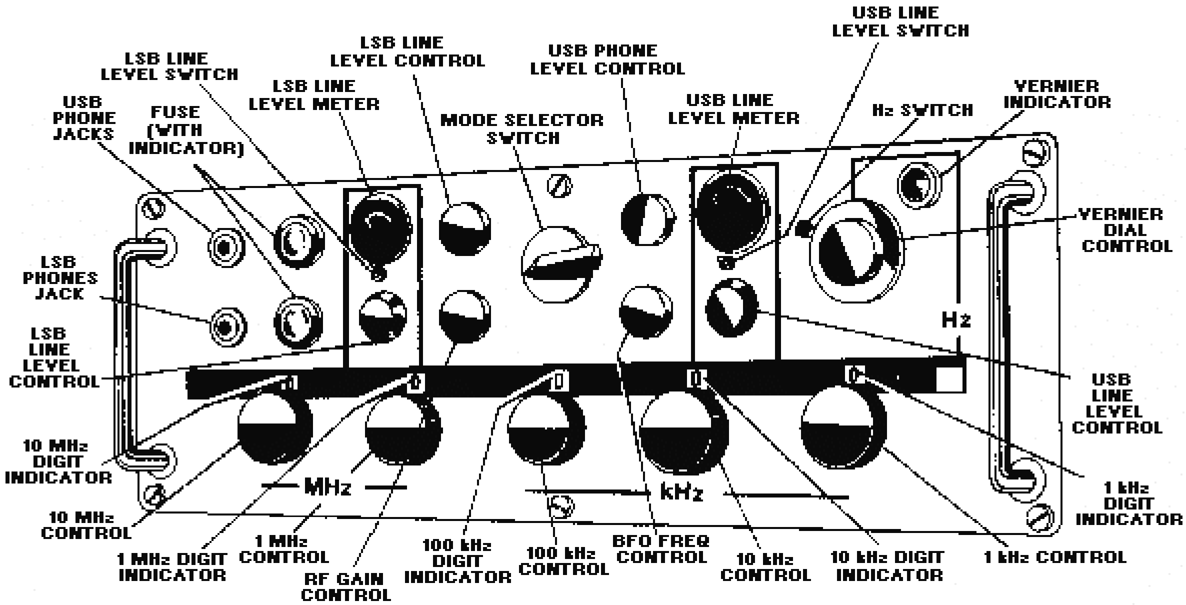

Figure 3-10.—Typical radio receivers

Q8. What are the transmitter operating modes?

Q9. What type of tuning does the receiver use?

ANTENNA DISTRIBUTION SYSTEMS

Receiving antenna distribution systems operate at low power levels and are built to fit a standard 19-inch rack. Each piece of distribution equipment is fitted with termination or patch fittings designed for ease of connecting and disconnecting. A basic patch panel is shown in figure 3-11. Even a fundamental distribution system has several antenna transmission lines and several receivers. Normally a patch panel consists of two basic patch panels. One panel is used to terminate the antenna transmission lines and the other the lines leading to the receivers. Any antenna can be patched to any receiver through the use of patch cords.

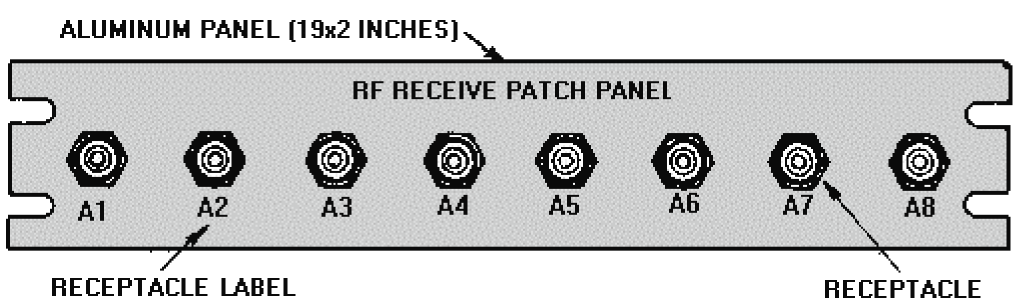

Figure 3-11.—Basic rf receive patch panel.

Many distribution systems are more complex. A complex distribution system to cover most situations is illustrated in figure 3-12. In this system you can patch four antennas to four receivers, or you can patch one antenna to more than one receiver via the multicouplers (multicouplers are covered later in this chapter). You can also patch rf and audio from one compartment to another. A frequency standard is connected (through a distribution amplifier not shown) to the receivers.

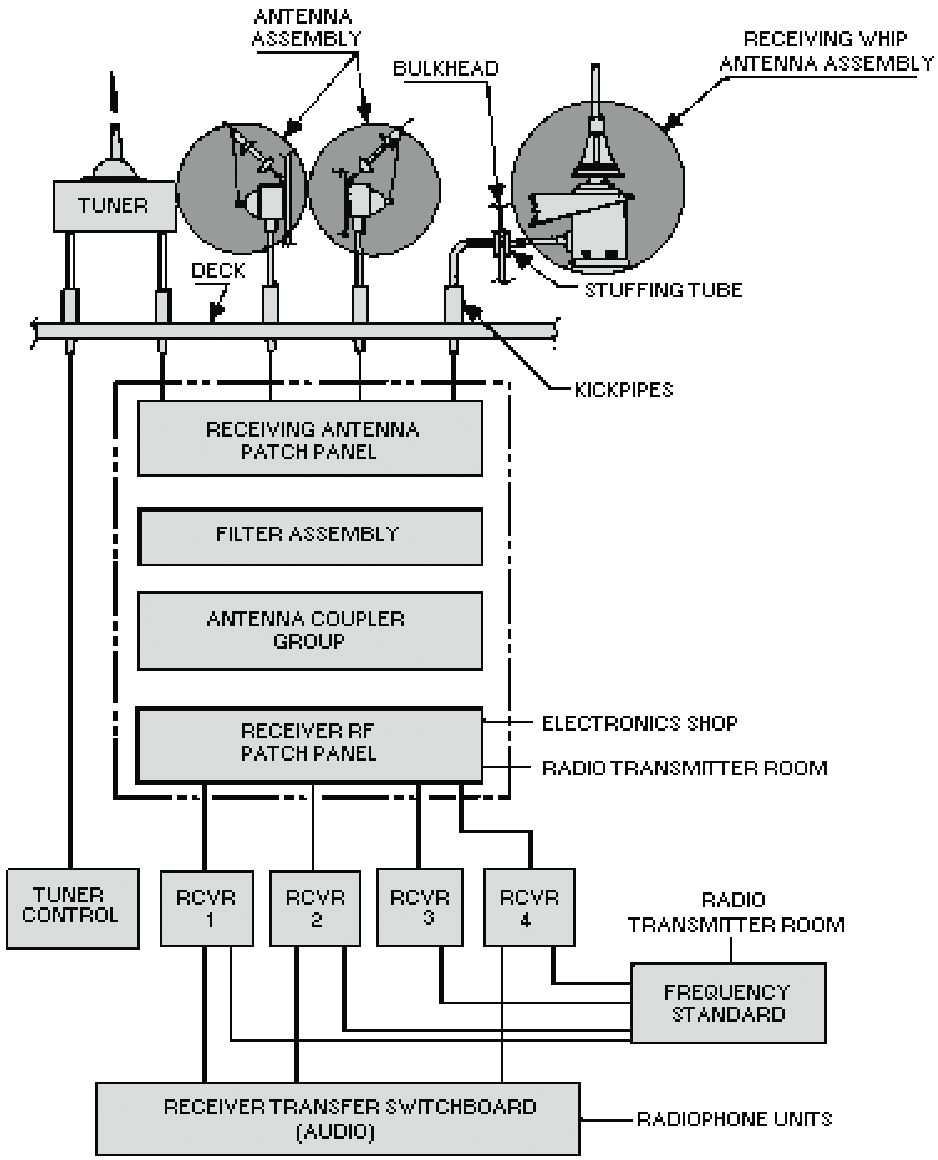

Figure 3-12.—Complex distribution system.

Transmitting antenna distribution systems perform the same functions as receiving systems. However, because of the higher power levels, design and fabrication problems are more difficult. The ideal design would be to have all the transmission lines designed for the highest power level. But because high-power patch cords are expensive, large, and difficult to handle, this approach is seldom followed.

In practice, the basic patch panel we just looked at in figure 3-11 is practical for low power levels. Another type of transmitter patch panel is shown in figure 3-13.

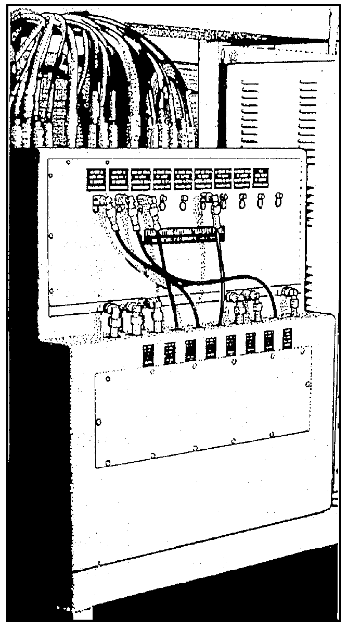

Figure 3-13.—Transmitting antenna patch panel.

This type of transmitting antenna patch panel is interlocked with the transmitter so that no open jack connection can be energized and no energized patch cord can be removed. This provides you with a greater degree of personnel and equipment safety.

Receive Multicoupler

Figure 3-14 is a filter assembly multicoupler that provides seven radio frequency channels in the 14-kilohertz to 32-megahertz range. Any or all of these channels may be used independently of any of the other channels, or they may operate simultaneously. You can make connections to the receiver by means of coaxial patch cords, which are short lengths of cable with plugs attached to each end.

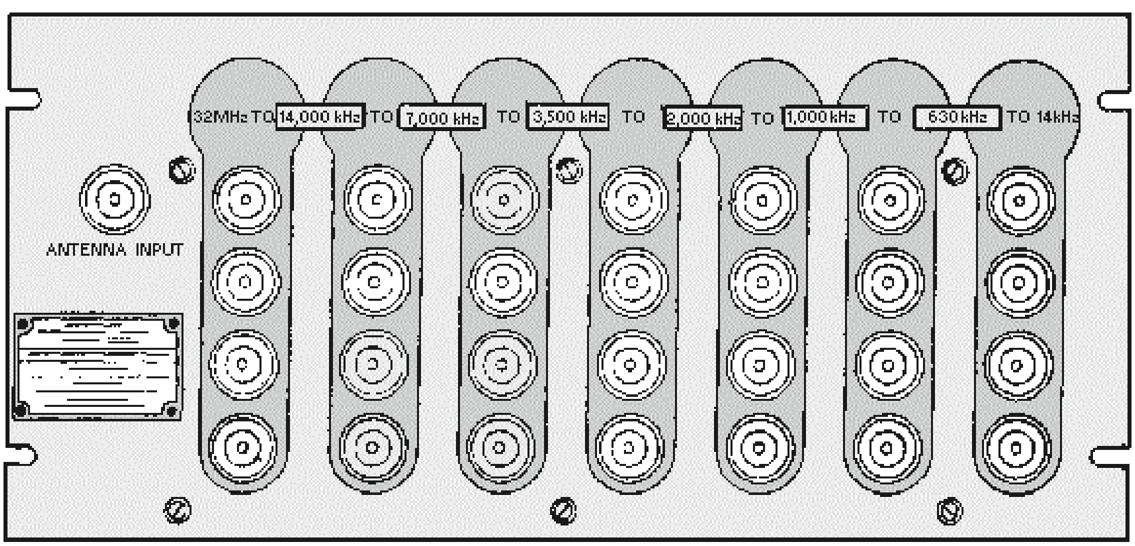

Figure 3-14.—Electrical filter assembly.

A set of nine plug-in type filter assemblies is furnished with the equipment and covers the entire vlf, lf, mf, and hf bands. Only seven of the assemblies may be installed at one time, and you have the option of selecting those you need to cover the most used frequency bands.

Figure 3-12 illustrates how the filter assembly is used in combination with other units to pass an rf signal from an antenna to one or more receivers.

Transmit Multicouplers

Most multicouplers for the hf range are designed for use with either transmitters or receivers, although some are used with both. There are a large number of channels in a multicoupler so that many transmitters can be used at the same time on one antenna. This is especially true in the 2- to 12-megahertz range.

Figure 3-15 shows you an antenna coupler group designed primarily for shipboard use. Each coupler group permits several transmitters to operate simultaneously into a single, associated, broadband antenna. You can see this reduces the total number of antennas required in the limited space aboard ship.

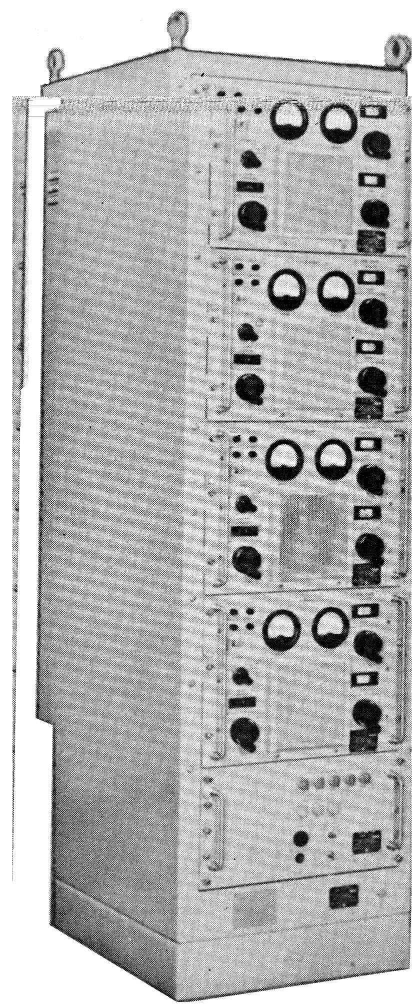

Figure 3-15.—Antenna coupler group.

These antenna coupler groups provide a coupling path of prescribed efficiency between each transmitter and its associated antenna. They also provide isolation between transmitters, tunable bandpass filters, and matching networks.

TELETYPEWRITER AND FACSIMILE EQUIPMENT

In previous areas we have discussed different methods of voice communications. At times, however, the message is too long for practical transmission by voice. To get information or an idea across to another person far away, you may also need a chart, map, or photograph. Teletypewriter (tty) and facsimile equipment allow us to do just that, with ease. Let's see how this is done.

BASIC PRINCIPLES

To give you an idea of how intelligence is sent via teletypewriter, let's take a look at the manual telegraph circuit. This circuit, shown in figure 3-16, includes a telegraph key, a source of power (battery), a sounder, and a movable sounder armature. If the key is closed, current flows through the circuit and the armature is attracted to the sounder by magnetism. When the key is opened, the armature is retracted by a spring. With these two electrical conditions of the circuit, intelligence can be transmitted by means of a teletypewriter code. These two conditions of the circuit are referred to as MARKING and SPACING. The marking condition occurs when the circuit is closed and a current flows; the spacing condition occurs when it is open and no current flows.

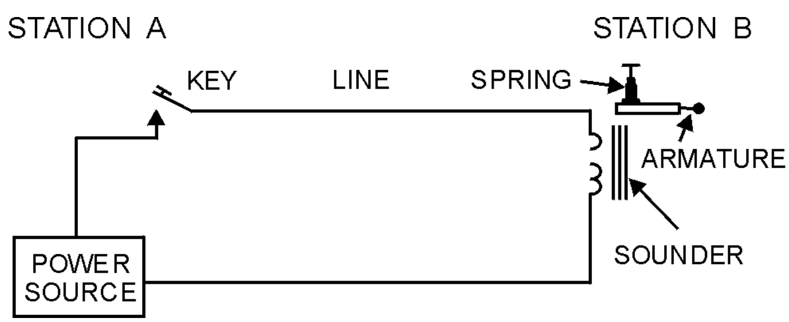

Figure 3-16.—Manual telegraph circuit.

If the key at station A is replaced by a transmitting teletypewriter and the sounder arrangement at station B is replaced by a receiving teletypewriter, the basic teletypewriter circuit (loop) shown in figure 3-17 is formed.

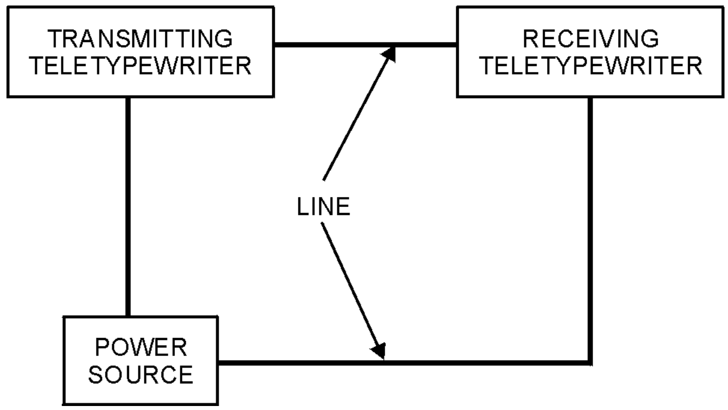

Figure 3-17.—Simple teletypewriter circuit.

If a teletypewriter signal could be drawn on paper, it would resemble figure 3-18. This is the code combination for the letter R. Shaded areas show intervals during which the circuit is closed, and the blank areas show the intervals during which the circuit is open. The signal has a total of seven units. Five of these are numbered and are called INTELLIGENCE units. The first and last units of the signal are labeled START and STOP. They are named after their functions: the first starts the signal, and the last stops it. These are a part of every teletypewriter code signal: the START unit is always spacing, and the STOP unit is always marking.

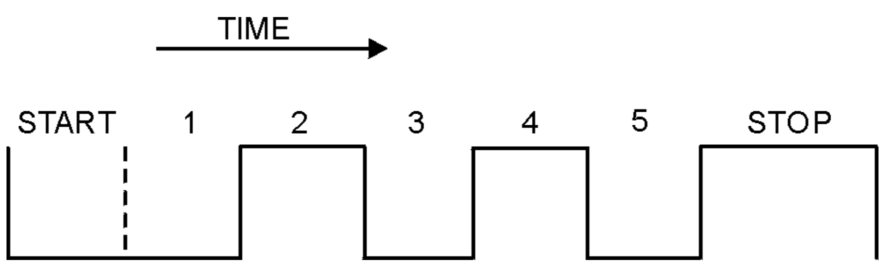

Figure 3-18.—Mark and space signals.

The teletypewriter signal is theoretically a perfect signal. The time between each unit remains the same during transmission of the signal. The shift from mark to space (and vice versa) is called a TRANSITION. A transition occurs at the beginning and end of each unit when it shifts from mark to space or space to mark; a character may have two, four, or six transitions.

When figuring the time duration of a signal character, no allowance for transition time is made since the transition is instantaneous and is considered to have zero time duration. The time duration for each unit is measured in milliseconds.

Q10. What is the function of an antenna patch panel?

Q11. What are the functions of a multicoupler?

Q12. What are the terms used to describe an open or closed telegraph circuit?

Q13. How many units are in a tty signal and what are they?

Codes

Two of the codes the Navy uses are found in manual telegraphy and in teletypewriter operation. One is very easy to understand while the other is more complex. Let's look at these two types and how they work.

MANUAL TELEGRAPHY.—In manual telegraphy, the most widely used code is the Morse code. In this code, two distinctive signal elements are employed-the dot and the dash. The difference between a dot and a dash is its duration, a dash being three times as long as a dot. Each character is made up of a number of dots and/or dashes. The dot and dash elements making up any character are separated from each other by a time interval equal to the duration of one dot. The time interval between the characters for each word is equal to the duration of three dots. The interval between words is equal to seven dots. (A signal-man uses the Morse code to send visual flashing-light messages. The radioman uses the Morse code to send messages electrically.)

TELETYPEWRITER MESSAGE TRANSMISSION.—In teletypewriter operation, the code group for each character is of uniform length. Since the Morse code is an uneven length code, it cannot be used in teletypewriter operation without additional code converters.

The FIVE-UNIT (five-level) CODE has been the most commonly used in modern printing telegraphy and is universally used in teletypewriter operation. This is also known as the Baudot code. The mechanical sending device in the teletypewriter divides the sending time for each character into five short code elements (impulses) of equal duration. The five-unit code is an example of what is called an even length or constant length code (one in which the number of signal elements for a character is the same for every character and the duration of each element is constant). In the five-unit code, each character consists of a combination of five signal elements; each element may be either a mark or a space. A total of thirty-two combinations of signal elements are possible with this arrangement.

The thirty-two possible combinations available from the five-unit code are insufficient to handle the alphabet and numbers since twenty-six combinations are required for the letters of the English alphabet alone. This leaves only six combinations for numerals, symbols, or nonprinting functions. This number of combinations is obviously inadequate; therefore, two of the thirty-two combinations are used as shift signals. The shift signals are often referred to as case-shift signals (one case is a letter shift, and the other a figure shift.) These two shift signals permit the remaining code combination to be used as letter-shift signals for letters and as figure-shift signals for numerals, function signs, and so forth. When a letter shift is transmitted, it sets the receiving instrument in a condition to recognize any letter signal combination. It will recognize letter combinations until a figure shift is received. Then the receiving instrument sets itself in a condition to recognize any figure signal combination received. The interpretation of a signal combination is determined by the previous shift signal. This plan enables 30 of the 32 available combinations to have two meanings.

Q14. There are not enough combinations of the five-unit code to handle the alphabet, symbols and so forth. What is used to increase the number of available code combinations?

Modes of Operation

The two basic modes of teletypewriter operation are ASYNCHRONOUS (start-stop) and SYNCHRONOUS. The most common mode used in teletypewriter operation is the start-stop mode. Synchronous operation is used more in high-speed data systems. Let's examine their differences.

ASYNCHRONOUS.—In the start-stop mode of operation, the receiving device is allowed to run for only one character. It is then stopped to await the reception of a start signal indicating the next character is about to start. In this manner any difference in speed between the transmitting and receiving devices can accumulate only during the duration of one character. However, you should note that a penalty must be paid for this advantage. The length of each character must be increased to include a unit (element) to start the receiving device and another to stop it.

The start unit precedes the first intelligence unit and is always a space signal. Its purpose is to start the receiving machine. The stop unit follows the last code unit and is always a mark signal. Its purpose is to stop the receiving machine in preparation for receiving the next character. The start unit must be equal to at least one unit of the code. The standard mode uses a stop unit that is 1.42 times the length of one intelligence unit. It is common practice to refer to a code unit as an element and to use the terms interchangeably. You will also hear duration of a unit referred to as the unit interval.

The length of time required to transmit the entire character is called the CHARACTER INTERVAL. Character interval becomes very important in some transmissions because certain items of equipment are character length conscious or code conscious. Stop unit intervals of various lengths are used or produced by various equipment (1.0, 1.27, 1.5, 1.96, 2.0, and so forth). Basically, the only difference between them is the length of time required to transmit one character.

SYNCHRONOUS.—Synchronous teletypewriter operation does not in all cases have to rely upon elements of the transmitted character to maintain proper position in relation to the receiving device. External timing signals may be used that allow the start and stop elements to be discarded. You will then see only the elements necessary to convey a character.

Synchronous systems have certain advantages over asynchronous systems. The amount of time taken to transmit stop and start elements is made available for information transmission rather than for synchronizing purposes. Only the intelligence elements are transmitted. In start-stop signaling, the ability of the receiving device to select the proper line signal condition is dependent upon signal quality. For example, suppose the stop-to-start transition arrives before it should; then, because of atmospherics, all subsequent selection positions in that character will appear earlier in time in each code element. A synchronous system has a higher capability for accepting distorted signals because it does not depend on a start-stop system for synchronization.

Modulation Rate

Several terms are used to refer to teletypewriter modulation rates or signaling speeds. These include BAUD RATE, BITS PER SECOND, and WORDS PER MINUTE. Baud is the only term that is technically accurate. The other terms are either approximations or require explanation.

The word baud by definition is a unit of modulation rate. You will sometimes see it used to refer to a signal element, but this reference is technically incorrect. Baud rate is the reciprocal of the time in seconds of the shortest signal element. To find the modulation rate of a signal in bauds, you must divide the number 1 by the time duration of the shortest unit interval present in the signal. For example, 22 milliseconds (.022 seconds) is the time interval of the shortest unit in the five-unit code at 60 words per minute. To find the number of bauds corresponding to 60 words per minute, divide 1 by .022. Rounding off the result of the division gives us the number 45.5, which is the baud equivalent of 60 words per minute. Each increase in words per minute will correspondingly decrease the signal unit time interval. (The defense communications system standard speed for teletypewriter operation is 100 words per minute or 75 baud.)

Words per minute is used only when speaking in general terms for an approximation of speed. The term *100 words per minute* means 100 five letter words with a space between them can be transmitted in a 60-second period. However, you can obtain this nominal words-per-minute rate in several systems by varying either modulation rate or the individual character interval (length). For this reason, the modulation rate (baud) method of reference rather than words per minute is used.

Formula for baud rate and words per minute are as follows

$$\text{Baud} = \frac{1}{\text{unit interval (in seconds)}}$$

$$\text{Words per minute} = \frac{\text{Baud rate}}{\text{unit code} \times 0.1}$$

BIT is an acronym for the words *binary digit*. In binary signals, a bit is equivalent to a signal element. Because of the influence of computer and data processing upon our language, modulation rate is sometimes expressed in bits per second. When you understand all signal elements being transmitted are of equal length, then the modulation rate expressed in bits per second is the same as the modulation rate expressed in baud.

Dc Circuits

You were told the two conditions *mark* and *space* may be represented by any convenient means. The two most common are NEUTRAL and POLAR operation. In neutral, current flow represents the mark, and no current flow represents the space; in polar operation, current impulses of one polarity represent mark, and impulses of the opposite polarity of equal magnitude represent the space.

NEUTRAL.—Neutral circuits make use of the presence or absence of current flow to convey information. A neutral teletypewriter circuit is composed of a transmitting device, a battery source to supply current, a variable resistor to control the amount of current, a receiving device, and a line for the transmission medium.

POLAR.—Polar operation differs from neutral operation in two ways. Current is always present in the polar system, and it is either positive or negative. A polar teletypewriter circuit contains the same items as a neutral circuit plus an additional "battery" source. The battery referred to here is not an actual battery but is a solid-state dc power supply. It provides variable current to the teletypewriters. The reason for having an extra battery source is because polar circuits use positive battery for marks and negative battery for spaces.

You will find in polar operation that the distortion of a signal is almost impossible through low line currents, high reactance, or random patching of signal circuits or equipment. In polar signaling when you experience a complete loss of current (a reading of zero on a milliammeter), you know you have line or equipment trouble; whereas the same condition with neutral signaling may indicate a steady space is being transmitted. This gives us a condition called RUNNING OPEN. Under this condition, the teletypewriter appears to be running because the machines is decoding the constant space as the Baudot character blank and the type hammer continually strikes the type box but there is no printing or type box movement across the page.

Q15. What are the two teletypewriter modes of operation?

Q16. Define baud.

Q17. Define bit.

Q18. What are the two types of dc operations used to represent mark and space conditions?

BASIC SYSTEMS

When two ttys are connected by communications wire or cable (over short or long distances), the exchange of information between them is direct. When the teletypewriters are not physically joined, exchange of information is more involved. Direct-current mark and space intervals cannot be sent through the air. The gap between the machines must be bridged by radio using a radio transmitter and receiver. The transmitter produces a radio frequency carrier wave to carry the mark and space intelligence. A KEYER is needed to change the dc pulses from the tty into corresponding mark and space modulation for the carrier wave in the transmitter. The radio receiver and a CONVERTER are required to change the radio frequency signal back to dc pulses.

Radio Teletypewriter Systems

The Navy uses two basic radio teletypewriter (ratt) systems. These are the TONE-MODULATED SYSTEM, referred to as audio-frequency tone shift (afts), and the CARRIER-FREQUENCY SHIFT SYSTEM, referred to as radio-frequency-carrier shift (rfcs). The rfcs system is also called frequency-shift keying (fsk).

Figure 3-19 shows a modulated carrier wave with audio tone impulses impressed on the radio-frequency carrier wave. These correspond to dc mark and space signals.

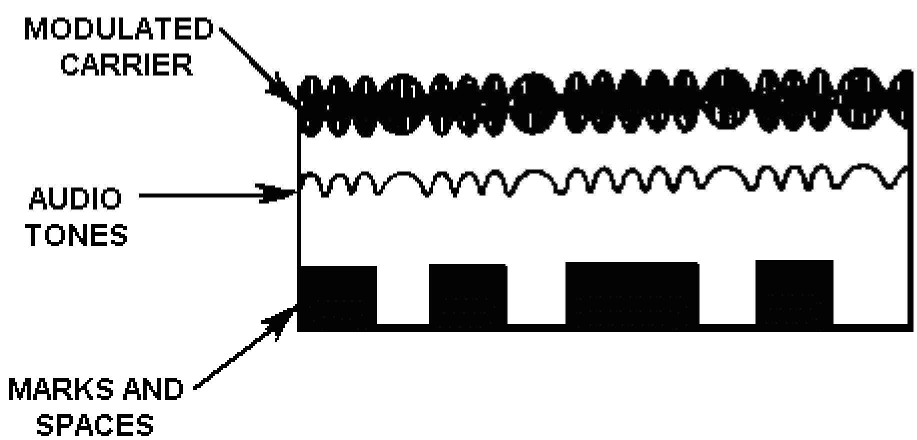

Figure 3-19.—Modulated carrier wave with audio tone for mark and space.

We can best explain the rfcs signal by comparing it to the on-off cw signal. Cw signals are essentially a constant frequency with no variations along the frequency axis. Figure 3-20, view A, is an example. The complete intelligence is carried as variations in the signal amplitude. Figure 3-20, view B, shows the same signal as a shift in frequency between the mark and space.

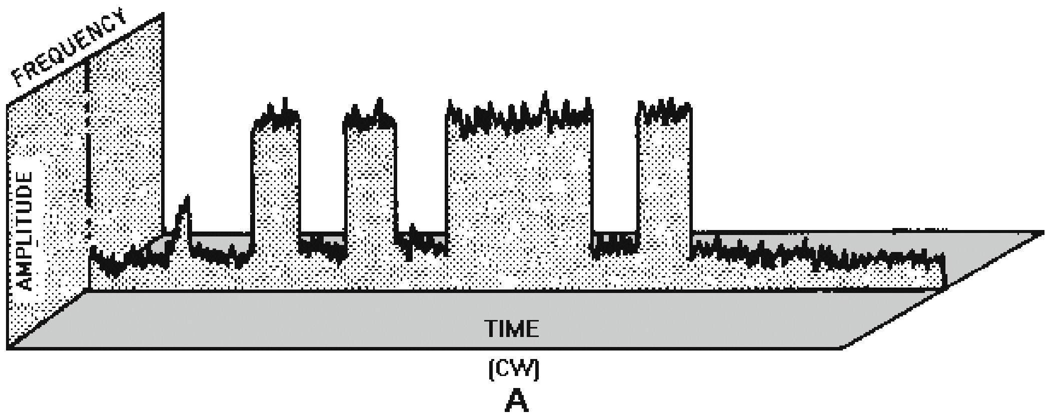

Figure 3-20A.—Cw compared to an rfcs teletypewriter signal.

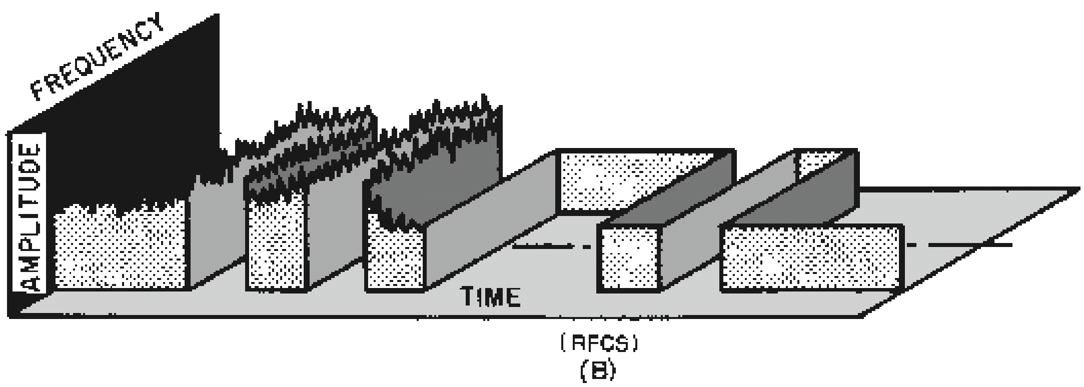

Figure 3-20B.—Cw compared to an rfcs teletypewriter signal.

AUDIO FREQUENCY TONE SHIFT.—Tone-modulated (afts) systems use amplitude modulation to change dc mark and space impulses into audio electrical impulses.

A basic tone-modulated system is shown in figure 3-21. Conversion to audio tones is accomplished by an audio oscillator in the tone converter. Rapid varying of the tone, according to the characters transmitted from the teletypewriter equipment, amplitude modulates the carrier wave in the transmitter. The receiver receives the modulated signal and separates the audio signal from the carrier. This process of separating the modulated signal is known as detection or demodulation.

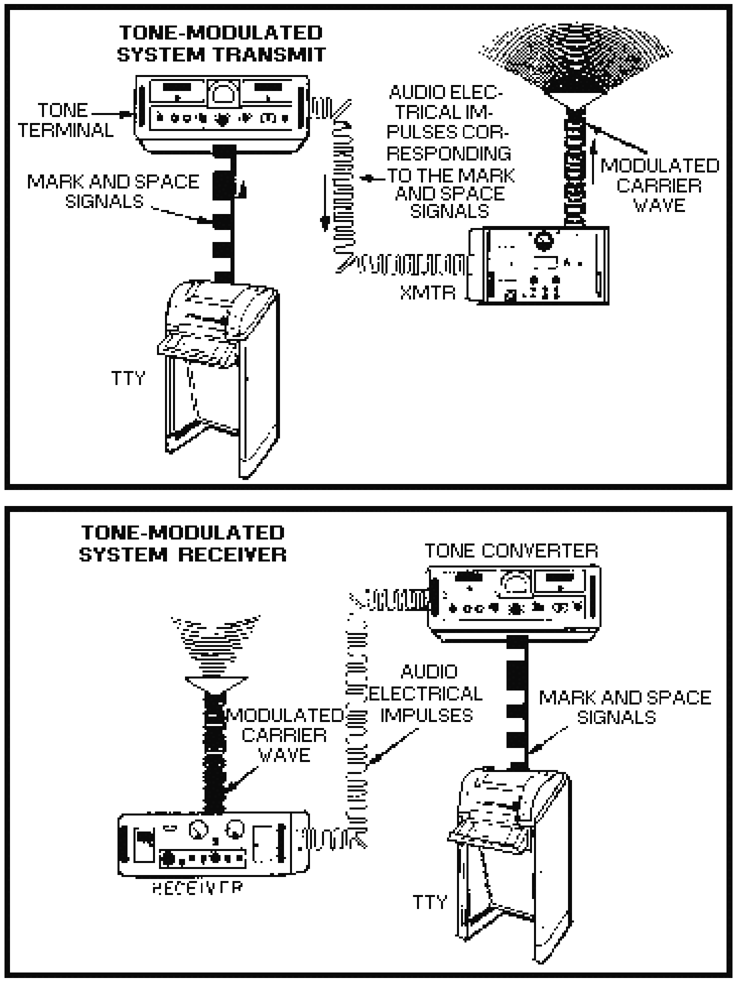

Figure 3-21.—Basic tone modulated (afts) system.

RADIO-FREQUENCY-CARRIER SHIFT.—For frequency-shift (fsk) systems, the transmitter provides a source of radio-frequency excitation. Figure 3-22 illustrates a basic frequency-shift keyed system. In modern systems, the keyer is built into the transmitter. The keyer shifts the signal box below or above the assigned frequency to correspond with the mark or space required to transmit tty characters. Normally the keyer is adjusted for an 850-hertz spread, 425 hertz above and 425 hertz below the assigned frequency. A spacing impulse will be 425 hertz above the operating frequency, and a marking impulse will appear 425 hertz below.

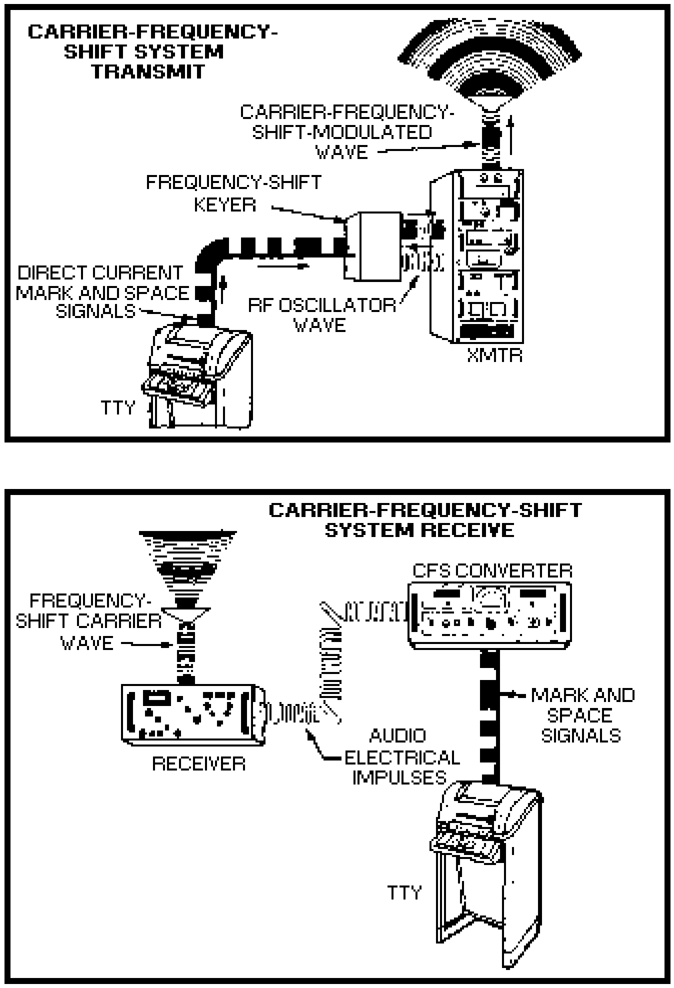

Figure 3-22.—Basic radio-frequency-carrier shift system (rfcs).

In both the tone-modulated system and the carrier-frequency shift system, all tty signals pass through the tty panel that controls the looping current in all the circuits. Looping current is the current supplied by the tty battery. The tty panel integrates the tone-modulated and the carrier-frequency shift systems. It provides every possible interconnection of available tty equipment. With this configuration maximum operational flexibility is achieved with the least amount of circuitry and equipment.

Q19. What is the function of a keyer?

Q20. What is the function of a converter?

Q21. Basically describe an afts system.

Q22. Basically describe an rfcs system.

Rfcs Send System

Figure 3-23 shows an rfcs teletypewriter transmit communications system. You should refer to this figure frequently while reading the functional descriptions of the equipment shown.

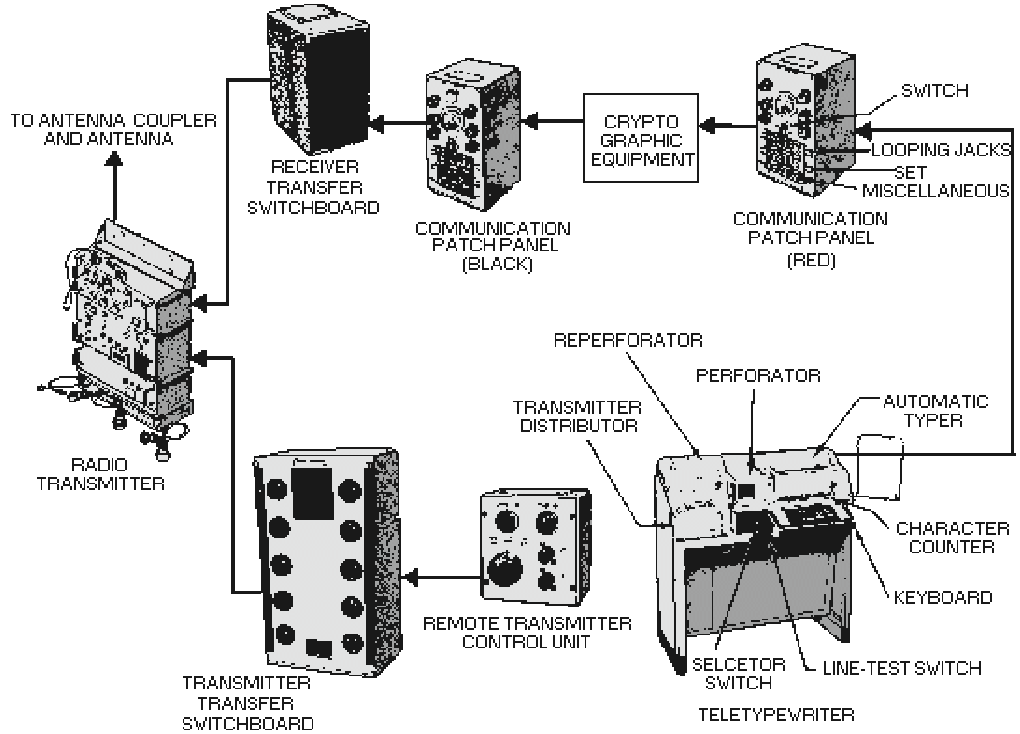

Figure 3-23.—Rfcs transmit (send) system.

TELETYPEWRITER SETS.—Most of the teletypewriter sets used by the Navy belong to one family of tty equipment. This equipment features various weights and sizes, quiet operation, and high operating speeds. They present relatively few maintenance problems. Because of this they are well suited for severe shipboard conditions of roll, vibration, and shock.

These teletypewriters operate at various speeds. Conversion from one speed to another is usually only a matter of changing the gears that are located within the equipment.

Teletypewriters may be send/receive units or receive only units. They may be designed as floor models, table models, or rack and wall-mounted sets. The teletypewriter shown is a send/receive floor model.

The teletypewriter receives messages and prints them on page-size copy paper. In addition, it can receive and record messages on perforated tape. You can use the keyboard or perforated tape to send messages. Page print monitoring is available with both methods. The set shown can prepare perforated and printed tape for separate transmission. It does this with or without simultaneous transmission and page-print monitoring. The combinations of services available are extensive.

The tty set may include a CABINET, KEYBOARD, PAGE PRINTER, TYPING PERFORATOR, TRANSMITTER DISTRIBUTOR, TYPING REPERFORATOR, power distribution panels, and a power supply.

In operation, the components are linked by electrical or mechanical connections. You are given a wide range of possibilities for sending, receiving, or storing tty messages. All equipment components are housed within the cabinet. Transmission signals are initiated through the keyboard (kybd) or through the transmitter distributor (td). Signals received or local transmissions can be monitored on the page printer. The typing perforator and typing reperforator are devices for preparing tapes on which locally initiated or incoming tty messages can be stored for future transmission through the td.

COMMUNICATION PATCHING PANELS.—Ttys are provided flexibility by jacks that are used to terminate all ttys and associated equipment. The jacks are wired in communications patching panels, usually referred to as tty patch panels. You are able to connect any combination of equipment electrically by means of patch cords.

The plugs on the patch cords are inserted into the jacks at the front of the panel. These plugs have three different parts. They are the tip, ring, and sleeve. The tip carries the intelligence signal while the ring carries the synchronizing (step) or timing signals. The sleeve carries an alarm signal that indicates (both visually and audibly) a problem to the operator. The problem may be equipment failure, loss of loop current, or improper patching. Commonly used combinations of equipment are often wired together within the panel (called normal-through). Individual pieces of equipment are wired on jacks to allow you to use them alone or in combination.

Tty patch panels also furnish a central point for connecting the dc voltage supply into the tty circuits. One source of supply can be used for all circuits passing through a particular panel.

RED and BLACK are used on patch panels to identify whether that panel is used for passing secure or nonsecure information. Red indicates that secure (encrypted) information is being passed through the panel. Black indicates that nonsecure (unencrypted) information is being passed. Patch panels through which secure information is passed are indicated by a red sign on the front that has inch high white block letters that say "RED PATCH PANEL." Panels through which nonsecure information is passed are indicated by two black signs on the front with inch high white block letters. One sign says "BLACK PATCH PANEL" and the other "UNCLAS ONLY."

Each panel contains six channels. Each channel has its own series circuit of looping jacks, set jacks, and a rheostat for adjusting line current. The number of looping and set jacks in each channel varies with the panel model. Each panel includes a meter and rotary selector switch for measuring the line current in any channel. There are six miscellaneous jacks. Any tty equipment not regularly assigned to a channel, may be connected to one of these jacks.

If the desired tty equipment is wired in the same looping channel as the radio adapter used, no patching is required. But, if the desired tty is not wired in the same looping channel as the keyer or converter, it must be patched. For example, let's put a tty on channel 1 and a converter on channel 3. If you want to receive, you must insert one end of the patch cord in the set jack for channel 1 and the other end in either one of the two looping jacks of channel 3.

In any switching operation between the plugs and jacks of a tty panel, the cord plug must be pulled from the looping jack before you remove the other plug from the set (machine) jack. Pulling the plug from the set jack first opens the circuits to the channel, causing all tty messages in the channel to be interrupted.

WARNING

Removing the set (machine) jack before the looping jack exposes a dangerous dc voltage on the exposed plug.

Q23. Most Navy tty sets operate at what speeds?

Q24. A receive tty set provides outputs in what formats?

Q25. What does the color red indicate on a tty patch panel?

CRYPTOGRAPHIC EQUIPMENT.—Cryptographic equipment is used to ENCRYPT and DECRYPT tty messages that require security handling. (Encrypting is the method used to code a transmitted message; decrypting is used to decode a received message.) To code or decode any message, the send and receive cryptographic equipment must be compatible.

REMOTE TRANSMITTER CONTROL UNIT.—The remote transmitter-control unit is mounted close to the kybd and permits remote control of the transmitter (xmtr). It has a transmitter power on-off switch, a power-on indicator lamp, a carrier-on indicator lamp, and a three-position rotary selector switch. For rfcs operation you set the switch to CFS SEND to transmit and to CFS REC to receive. Use the TONE S/R position for both transmitting and receiving afts signals.

An audio frequency tone-shift system will be discussed later in this chapter.

TRANSMITTER TRANSFER SWITCHBOARD.—The transmitter transfer switchboard is used in this system to connect the remote transmitter control unit to the radio transmitter.

RADIO TRANSMITTER.—The radio transmitter transmits the tty signal. You should be careful when tuning the transmitter for rfcs operation. The carrier frequency setting is critical and must be properly set to ensure a correct output from the transmitter.

Q26. What are the functions of cryptographic equipment?

Rfcs Receive System

Figure 3-24 shows the rfcs receive system used to receive the transmitted signal and translate it back to a usable output. You should look at this figure while studying the units in this section.

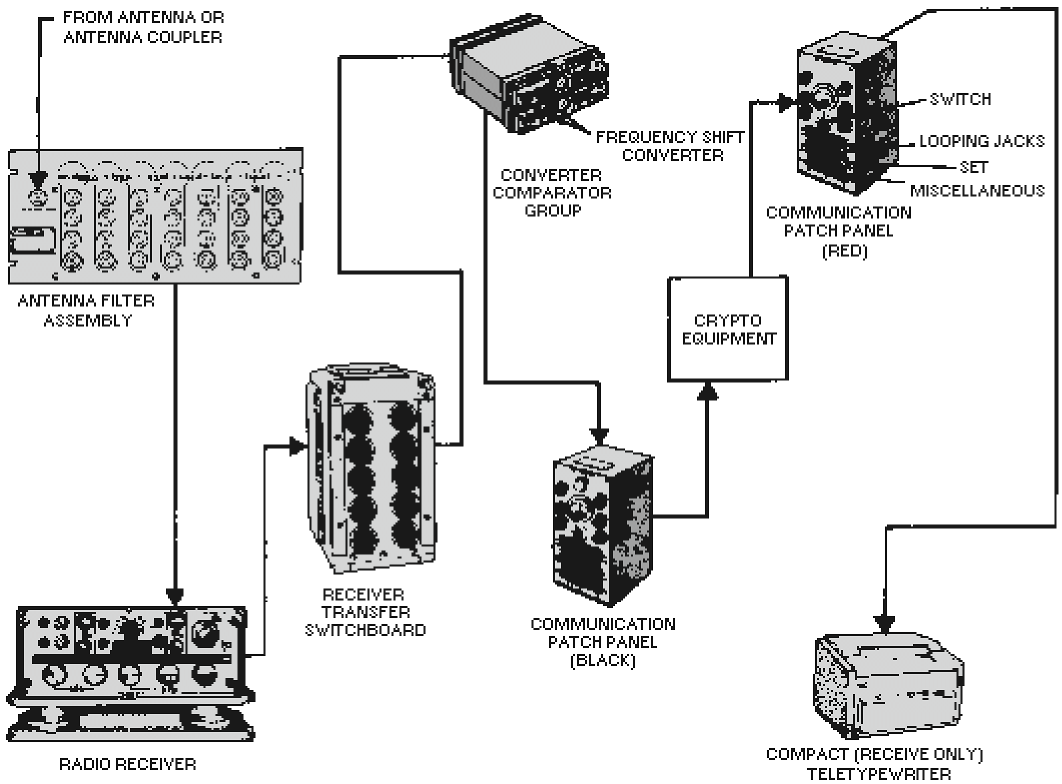

Figure 3-24.—Rfcs receive system.

ANTENNA FILTER ASSEMBLY.—The antenna filter assembly is connected to the antenna and receives the rf signal from the antenna. It filters out any unwanted rf signals and allows the desired band of frequencies to pass.

RADIO RECEIVER.—The radio receiver takes the rf signal passed on by the antenna filter and translates it to an audio signal.

RECEIVER TRANSFER SWITCHBOARD.—The receiver transfer switchboard is used to tie the receiver to any converter unit connected to it. This allows you a wide selection of equipment for connection to the same receiver.

CONVERTER-COMPARATOR GROUP.—The converter-comparator group is used with receivers in either space or frequency diversity operation. When diversity operation is not required, each converter can be used separately with a single receiver.

Each converter has its own COMPARATOR circuitry. This built-in design feature results in a considerable reduction in size from older units. The comparator was located in a separate chassis in the older units. Size has been further reduced through the use of microelectronics.

Figure 3-25 shows the basic method we use to convert a frequency-shift rf signal into a signal that controls the dc loop of a tty. The frequency shifts of the af output from the receiver are converted into dc pulses by the af discriminator. The dc pulses are then fed into the keyer. The keyer opens and closes the dc loop of the tty according to the mark and space characters received.

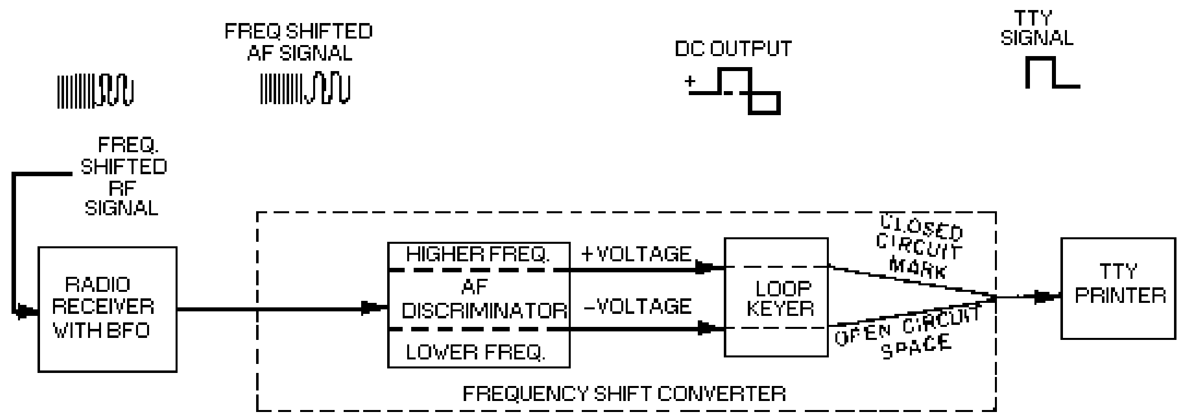

Figure 3-25.—Frequency shift receiving system simplified block diagram.

In diversity operation the comparator section of the converter-comparator group (shown in figure 3-24) compares the strength of the signals from two receivers. Signals from each converter are fed into a comparator circuit that compares the signals. This comparison is displayed on a crt on the front of the equipment. The comparison is in the form of LISSAJOUS PATTERNS. A lissajous pattern is a combined, simultaneous display of the amplitude and phase relationships of two input signals. One signal is applied to the vertical and the other to the horizontal deflection circuits. Lissajous patterns have many applications in electronics. They have operational uses as well as uses in corrective and preventive maintenance. Further coverage on lissajous patterns can be found in NEETS, Module 19, *The Technician's Handbook*. Figure 3-26 shows several typical lissajous monitoring patterns for the converter-comparator group. Once we have a correctly tuned signal, the comparator feeds it to the communication patching panel for patching to the tty. Now let's refer back to figure 3-24 while we discuss the rest of the units in the system.

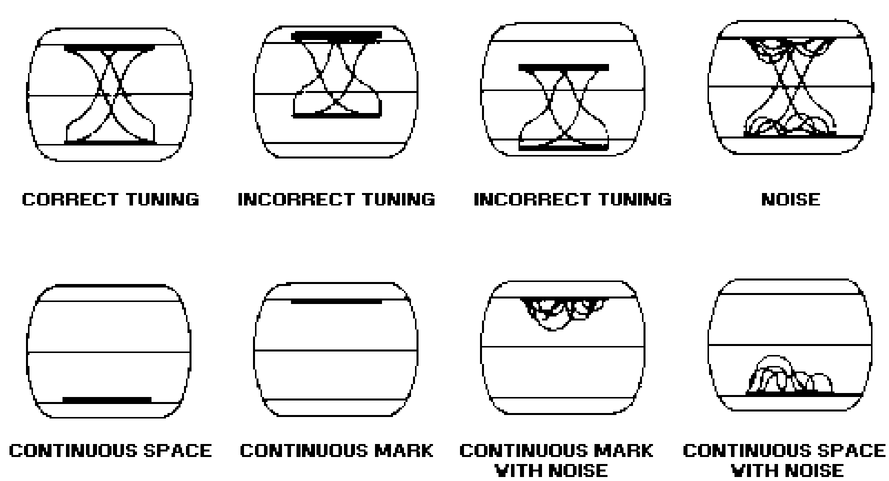

Figure 3-26.—Typical lissajous monitoring patterns.

COMMUNICATION PATCH PANEL.—The communication patch panel serves the same functions on the receive side of the rfcs system as it did on the transmit side. It routes the dc signal to the proper cryptographic equipment. It also routes the decoded teletypewriter signal from the cryptographic equipment to the selected tty.

CRYPTOGRAPHIC EQUIPMENT.—The cryptographic equipment converts the transmitted coded signal to a decoded signal that can be printed out in its original state.

TELETYPEWRITER.—The tty equipment is used to convert the dc signal received from the communication patch panel to a printed copy of the original transmitted message. The tty shown is used only for receive and does not have the ability to transmit.

Q27. What are the functions of a converter-comparator group?

Afts System

Figure 3-27 is a simplified block diagram of a HALF-DUPLEX (send or receive) uhf, audio-frequency-tone shift system. A half-duplex communications circuit permits two-way communications between stations. Communications can be in either direction but not simultaneously. The term half-duplex is qualified by adding send only, receive only, or send or receive. Let's use the block diagram to trace a signal through the system.

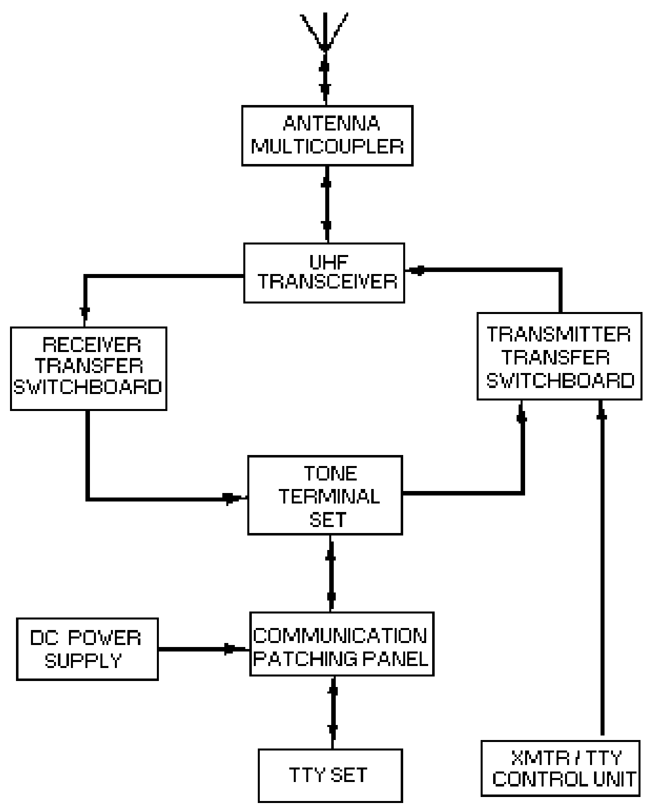

Figure 3-27.—Half-duplex afts teletypewriter system.

SIGNAL FLOW.—On the transmit side, dc signals from the tty set are fed to the communication patching panel. From the panel they are patched to the tone terminal set. The tone terminal set converts the dc signals into audio tone-shift signals. These signals are then patched to the transmitter section of the transceiver through the transmitter transfer switchboard. The audio tone-shift signals modulate the rf carrier generated by the transmitter (xmtr). The rf tone-modulated signals are then radiated by the antenna.

On the receive side, the rf tone-modulated signals are received at the antenna. You then patch the signal via the multicoupler to the receiver section of the transceiver. Demodulation takes place at this point. The resulting audio tone-shift signals are then patched through the receiver transfer switchboard. The signals now go from the switchboard to the tone terminal set, where they are converted back to dc signals. The dc signals are then patched through the communication patching panel to the tty for printing.

TONE TERMINAL SET.—In tone modulation transmission, the tty pulses are converted into corresponding audio tones. These tones amplitude modulate the rf carrier in the transmitter. Conversion to audio tones is accomplished by an audio oscillator in the tone converter.

An internal relay in the tone converter closes the control line to the transmitter. This keys the transmitter on the air when the operator begins typing a message. The transmitter remains keyed until after the message has been transmitted.

On the receive side, the tone converter accepts the mark and space tones coming in from a receiver and converts them into signals suitable to operate a relay in the converter. The make and break contacts of the relay are connected in the local tty dc loop circuit. This causes the teletypewriter to print in unison with the mark and space signals from the distant tty.

Multiplexing Equipment

The number of communications networks in operation throughout any given area is increasing. As a result, all areas of the rf spectrum have become highly congested.

The maximum number of intelligible transmissions taking place in the radio spectrum is being increased through the use of MULTIPLEXING. Multiplexing is the simultaneous transmission of a number of intelligible signals (messages) in either or both directions using only a single rf carrier. You may use two methods of multiplexing. These are TIME-DIVISION and FREQUENCY-DIVISION.

TIME-DIVISION.—With AM voice and tone communications, we want to transmit and receive for 360 degrees of each sine wave. However, an audio signal may be transmitted and received satisfactorily by periodically sampling the signal. The sampling process yields a received signal like the one shown in figure 3-28. There is no limit to the maximum number of samples that may be made, but you must sample at least twice per cycle of audio to get satisfactory results. In practical systems, 2.4 samples per cycle are usually taken. This concept of sampling forms the basis for time-division multiplex (tdm) operation.

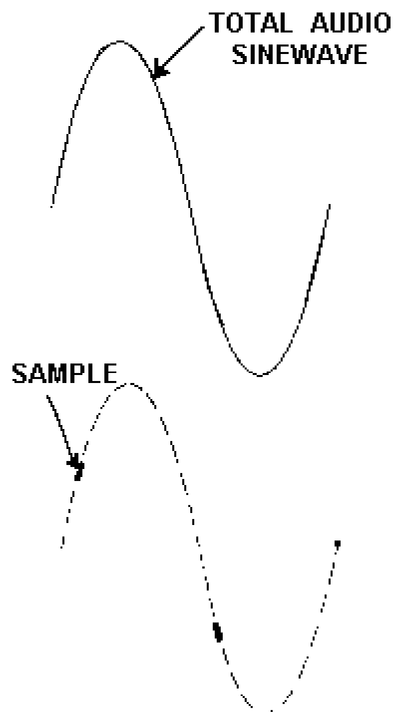

Figure 3-28.—Components of a sine wave.

Figure 3-29, view A, illustrates, the fundamental principle of tdm. Let's look at an example. Assume that a 3,000-hertz tone is applied to each of the six channels in the transmitter. Assume also that the rotating switch turns fast enough to sample, in turn, each of the six channels 2.4 times during each cycle of the 3,000-hertz tone. The speed of rotation of the switch must then be $2.4 \times 3,000$ or 7,200 rotations per second. This is the optimum sampling for a practical system.

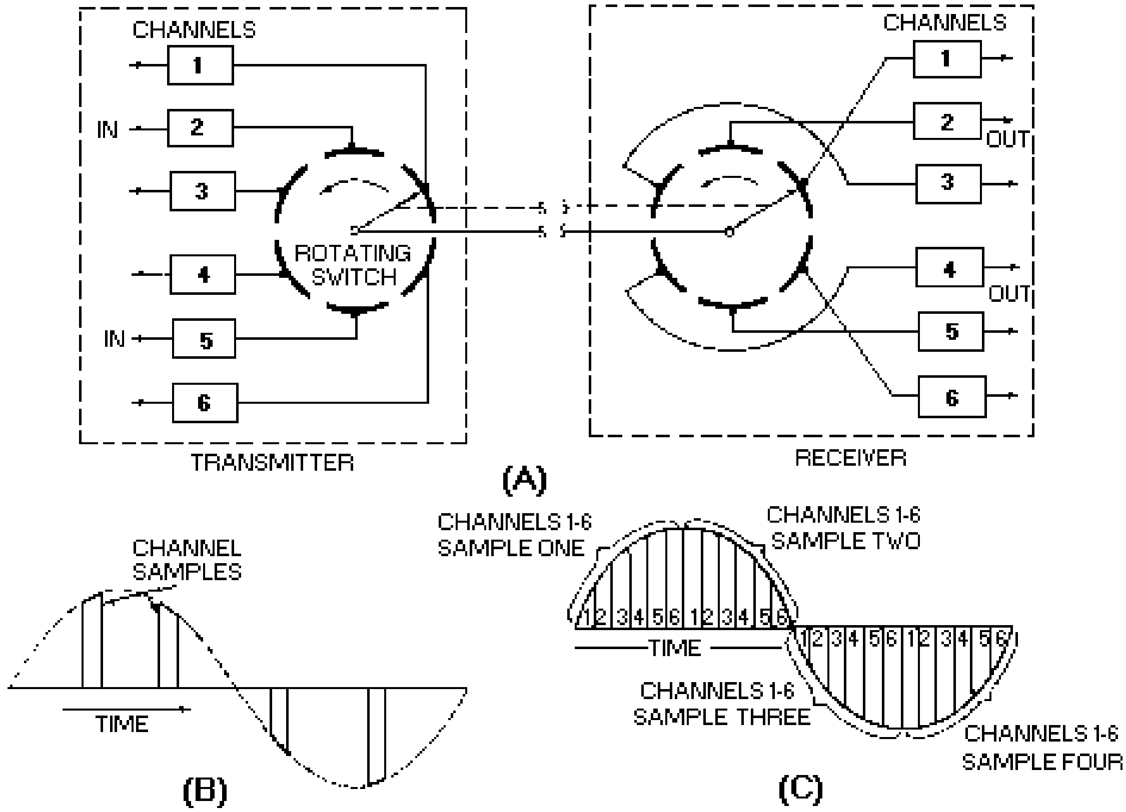

Figure 3-29.—Fundamental principle of time-division multiplexing.

When the transmitter and receiver switches are synchronized, the signals will be fed in the proper sequence to the receiver channels. The samples from transmitter channel one will be fed to receiver channel one. In this way, many channels of audio are combined to form a single output (multiplexed) chain. Time spacing occurs between the components of the separate channels. The chain is transmitted (via wire or radio path) to distant demultiplexing receivers. Each receiving channel functions to select and reconstruct only the information included in the originally transmitted channel.

In most present day applications, electronic switching is used as the sampling component. The main advantage to electronic sampling is the longer life of an electronic switch when compared to an electromechanical switch. We use a mechanical system in our example to make this concept easier for you to see.

Now let's look at figure 3-29, view B, where channel one is shown sampled four times. (This is the output of channel one in our transmitter.) Figure 3-29, view C, shows all six channels being sampled four times during each cycle. (This is the output of the rotating switch in our transmitter.) What you see here is a continuous, time-sharing waveform.

More than six channels (perhaps 24 or more) may be used. As we increase the number of channels, the width of each sample segment must be reduced. The problem with reducing the width of the pulse is that the bandwidth (bw) necessary for transmission is greatly increased. Decreasing the pulse width decreases the minimum required rise time of the sampling pulse and increases the required bandwidth. When you increase the number of channels, you increase the bw. The bw is also affected by the shape of the sampling pulse and the method used to vary the pulse.

Common methods of time-division multiplexing include PULSE AMPLITUDE MODULATION (pam), PULSE WIDTH or PULSE DURATION MODULATION (pwm or pdm), PULSE POSITION MODULATION (ppm), and PULSE CODE MODULATION (pcm). We have been studying an example of pulse amplitude modulation. (These methods of tdm were discussed in NEETS, Module 12, *Modulation Principles*.)

FREQUENCY DIVISION.—Frequency division multiplexing (fdm), unlike tdm, transmits and receives for the full 360 degrees of a sine wave. Fdm used presently by the Navy may be divided into two categories. One category is used for voice communications and the other for tty communications.

The normal voice speaking range is from 100 to 3,500 hertz. During single channel AM voice communications, the audio frequency amplitude modulates a single rf (carrier frequency). However, in voice fdm, each voice frequency modulates a separate frequency lower than the carrier frequency (subcarrier frequency). If these subcarrier frequencies are separated by 3,500 hertz or more, they may be combined in a composite signal. This signal modulates the carrier frequency without causing excessive interference.

In figure 3-30, the output of channel one is the voice frequency range of 100 to 3,500 hertz. The output of channel two is the combination of a different voice frequency with a subcarrier frequency of 4,000 hertz. The output of channel three is another voice frequency. This voice frequency combined with a subcarrier frequency of 8,000 hertz gives you an output frequency range of 8,100 to 11,500 hertz. The overall bw for the composite modulation package shown is 100 to 15,500 hertz. Each separate channel occupies its own band of frequencies. The composite signal is used to modulate the carrier frequency of the transmitter.

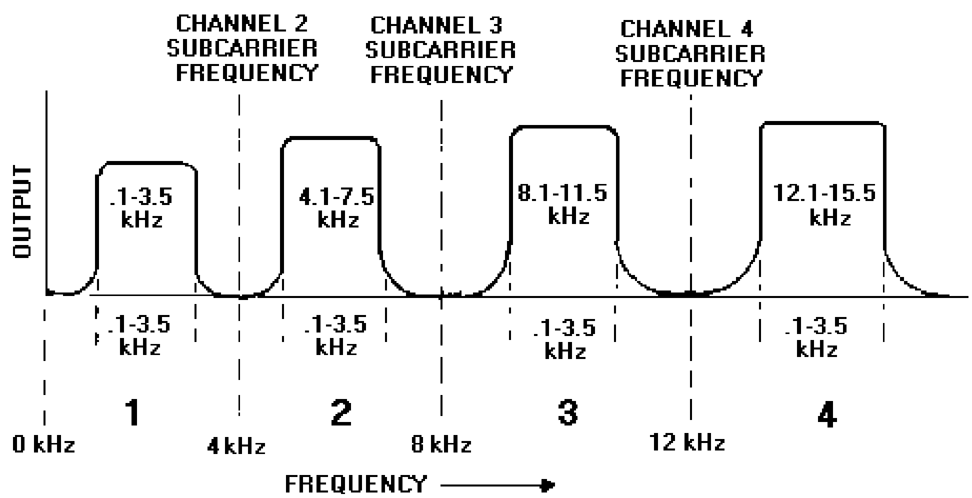

Figure 3-30.—Block diagram of a frequency-division multiplexing system.

Multichannel broadcast and ship/shore terminations use tty fdm. With this system, each channel of the composite tone package of the broadcast is assigned an audio frequency. By multiplexing tty circuits, up to 16 circuits may be carried in any one of the 3,000 hertz multiplexed channels described above. Don't confuse the two types of multiplexing. In the first case, 3,000 hertz audio channels have been combined. In the second case, a number of dc tty circuits are converted to tone keying and combined in a single 3,000-hertz audio channel. Figure 3-31 illustrates a 16-channel, tty-multiplexing system. The output of the dc pulsed circuits is converted to audio keying. Each channel has a separate audio center frequency. Channel frequencies range from 425 hertz for the lowest channel to 2,975 hertz for the highest channel. A mark in an individual tty loop keys an audio tone 42.5 hertz below the center frequency. A space in the input signal keys an audio tone 42.5 hertz above the center frequency. Let's look at an example. The mark and space frequencies for channel one are calculated as 382.5 hertz and 467.5 hertz, respectively (425 ± 42.5). Combining these keyed tones into a composite signal results in a tone package within a standard 3,000-hertz bandwidth. By occupying no more than 3,000 hertz of the audio spectrum, the output signal is suitable for transmission via radio or landline.

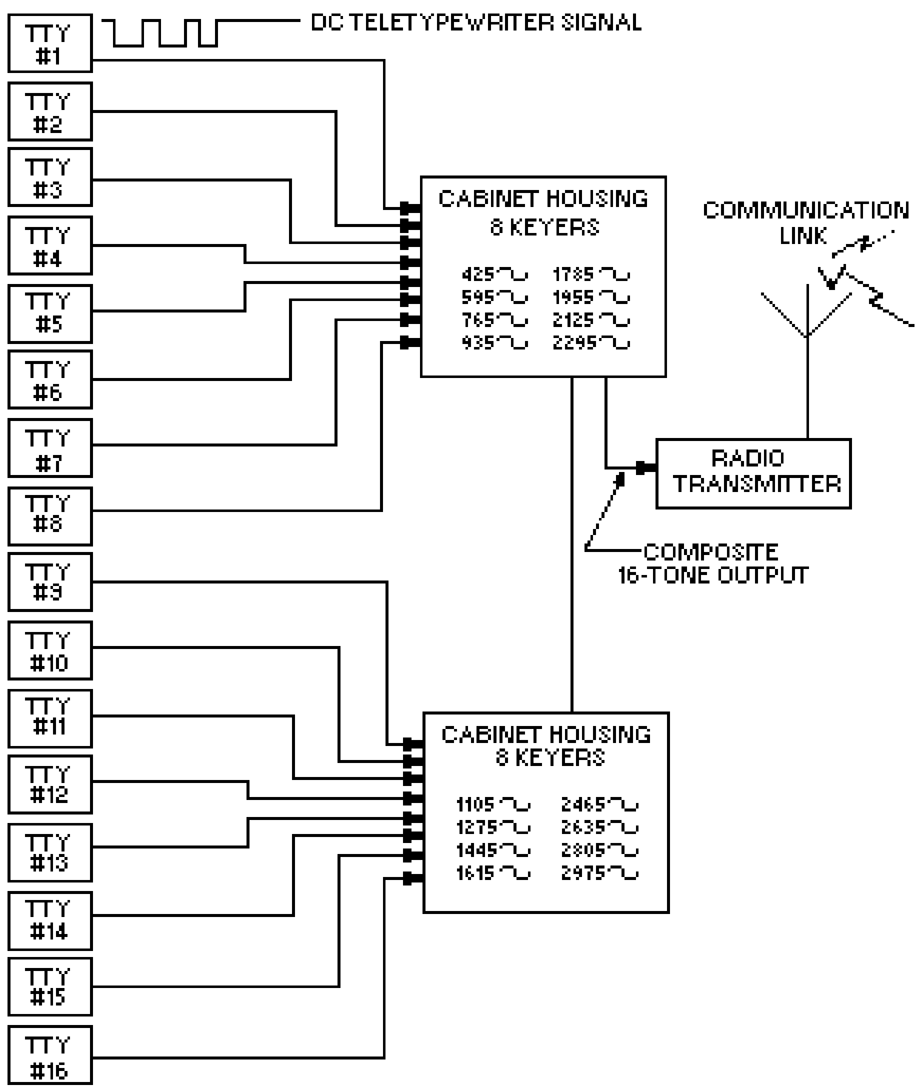

Figure 3-31.—Block diagram of modulator units.

Q28. What is the function of a tone terminal set?

Q29. What are the two types of multiplexing?

Q30. What is the purpose of multiplexing?

Facsimile

FACSIMILE (fax) is a method of transmitting still images over an electrical communications system. The images, called "pictures" or "copy" in fax terminology, may be weather maps, photographs, sketches, typewritten or printed text, or handwriting. Figure 3-32 shows a facsimile transceiver. You must realize that the still image serving as the fax copy or picture cannot be transmitted instantly in its entirety. Three distinct operations are performed. These are (1) scanning, (2) transmitting, and (3) recording or receiving.

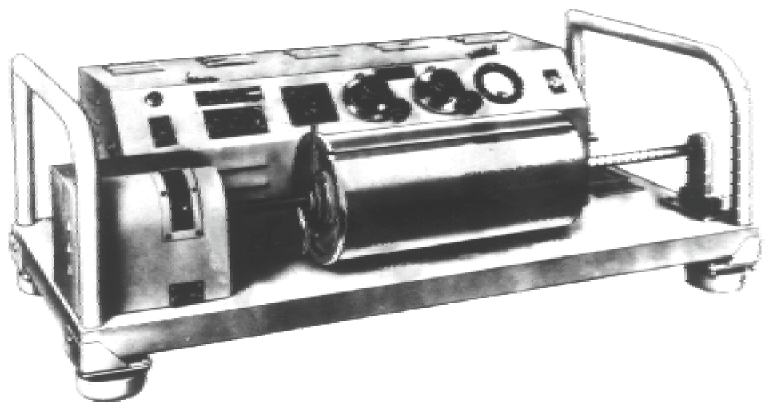

Figure 3-32.—Facsimile transceiver.

Scanning consists of subdividing the picture in an orderly manner into a large number of segments. This process is accomplished in the fax transmitter by a scanning drum and phototube arrangement.

The picture you want to transmit is mounted on a cylindrical scanning drum. This drum rotates at a constant speed and at the same time moves longitudinally along a shaft. Light from an exciter lamp illuminates a small segment of the moving picture and is reflected by the picture through an aperture to a phototube. During picture transmission, the light crosses every segment of the picture as the drum slowly spirals past the fixed lighted area.

The amount of light reflected back to the phototube is a measure of the lightness or darkness of the segment of the picture being scanned. The phototube changes the varying amounts of light into electrical signals. These are used to amplitude modulate the constant frequency output of a local oscillator. The modulated signal is then amplified and sent to the radio circuits.

Signals received by the fax receiver are amplified and actuate a recording mechanism. This recorder makes a permanent recording (segment by segment) on paper. The paper is attached to a receiver drum similar to the one in the fax transmitter. The receiver drum rotates synchronously with the transmitter drum. Synchronization of the receiver and transmitter is done to reduce distortion. Synchronization is obtained by driving both receiver and transmitter drums with synchronous motors operating at the same speed. Drum rotation continues until the original picture is reproduced. The recording mechanism may reproduce the picture photographically by using a modulated light source shining on photographic paper or film. It may also reproduce directly by burning a white protective coating from specially prepared black recording paper.

The receiver drum is FRAMED with respect to the transmitter drum by a series of phasing pulses that are transmitted just before transmission. The pulses operate a clutch mechanism that starts the scanning drum in the receiver. This ensures proper phasing with respect to the starting position of the scanning drum in the transmitter.

Figure 3-33 is a block diagram of the equipment necessary for radio facsimile operation. View A shows the receiving system. This system consists of a standard radio receiver, a frequency-shift converter, and a facsimile recorder. View B shows two systems for transmitting TIF signals. The upper row of blocks is for carrier-frequency shift transmission. This system consists of a facsimile transceiver, a keyer adapter, a frequency shift keyer and a transmitter capable of fsk emission. The lower row of blocks is for audio-frequency shift transmission and uses a fax transceiver, a radio modulator, and an AM transmitter.

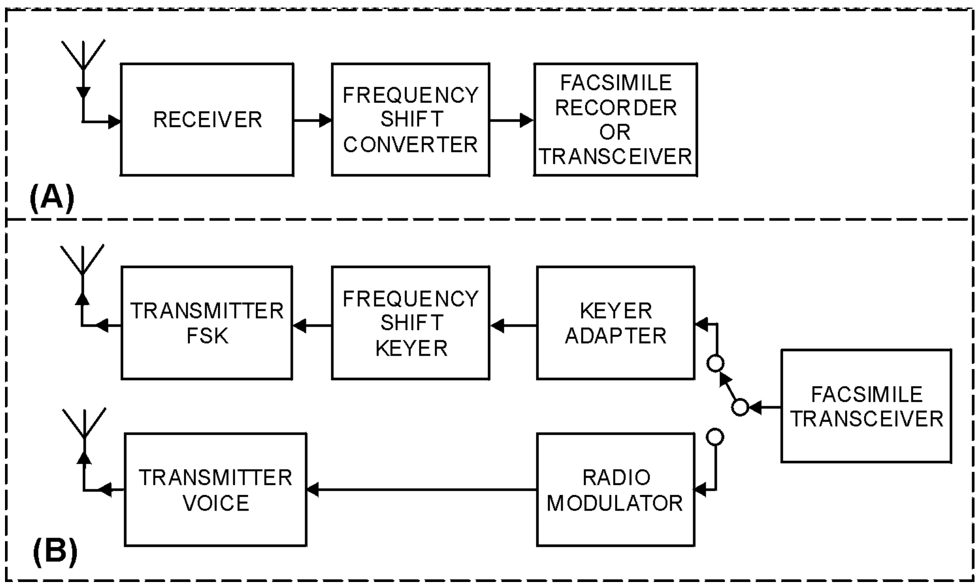

Figure 3-33.—Radio facsimile systems.

SECURITY, QUALITY MONITORING, AND SAFETY

Security, quality monitoring, and safety are important areas that you must be aware of. If the fundamentals are followed, you will see higher quality communications. You will also help meet the communications goals of the Navy. Let's find out what these fundamentals are and what they will do for you.

TEMPEST

Compromising emanations (ce) are, generally referred to as TEMPEST. These signals may be unintentional, data-related, or intelligence-bearing. If intercepted or analyzed, these signals could disclose classified information. TEMPEST problems are associated with material transmitted, received, handled, or otherwise processed by electrical information processing equipment or systems. Any electrical information processing device may cause problems. Even your electric typewriter or a large, complex data processor may emit interceptable compromising emanations. Some countermeasures taken to ensure against TEMPEST problems are listed below:

- Design of equipment in which ce is suppressed
- Approved installation criteria that limits interaction between classified and unclassified signal lines, power lines, grounds, equipment, and systems
- Low level keying and signaling
- Shielded enclosures for equipment installations
- Proper shipboard grounding of equipment, including ground straps

TRANSMISSION SECURITY

Transmission security includes all measures designed to protect transmission from interception, traffic analysis, and imitative deception. Every means of transmission is subject to interception. In radio transmission, it should be assumed that all transmissions are intercepted.

Speed Versus Security

Three fundamental requirements of a military communications system are *reliability, security*, and *speed*. Reliability is always first. Security and speed are next in importance and, depending on the stage of an operation, are interchangeable. During the planning phase, security is more important than speed. During the execution phase, speed sometimes passes security in importance.

Radio Transmission Security

When a message is transmitted by radio, the originator may know some of those who are receiving it, but will never know *all* of those who are receiving the message. You must assume that an enemy receives every transmission. Property prepared messages using modern cryptographic systems may prevent an enemy from understanding a message. However, they can still learn a lot. For example, as time for a planned operation approaches, the number of messages transmitted increases. An enemy then knows that something will occur soon, and their forces are alerted. Strict radio silence is the main defense against radio intelligence.

The amount of radio traffic is not the only indicator used by an enemy. Statistical studies of message headings, receipts, acknowledgments, relays, routing instructions, and services are also used by an enemy. Communications experts can often learn much about an opponent from these studies. Direction finders are another aid the enemy can use to determine where messages originate.

Radiotelephone Security

Radiotelephone networks are operated so frequently that many operators tend to be careless. There are too many instances of interception of vhf and uhf transmissions at distances of many thousands of miles. You may have occasion to work on or around this type of equipment. If you are ever required to bring any transmitter on the air for any purpose, you must be familiar with and use all the correct procedures.

Q31. The transmission of still images over an electrical communications system is known as what?

Q32. The term TEMPEST refers to what?

Q33. What are the three fundamental requirements of a military communications system?

Q34. Which of the above requirements is most important?

SHIPBOARD COMMUNICATIONS SYSTEMS QUALITY MONITORING (QMCS)

In recent years the volume of shipboard communications has increased greatly. This expansion has led to the shipboard installation of sophisticated equipment. Factors such as frequency accuracy and dc signal distortion are critical to the operation of communications systems. These systems demand precise initial lineup and monitoring to ensure satisfactory operations are maintained. System degradation is often caused by many small contributing factors. When these factors are added together, the system becomes unusable.

Scheduled Maintenance

When you perform scheduled, logical checks that ensure continuous, optimum performance of shipboard communications systems, you are doing SCHEDULED MAINTENANCE. In many cases this maintenance prevents outages before they occur. Some of the scheduled checks will include the following:

- Transmitter/receiver frequency
- Transmitter power out
- Receiver sensitivity/bandwidth
- Primary power (voltage, current, cycles)

Electromagnetic Interference (emi)

Many complex electronic systems are installed aboard Navy ships. In modern ships, complex systems with higher power and greater sensitivity are being crowded into a restricted and corrosive area. Figure 3-34 is a Spruance class destroyer with its crowded (compact) communications environment. The ability of these systems to perform their individual functions without interference is known as ELECTROMAGNETIC COMPATIBILITY (emc). Emc is concerned with the structure of the ship and its electrical and electronic system. Compact environment is a major limitation to the effectiveness of a total ship system concept.

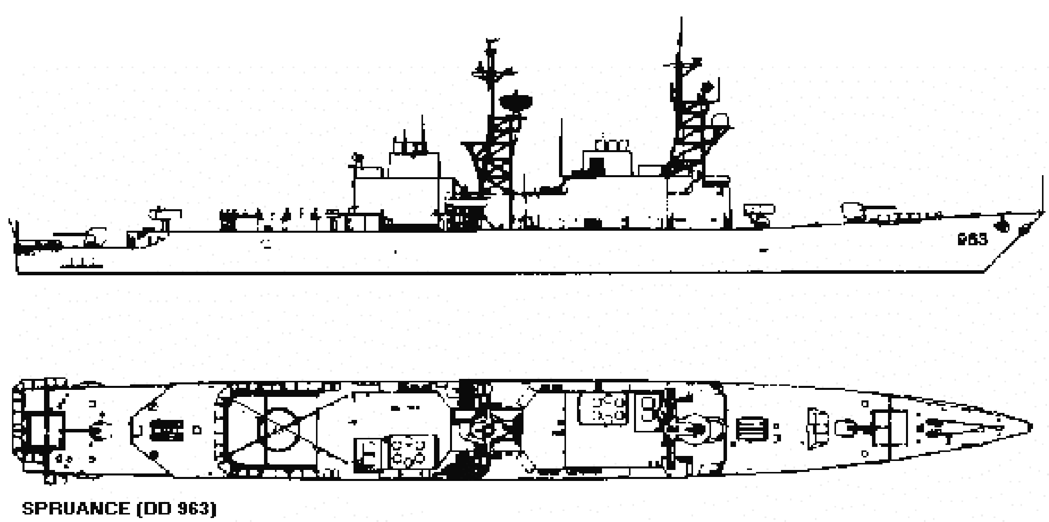

Figure 3-34.—Total ship.

Operation of a total ship system in this unique shipboard environment presents a challenge to all concerned. You must always consider the effects that motion, temperature variations, and exposure to adverse elements will have on the performance of the total ship system. This is particularly true on those system components that are mounted topside.

On board ship, you will find much attention is given to keeping the topside cosmetically and mechanically shipshape. It is equally important to keep it electronically shipshape. Minor mechanical problems, such as loose connections, broken bond straps, or rusty junctions can cause serious communications problems. These sources of electromagnetic radiations reduce receiver performance and are known as ELECTROMAGNETIC INTERFERENCE (emi). Sources of emi can be divided into the following broad categories:

- Functional. Emi can originate from any source designed to generate electromagnetic energy and which may create interference as a normal part of its operation. The interference may be unintentional or caused by other on board or adjacent platform systems. This interference also may be intentional or caused by electronic countermeasures (ECM).
- Incidental. Emi can originate from man-made sources. These are sources not designed specifically to generate electromagnetic energy but which do in fact cause interference. Examples of incidental emi sources include power lines, motors, and switches.
- Natural. Emi can be caused by natural phenomena, such as electrical storms, rain particles, and solar and interstellar radiation. It is recognized by the following audible noises:
  - Intermittent impulses of high intensity that are caused by nearby electrical storms
  - Steady rattling or cracking caused by distant electrical storms
  - Continuous noise of precipitation static caused by electrically charged rain drops
  - A steady hiss at high frequencies caused by interstellar noise
- Hull-generated. Emi can be caused by the interaction of radiated signals with elements of the hull and rigging of a ship. (The functional signals themselves do not cause interference.)

The following are two general methods by which emi is transmitted:

Conduction. Undesired energy from one equipment is coupled to interconnecting cables or components of another equipment. This energy is conducted via the wiring in the shielded enclosure that protects sensitive circuits. You will find proper design, adequate isolation, and shielding of cables and equipment can control this problem.

Radiation. Energy is beamed directly from the transmitting antenna, or source, to the victim receiving antenna. When this interference is picked up by a receiver, you have two solutions. Interfering energy can be eliminated at the source or you can filter, or blank it out at the victim equipment. Filtering is far less desirable. Interference may be on the same frequency as the desired signal and will not be eliminated without affecting the reception of all desired signals.

Most unprotected shipboard receivers are susceptible to emi over a frequency range much wider than their normal bandpass. Off-frequency rejection rarely excludes strong, adjacent-channel signals. These signals enter the receiver and degrade receiver performance by being processed along with the desired, tuned signal. Usually, the presence of emi will be apparent to you. It has a bad effect. Upon the desired signal quality, such as that in CROSS-MODULATION where a spurious response occurs when the carrier of a desired signal intermodulates with the carrier of an undesired signal. Extremely strong, off-frequency signals may even burn out the sensitive front-end stages of a receiver. Emi also can degrade overall receiver performance in a less noticeable way. It does this by desensitizing the receiver front end. The noise level is raised and effectively lowers the signal to noise ratio and thus the sensitivity. This causes a decrease in desired signal amplification. For these reasons, shipboard receive systems are designed to include protective circuitry between the antenna and receiver to filter out off-frequency signals. This prevents or limits interference, desensitization, or burnout. Depending upon the system, these protective devices may include filters, multicouplers, preselectors, and so forth. These devices can minimize interference caused by inadequate frequency separation or poor physical isolation between transmit and receive antennas.

Q35. What is the purpose of QMCS?

Q36. What is emi?

Q37. What are the two emi transmission methods?

ELECTROMAGNETIC RADIATION

Radio-frequency (rf) transmitting systems with high-power transmitting tubes and high-gain antennas have increased the possibility of injury to personnel working in the vicinity.

An electromagnetic radiation hazard exists when electronic equipment generates a strong enough electromagnetic field to fall in a category listed below:

- Causes harmful or injurious effects to humans and wildlife
- Induces or otherwise couples currents and/or voltages of magnitudes large enough to initiate electroexplosive devices or other sensitive explosive components of weapons systems, ordnance, or other explosive devices
- Creates sparks large enough to ignite flammable mixtures or materials that must be handled in the affected areas

These hazardous situations can be caused by a transmitter or antenna installation. These generate electromagnetic radiation in the vicinity of personnel, ordnance, or fueling operations in excess of established safe levels. Sometimes the existing electromagnetic radiation levels increase to a hazardous level. When personnel, ordnance, or fueling evolutions are located in an area that can be illuminated by electromagnetic radiation, hazardous situations may occur.

Electromagnetic radiation is hazardous to personnel in two ways. It can cause rf burns; and it can cause biological, thermal, and neurological effects to personnel (RADHAZ). Because of the differences in characteristics and safety precautions required for each of the two types, they will be discussed separately.

An rf burn hazard is a hazardous condition caused by the existence of radio frequency (rf) voltages in places where they are not intended to be. Any ship with high-power hf transmitters is susceptible. Potentially hazardous voltages have been found in many areas. Some of these areas are lifelines, vertical ladders, ASROC launchers, gun mounts, rigging for underway replenishment, and boat davits. Another of these areas is on aircraft tied down on carrier and helicopter flight decks.

Whether or not an induced voltage creates an rf burn hazard depends on whether personnel will come into contact with the object being energized. Generally, only the voltage between an object and the deck is important. The rf burn occurs when a person comes into contact with a source of rf voltage in a manner that allows rf current to flow through the area of contact. Resistance of the skin to the current flow at the areas of contact causes heat. The effect of the heat on a person at the point of contact ranges from noticeable warmth to a painful burn.

The most useful and widespread technique in the reduction of rf burn hazards is the proper bonding and grounding of all metallic objects in the rf radiation field.

In some cases, the rf burn hazard can be eliminated only through the use of restrictive operating procedures. These procedures govern the simultaneous use of transmitting and cargo equipment. Techniques such as operation of transmitters at reduced power and the prohibition of simultaneous use of certain combinations of antennas, frequencies, and cargo handling equipment are used.

Figure 3-35 shows typical rf radiation hazard warning signs.

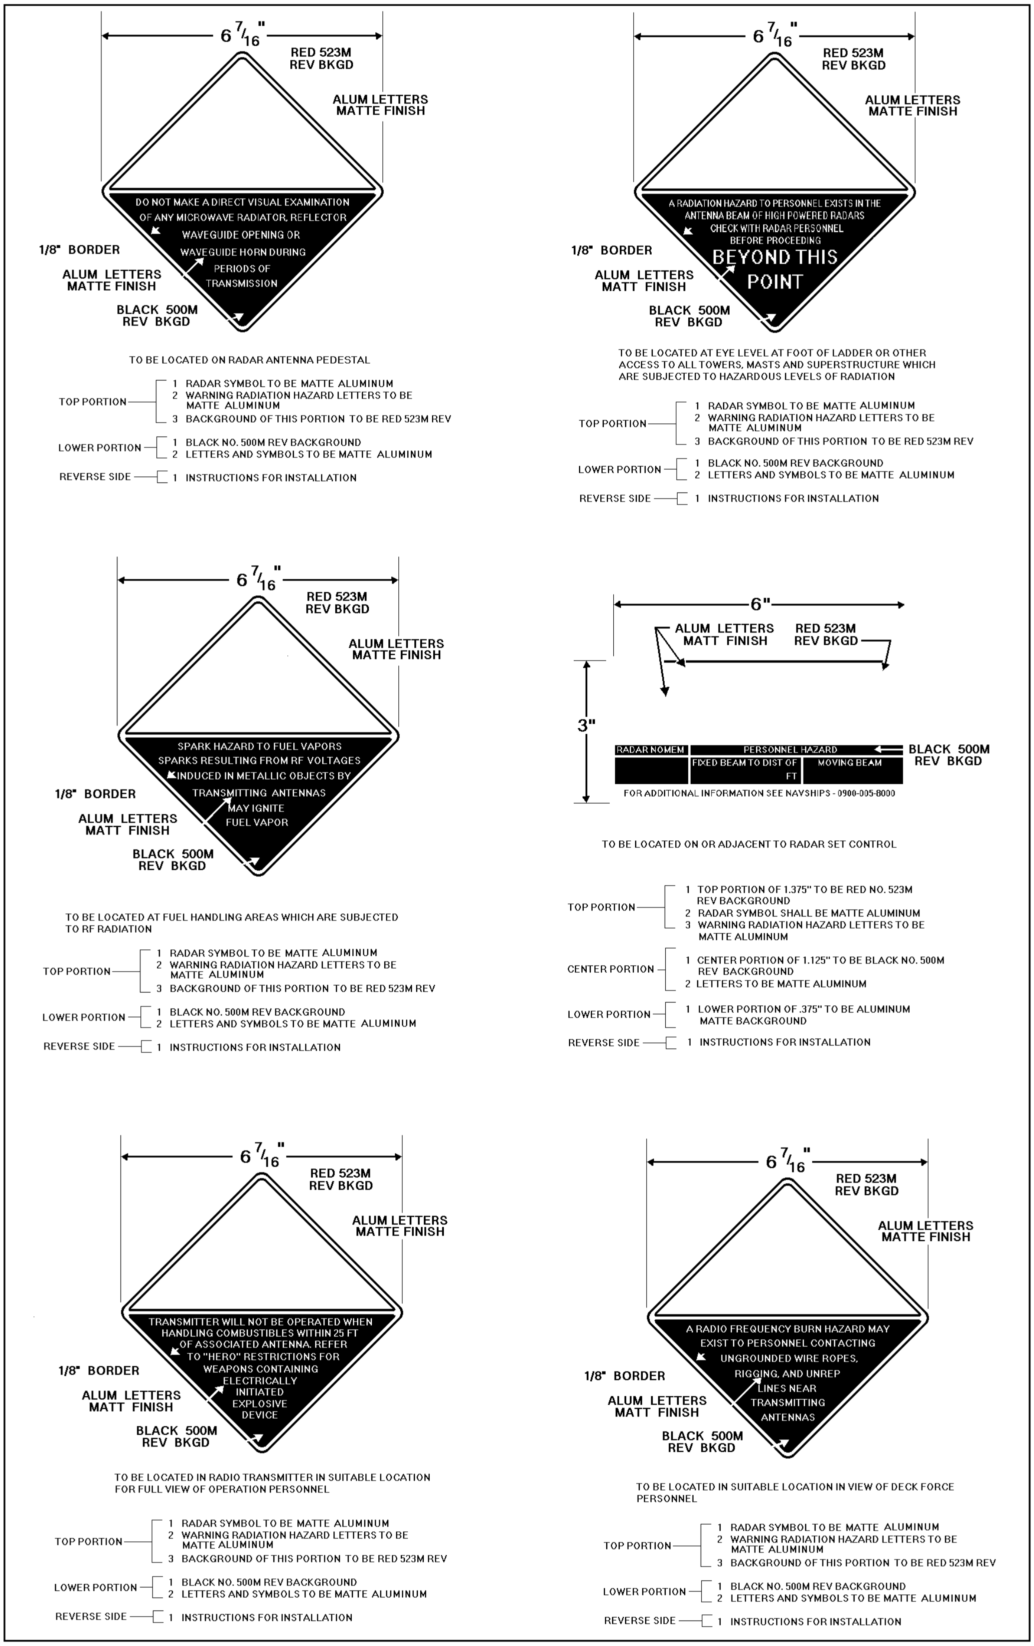

Figure 3-35.—Typical rf radiation hazard warning signs.

Most studies on the subject of radiation hazards (RADHAZ) have emphasized the impact of electromagnetic radiation on man. Man is singled out because of the biological, thermal, and neurological effects that occur in human organs and other biological tissues. Certain organs of the body are considered to be more susceptible than others to the effects of electromagnetic radiation. Presently available information and experience indicate that the eyes and testes are the most vulnerable body organs. The overwhelming danger to date appears to be the hazard from thermal effects, which are a function of intensity of radiation and frequency. This is particularly true in the range of 1 to 3 gigahertz. Thermal effects appear to taper off in severity outside this range.

When the body is irradiated by energy from a point source, the total body surface is usually not exposed. The larger the area exposed and the larger the radiation power density, the higher the body temperature rise and the greater the hazard. Microwave radiation from a radar source will "cook" you internally, just as a microwave oven cooks a chicken.

An injury of great concern is that to the lens of the eye. Exposure of the lens to high-intensity microwaves may cause cataracts. Current medical evidence indicates that a significant temperature elevation of the lens is required for cataract formation. If exposure is limited to 10 milliwatts per centimeter squared, the lens temperature is not elevated to levels at which cataracts occur.

In addition to thermal effects, nonionizing radiation is known to produce nonthermal effects. An association of a biological hazard with the nonthermal effects has not been demonstrated.

A peculiar effect experienced by some personnel is the sensation of sound when they are exposed to pulsed microwave fields. This occurs at levels below stated hazard limits and is not, by itself, considered dangerous.

Q38. Electromagnetic radiation is hazardous to personnel in what two ways?

Q39. What is the most useful and widespread technique to reduce rf burn hazards?

SUMMARY

Now that you have completed this chapter, a short review of what you have learned is in order. The following summary will refresh your memory of basic systems equipment, its principles, terms, and typical circuitry required for you to understand this concept.

A **RADIO SET CONTROL UNIT** is used to remotely control certain transmitter and receiver functions.

TRANSMITTER TRANSFER SWITCHBOARDS selectively transfer remote control station functions and signals to transmitters.

RECEIVER TRANSFER SWITCHBOARDS transfer receiver audio outputs to remote control station audio circuits.

A **TRANSMITTER** generates an rf carrier, modulates it with intelligence, amplifies it, and applies it to an antenna.

An **ANTENNA COUPLER** is a device used for impedance matching between an antenna and a transmitter or receiver.

A **RECEIVER** receives electromagnetic energy (rf) and may convert it to a visible or audible form.

MULTICOUPLERS patch several receivers or transmitters to one antenna. They also filter out harmonics and spurious responses, and provide impedance matching.

MARKING is when a circuit is closed and current flows in teletypewriter operation.

SPACING is when a circuit is open and no current flows in teletypewriter operation.

INTELLIGENCE is any signal that conveys information (voice, teletypewriter, facsimile).

A **START** unit is the first unit of a teletypewriter signal. It is always a space.

A **STOP** unit is the last unit of a teletypewriter signal. It is always a mark.

A **TRANSITION** is the time it takes to shift from a mark to a space condition or from a space to a mark condition.

A **CODE** in teletypewriter operation is a combination of mark and space conditions representing symbols, figures, or letters.

NONSYNCHRONOUS teletypewriter operation is when both transmitter and receiver do not operate continuously.

SYNCHRONOUS teletypewriter operation is when both transmitter and receiver operate continuously.

WORDS-PER-MINUTE is an approximate rate of speed. It means the number of five letter words with a space between them that can be transmitted or received in a one-minute period.

BAUD is a measurement of speed based on the number of code elements or units per second.

BITS-PER-SECOND is an acronym of the words binary digit. One bit is equal to one signal unit or element.

NEUTRAL teletypewriter operation is where current flow represents a mark and no flow represents a space.

POLAR teletypewriter operation is where current flow of one polarity represents a mark and current of the opposite polarity is a space.

RUNNING OPEN is the teletypewriter condition where the type hammer constantly strikes the type box but does not print or move across the page.

A **KEYER** is a device that changes dc pulses to mark and space modulation for teletypewriter transmissions.

A **CONVERTER** changes an audio signal back to dc pulses during teletypewriter reception.

AUDIO FREQUENCY TONE SHIFT systems use amplitude modulation to change dc mark and space impulses into audio impulses.

RADIO FREQUENCY CARRIER SHIFT systems use a keyer to shift a radio frequency signal above or below an assigned frequency. These shifts correspond to marks and spaces.

A **TELETYPEWRITER** is a machine that can transmit and or receive letters, numbers, or symbols. It may have a keyboard similar to a typewriter.

A **PERFORATOR** is a device that stores a teletypewriter message on a paper tape by punching Baudot coded messages into it.

TRANSMITTER DISTRIBUTOR is a device that reads Baudot code from paper tape and allows a message to be sent or a message to be printed on a page printer.

A **REPERFORATOR** stores an incoming tty signal on paper tape.

A **PAGE PRINTER** prints teletypewriter characters one at a time in a full-page format. This is usually a high-speed printer.

RED is the reference color of equipment that passes classified information. It normally refers to patch panels.

BLACK is the reference color of equipment that passes unclassified information. It normally refers to patch panels.

A **PATCH PANEL** is used to tie a receiver or transmitter to its associated equipment.

A **COMPARATOR** compares incoming signals and selects the strongest to be fed to a teletypewriter through a patch panel. This is used in diversity operation

A **LISSAJOUS PATTERN** is a combined, simultaneous display of the amplitude and phase relationships of two input signals on a crt.

A **TONE-TERMINAL** set converts tty dc pulses into audio tones for modulation of a transmitter in audio-frequency tone shift transmissions.

MULTIPLEXING is the process of transmitting a number of intelligence signals simultaneously over a single rf carrier.

TIME-DIVISION multiplexing is the process that periodically samples several intelligence signals. This can be a received signal or one to be transmitted.

FREQUENCY-DIVISION multiplexing transmits and receives the full 360 degrees of each sine wave.

FACSIMILE is the method for transmitting and receiving still images. These images can be maps, photographs, and handwritten or printed text.

SCANNING is the process of subdividing a picture in an orderly manner into segments. This is used in facsimile transmission.

FRAMING is the process of synchronizing a facsimile receiver to a transmitter. This allows proper picture reproduction.

TEMPEST is a term normally used to describe compromising emanations. These emanations are unintentionally radiated signals that could disclose classified information.

ELECTROMAGNETIC INTERFERENCE is a term used to describe the degradation of a receiver or system by externally produced rf energy.

ANSWERS TO QUESTIONS Q1. THROUGH Q39.

A1. To convert energy electrical/acoustic to acoustic/electrical and to key/unkey a transmitter. Also it mutes a receiver when transmitting.

A2. Transferring remote control functions and signals to transmitters.

A3. Transfers receiver audio outputs to remote control stations.

A4. 800 watts.

A5. Automatic, semiautomatic, and manual.

A6. It matches the impedance of an antenna to that of a transmission line at any desired frequency.

A7. To aid in heat transfer and prevent corona and arcing.

A8. Lsb, usb, isb, AM, cw, fsk.

A9. Digital.

A10. To connect an antenna/transmission line to a receiver/transmitter.

A11. Patching and filtering and permits the multiple use of receivers and/or transmitters on a single antenna.

A12. Space and mark.

A13. Intelligence (5), start (1), stop (1).

A14. Shift signals.

A15. Synchronous and nonsynchronous.

A16. A unit of modulation rate.

A17. Binary digit.

A18. Neutral and polar.

A19. Converts dc to corresponding mark and space modulation.

A20. Converts the audio signal to dc pulses.

A21. Uses AM to change dc to audio.

A22. A keyer provides rf excitation, which can be shifted above or below the assigned frequency.

A23. 60, 75, or 100 wpm.

A24. Page-size copy paper and perforated tape.

A25. It handles classified information.

A26. To code or decode messages.

CHAPTER 4

INTRODUCTION TO SATELLITE COMMUNICATIONS

LEARNING OBJECTIVES

Upon completion of this chapter you will be able to:

1. Describe the basic operation of the two types of satellites.
2. Describe the basic components of an operational satellite system.
3. Describe the function of earth terminal equipment.
4. Describe the basic signal flow of a typical shipboard receive-only system.
5. Describe the basic signal flow of a typical shipboard transceiver system.
6. Describe the advantages of satellite communications in terms of capacity, reliability, vulnerability, and flexibility.
7. Describe the limitations of satellites in terms of power, receiver sensitivity, and availability.

HISTORY OF SATELLITE COMMUNICATIONS

The first artificial satellite was placed in orbit by the Russians in 1957. That satellite, called *Sputnik*, signaled the beginning of an era.

The United States, who was behind the Russians, made an all-out effort to catch up, and launched *Score* in 1958. That was the first satellite with the primary purpose of communications.

The first regular satellite communications service was used by the Navy in 1960. The moon was used to bounce teletypewriter signals between Hawaii and Washington, D.C. During the early 1960s, the Navy used the moon as a medium for passing messages between ships at sea and shore stations. This method of communications proved reliable when other methods failed.

Military satellite communications technology was at a low level until 1965. At that time high quality voice transmissions were conducted between a satellite and two earth stations. That was the stepping stone to the Initial Defense Communications Satellite Program (IDCSP), which will be covered later in this chapter.

Experience with satellite communications has demonstrated that satellite systems can satisfy many military requirements. They are reliable, survivable, secure, and a cost effective method of telecommunications. You can easily see that satellites are the ideal, if not often the only, solution to problems of communicating with highly mobile forces. Satellites, if properly used, provide much needed options to large, fixed-ground installations.

For the past fifty years, the Navy has used high-frequency (hf) transmissions as the principal method of sending messages. In the 1970s, the hf spectrum was overcrowded and "free" frequencies were at a premium. Hf jamming and electronic countermeasures (ECM) techniques became highly sophisticated during that period. As a result the need for new and advanced long-range transmission methods became apparent.

Communications via satellite is a natural outgrowth of modern technology and of the continuing demand for greater capacity and higher quality in communications.

In the past, the various military branches have had the resources to support their communications needs. Predicted usage indicates that large-scale improvements will have to be made to satisfy future needs of the Department of Defense. These needs will require greater capacity for long-haul communications to previously inaccessible areas. Satellite communications has the most promise for satisfying these future requirements.

DEFENSE COMMUNICATIONS SATELLITE PROGRAM (DCSP)

The Defense Communications Satellite Program (DCSP) was initiated by the Secretary of Defense in 1962. Phase I of the program was given the title Initial Defense Communications Satellite Program (IDCSP). The first satellite launch occurred in June 1966 when seven experimental satellites were placed into orbit. The final launch of this program consisted of eight satellites and occurred in June 1968.

DEFENSE SATELLITE COMMUNICATIONS SYSTEM (DSCS) PHASE II

The Phase II Defense Satellite Communications System (DSCP Phase II) has changed from an all-analog communications system to an all-digital communications system. The performance capability provided by the Phase II DSCS is limited by equipment availability. Extensive digital traffic capability has become common. You can credit this to the availability of digital modems (modulator/demodulator) and broadband equipment. Overall performance of the Phase II DSCS is a great improvement over the capabilities provided by Phase I DSCS. The Phase II satellites provide a great increase in effective radiated power and rf bandwidths. You will find these satellite configurations use wide coverage and narrow beam antennas. They provide an extensive range of communications services and capabilities. (This will be further discussed later, in this chapter.)

FUNDAMENTAL SATELLITE COMMUNICATIONS SYSTEM

A satellite communications system uses satellites to relay radio transmissions between earth terminals. The two types of communications satellites you will study are ACTIVE and PASSIVE. A passive satellite only reflects received radio signals back to earth. An active satellite acts as a REPEATER; it amplifies signals received and then retransmits them back to earth. This increases signal strength at the receiving terminal to a higher level than would be available from a passive satellite.

A typical operational link involves an active satellite and two or more earth terminals. One station transmits to the satellite on a frequency called the UP-LINK frequency. The satellite then amplifies the signal, converts it to the DOWN-LINK frequency, and transmits it back to earth. The signal is next picked up by the receiving terminal. Figure 4-1 shows a satellite handling several combinations of links simultaneously.

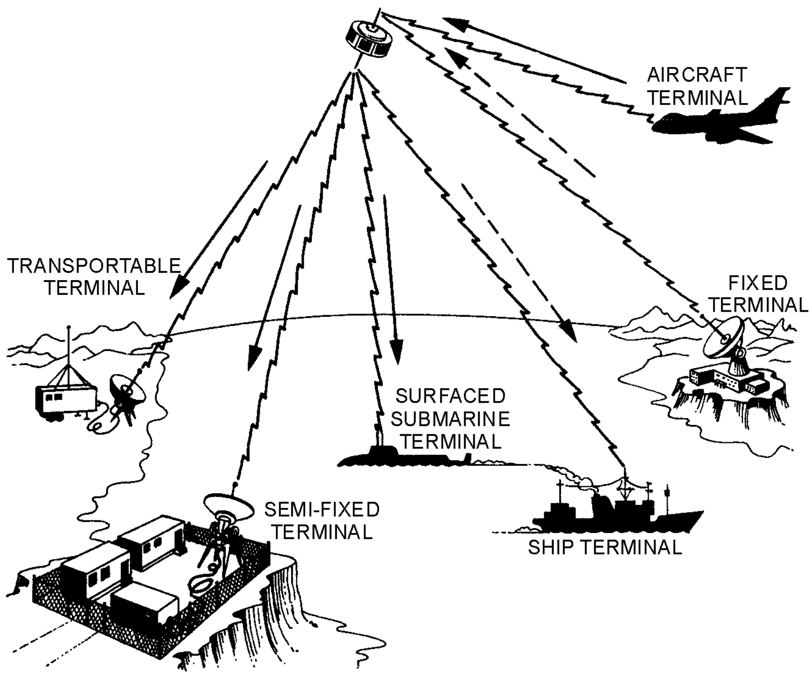

Figure 4-1.—Satellite communications system.

DESCRIPTION OF COMMUNICATIONS SATELLITE SYSTEM

The basic design of a satellite communications system depends to a great degree upon the characteristics of the orbit of the satellite. In general terms, an orbit is either elliptical or circular in shape. A special type of orbit is a SYNCHRONOUS ORBIT. In this type you will find the period (time required for one revolution) of the orbit the same as that of the earth. An orbit that is not synchronous is called ASYNCHRONOUS. A period of orbit that approaches that of the earth is called NEAR SYNCHRONOUS (subsynchronous). Orbits are discussed in more detail later in this chapter.

In addition to the fundamental components shown in figure 4-1, the design of the overall system determines the complexity of the various components and the manner in which the system operates. Current satellites are capable of handling many teletypewriter (tty) and voice circuits at the same time.

Orbit Descriptions

Orbits generally are described according to the physical shape of the orbit and the angle of inclination of the plane of the orbit. These terms aye discussed in the following paragraphs:

PHYSICAL SHAPE.—All satellites orbit the earth in elliptical orbits. (A circle is a special case of an ellipse.) The shape of the orbit is determined by the initial launch parameters and the later deployment techniques used.

PERIGEE and APOGEE are two, of the three parameters used to describe orbital data of a satellite. These are shown on figure 4-2. Perigee is the point in the orbit nearest to the center of the earth. Apogee is the point in the orbit the greatest distance from the center of the earth. Both distances are expressed in nautical miles.

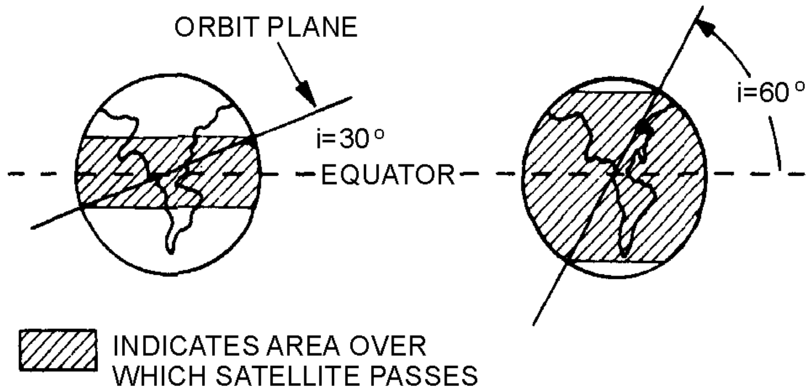

Figure 4-2.—Elliptical satellite orbit.

ANGLE OF INCLINATION.—The ANGLE OF INCLINATION (angle between the equatorial plane of the earth and the orbital plane of the satellite) is the third parameter used to describe the orbit data of a satellite. Figure 4-3 depicts the angle of inclination between the equatorial plane and the orbital plane. Most satellites orbit the earth in orbital planes that do not coincide with the equatorial plane of the earth. A satellite orbiting in any plane not identical with the equatorial plane is in an INCLINED ORBIT.

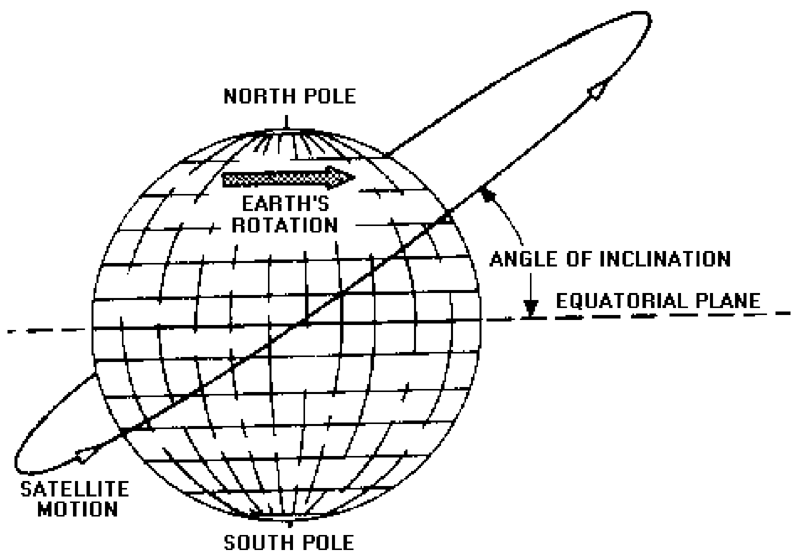

Figure 4-3.—Inclined satellite orbit.

The inclination of the orbit determines the area covered by the path of the satellite. As shown in figure 4-4, the greater the inclination, the greater the amount of surface area covered by the satellite.

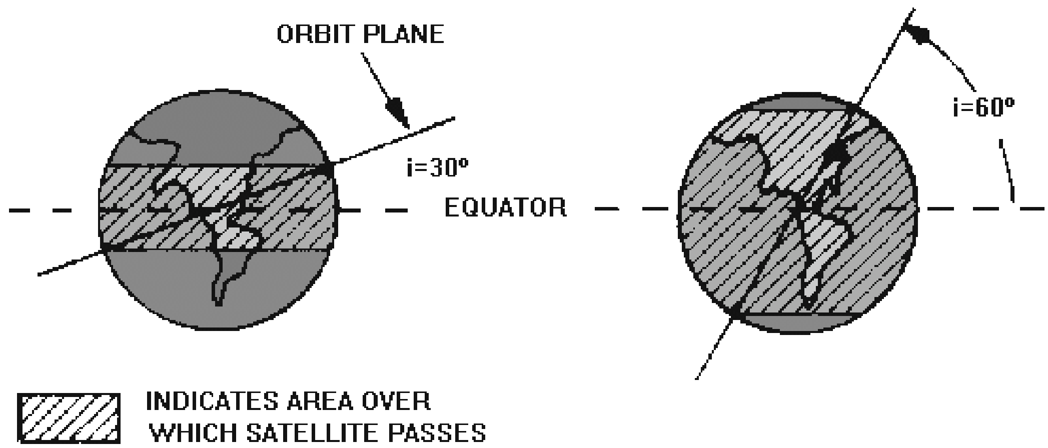

Figure 4-4.—Effect of orbit plane inclination on satellite coverage.

SPECIAL TYPES OF INCLINED ORBITS.—A satellite orbiting in a plane that coincides with the equatorial plane of the earth is in an EQUATORIAL ORBIT. A satellite orbiting in an inclined orbit with an angle of inclination of 90 degrees or near 90 degrees is in a POLAR ORBIT.

SPECIAL TYPES OF CIRCULAR ORBITS.—We stated previously that a circular orbit is a special type of elliptical orbit. You should realize a circular orbit is one in which the major and minor axis distances are equal or approximately equal. Mean height above earth, instead of perigee and apogee, is used in describing a circular orbit. While we are discussing circular orbits, you should look at some of the terms mentioned earlier in this chapter. A satellite in a circular orbit at a height of approximately 19,300 nautical miles above the earth is in a synchronous orbit. At this altitude the period of rotation of the satellite is 24 hours, the same as the rotation period of the earth. In other words, the orbit of the satellite is in sync with the rotational motion of the earth. Although inclined and polar synchronous orbits are possible, the term synchronous usually refers to a synchronous equatorial orbit. In this type of orbit, satellites appear to hover motionlessly in the sky. Figure 4-5 shows how one of these satellites can provide coverage to almost half the surface of the earth.

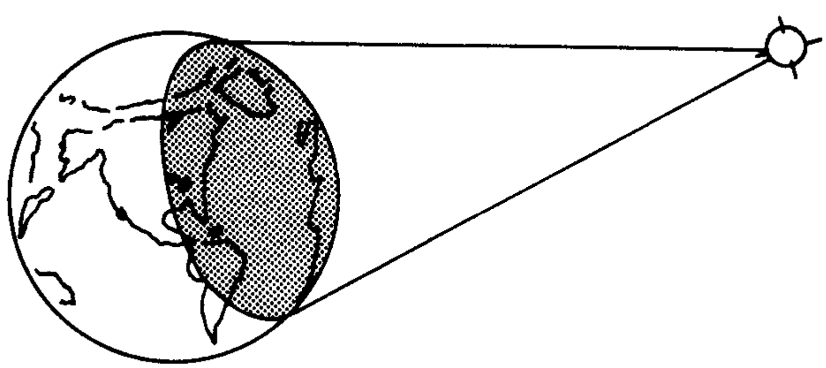

Figure 4-5.—Illumination from a synchronous satellite.

Three of these satellites can provide coverage over most of the earth (except for the extreme north and south polar regions). A polar projection of the global coverage of a three-satellite system is shown in figure 4-6.

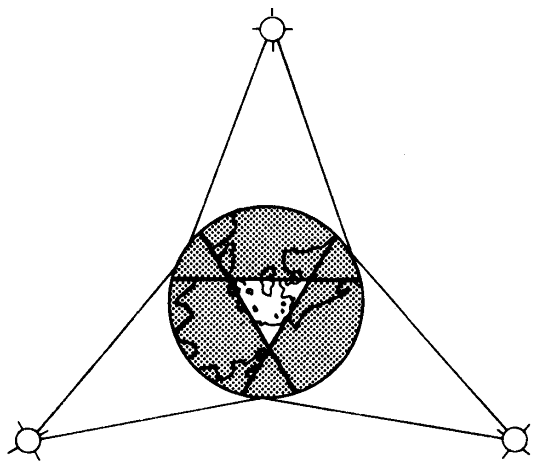

Figure 4-6.—Worldwide synchronous satellite system viewed from above the North Pole.

A satellite in a circular orbit at other than 19,300 nautical miles above the earth is in a near-synchronous orbit. If the orbit is lower than 19,300 nautical miles, the period of orbit of the satellite is less than the period of orbit of the earth. The satellite then appears to be moving slowly around the earth from west to east. (This type of orbit is also called subsynchronous.) If the orbit is higher than 19,300 nautical miles, the period of orbit of the satellite is greater than the period of orbit of the earth. The satellite then appears to be moving slowly around the earth from east to west. Although inclined and polar near-synchronous orbits are possible, near synchronous implies an equatorial orbit.

A satellite in a circular orbit from approximately 2,000 miles to 12,000 miles above the earth is considered to be in a MEDIUM ALTITUDE ORBIT. The period of a medium altitude satellite is considerably less than that of the earth. When you look at this altitude satellite, it appears to move rather quickly across the sky from west to east.

Q1. What are the two types of communications satellites?

Q2. A typical satellite communications operational link consists of a satellite and what two other components?

Q3. A satellite in a synchronous orbit can cover how much of the surface of the earth?

Q4. What areas of the earth are not normally covered by satellites?

SATELLITE CHARACTERISTICS

Early communications satellites were limited in size to the diameter of the final stage of the rocket that was used for launching. Weight was determined by the thrust of the rocket motors and the maximum weight the rocket could lift into orbit.

As early as June 1960, two satellites were successfully placed in orbit by the same launch vehicle. With the development of multilaunch capability, added flexibility became available. We then had choices as to the size, weight, and number of satellites to be included in each launch.

Using our multilaunch capabilities, the Defense Satellite Communications System (DSCS) has placed larger and heavier satellites in synchronous equatorial orbits. Figure 4-7 is a drawing of a DSCS satellite. It shows each pair of transmit and receive dish antennas. As you can see, a large area of the earth can be covered using only one satellite.

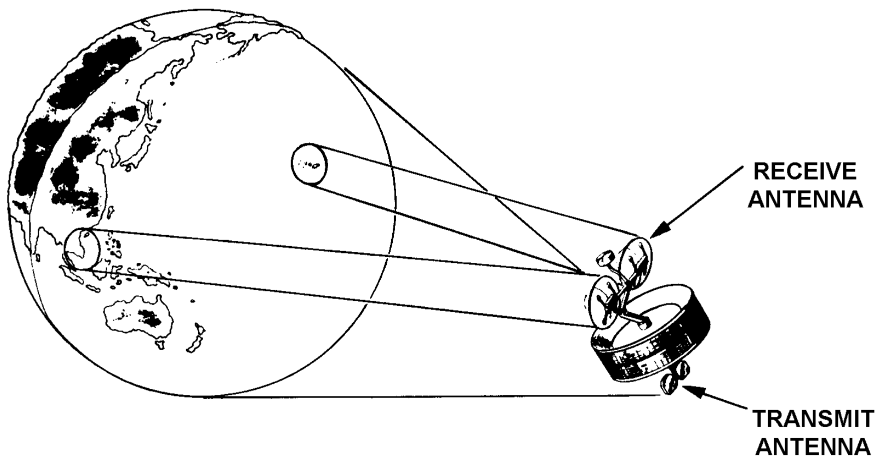

Figure 4-7.—DSCS satellite.

Satellite Power Sources

Early communications satellites were severely limited by the lack of suitable power sources. This severely limited the output power of the satellite transmitter. The only source of power available within early weight restrictions was a very inefficient panel of solar cells without battery backup. A major disadvantage of this type of power source is that the satellite has no power when it is in ECLIPSE (not in view of the sun). For continuous communications, this outage is unacceptable.

A combination of solar cells and storage batteries is a better prime power source. This is a practical choice, even though the result is far from an ideal power source. About ten percent of the energy of the sunlight that strikes the solar cells is converted to electrical power. This low rate is sometimes decreased even further. You find this when the solar cells are bombarded by high-energy particles that are sometimes found in space.

Early satellites had over 8,500 solar cells mounted on the surface of the satellite, which supplied about 42 watts of power. No battery backup was provided in these satellites.

Newer communications satellites have about 32,000 solar cells mounted on the surface of the satellite, and they supply about 520 watts. A nickel cadmium battery is used for backup power during eclipses.

Nuclear power sources have been used in space for special purposes, but their use stops there. Technology has not progressed sufficiently for nuclear power sources to be used as a power source.

Satellite Orientation

Satellite orientation in space is important for continuous solar cell and antenna orientation. Since the primary source of power in most satellites is from solar cells, a maximum number of the solar cells must be exposed to the sun at all times. The satellite antenna must also be pointed at the appropriate earth terminals. Our communications satellites use what is termed spin stabilization to meet these important requirements.

Spin stabilization operates on the principle that direction of the spin axis of a rotating body tends to remain fixed in space. An example of spin stabilization is the effect of the rotation of the earth in keeping its axis fixed in space. A satellite that has a spin axis parallel to the axis of the earth will maintain this position since both axes are fixed in space. Figure 4-8 illustrates the use of this principle. It depicts an equatorial orbit satellite used to keep a doughnut-shaped antenna pattern pointing toward the earth.

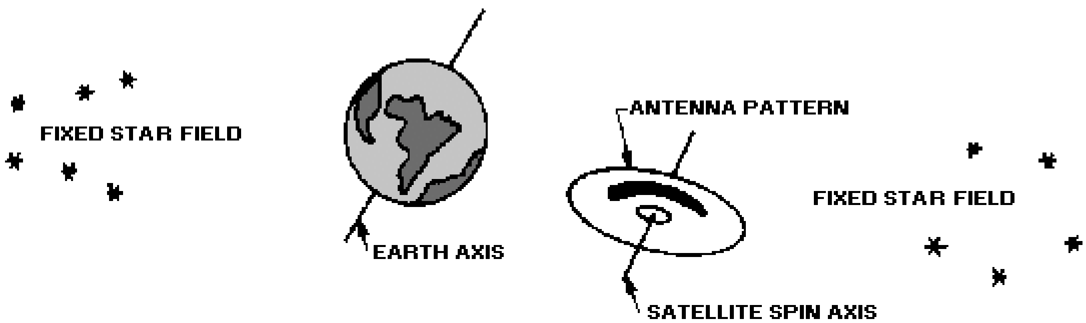

Figure 4-8.—Spin-stabilized satellite antenna pattern.

Once the system is in motion, spin stabilization requires virtually no additional energy. A spin-stabilized satellite is usually constructed like a flywheel. Its heavier equipment is mounted in the same plane and as close to the outside surface as possible.

After reaching its orbit, the radial jets are pulsed to start the satellite spinning. The satellite spin axis is orientated to the axis of the earth by means of small axial jets. Velocity jets are used to place the satellite in orbit position and provide velocity correction. Figure 4-9 is an example of spin stabilization.

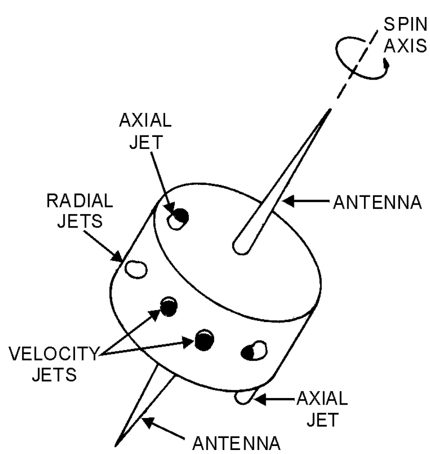

Figure 4-9.—Spin-stabilized satellite controls.

Solar cells are installed around the outside surface of a spin-stabilized satellite. This gives you a large number of solar cells exposed to the sun at all times (except when the satellite is in eclipse). The use of omnidirectional antennas causes a small part of the total radiated energy to be directed toward the earth at all times.

Ominidirectional antennas radiate only a small amount of energy toward the earth. Many techniques have been tried to achieve an earth-oriented antenna system. One system developed uses spin stabilization for orientation of the satellite. It uses a stationary inner platform for mounting remote controlled antennas. The satellite is constructed in two parts with both parts having radial jets. The inner platform contains the communications antennas and the communications package. After the satellite is stabilized in space, inner radial jets spin the inner platform. The inner platform is stationary with respect to earth and is oriented to such a position that the communications antennas point continuously toward the earth. This arrangement allows the use of high-gain directional antennas that concentrate the majority of the radiated energy in the direction of the earth.

The latest versions of communications satellites use a stationary platform with four high-gain antennas. Two steerable narrow beam antennas are used for communications between and within regions of high traffic density. Two horn antennas provide for earth communications between facilities outside the narrow beam coverage. The antenna arrangement for these types of communications satellites is shown in figure 4-7.

Q5. What was the major operational limitation of early communications satellites?

Q6. Satellite orientation in space is important for what two reasons?

EARTH TERMINAL CHARACTERISTICS

Communications satellite earth terminals are usually located in areas remote from the actual users of these communications. This is necessary to minimize rf interference to the satellite.

Locating the terminals in these remote locations requires interconnecting communications links. Links permit communications flow to and from the users of the satellite systems. Interconnect links are usually connected via telephone cables or microwave radio links with normal terminal equipment.

Earth satellite communications terminals generally have a single, large antenna; a highly sensitive receiver; a powerful transmitter; multiplex equipment; modulating-demodulating equipment; and telemetry equipment. Each of these elements will be discussed later in this chapter.

Antennas

Earth terminal antennas are highly directional, high-gain antennas capable of transmitting and receiving signals simultaneously. Generally, large, high-gain, parabolic antennas are used.

Generally speaking, three sizes of parabolic-type antennas are currently in use at earth terminal sites. These are a parabolic antenna sixty feet in diameter, a parabolic antenna forty feet in diameter, and a cluster of four parabolic antennas, each ten feet in diameter. These four in combination are equal to a parabolic antenna eighteen feet in diameter. They are shown in figures 4-10, 4-11, and 4-12, respectively.

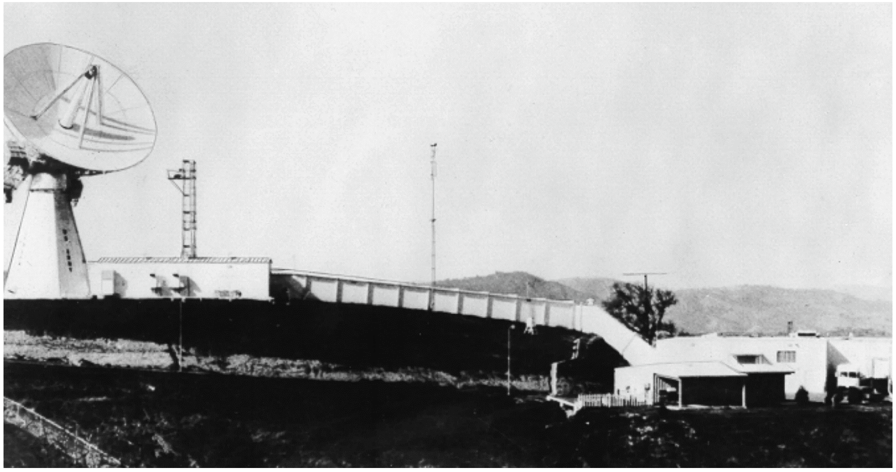

Figure 4-10.—Typical satellite earth terminal with sixty-foot antenna.

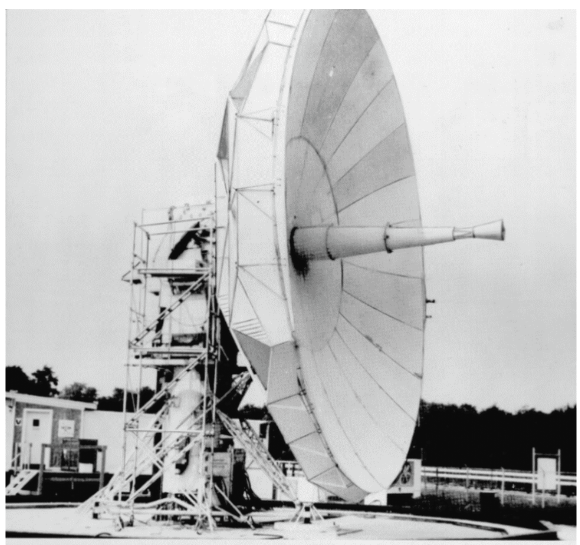

Figure 4-11.—Forty-foot antenna and pedestal.

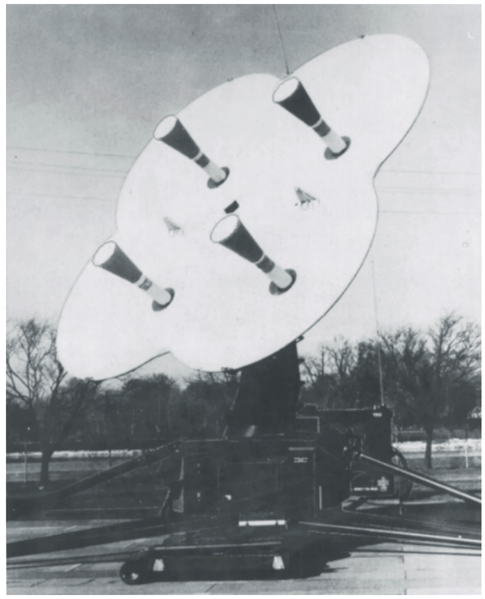

Figure 4-12.—Parabolic antenna cluster.

Receivers

All satellite communications earth terminals are equipped with specially designed, highly sensitive receivers. These receivers are designed to overcome down-link power losses and to permit extraction of the desired communications information from the weak received signal. The terminals currently in use have specially designed preamplifiers mounted directly behind the antennas.

Transmitters

All earth terminal transmitters generate high-power signals for transmission to the communications satellites. High-powered transmitters and highly directional, high-gain antennas are combined in this configuration. This is necessary to overcome up-link limitations and to ensure that the signals received by the satellite are strong enough to be detected by the satellite. Each transmitter has an exciter/modulator and a power amplifier. The modulator accepts the input signal from the terminal equipment and modulates an IF carrier. The exciter translates the IF signal to the up-link frequency and amplifies it to the level required by the power amplifier.

Transmitters used in earth terminals have output power capabilities that vary from 10 watts to 20 kilowatts, depending on the type used and the operational requirements.

Telemetry Equipment

Telemetry equipment is included in all communications satellite systems. This permits monitoring of the operating conditions within the satellite. Telemetry can be used also for remote control of satellite operations, such as energizing axial jets for changing the spin axis of the satellite.

Q7. What type of antennas are generally used at earth terminals?

Q8. Why do earth terminals require highly sensitive receivers?

Q9. What is the range of earth terminal transmitter output power?

SHIPBOARD RECEIVE-ONLY EQUIPMENT SYSTEMS

The purpose of a shipboard receive-only system is to receive fleet multichannel teletypewriter broadcasts, which, as you recall from chapter 1, require no receipt. These are transmitted from a ground station and relayed to naval vessels by satellite.

Figure 4-13 is a typical shipboard receive-only system. In this system the transmitted carrier may be frequency modulated (fm) or phase-shift-key (psk) modulated for tty operation. The receiving antennas for this system are positioned about the ship. They are arranged in a manner (normally one in each quadrant of the ship) that at no time allows the line-of-sight to be blocked between the relay satellite and one or more of the antennas. Incoming signals pass from the antennas to an amplifier-converter. Each amplifier-converter routes an IF signal on one line of a twin axial cable that connects it to the combiner-demodulator. An operating power and local-oscillator signal are coupled from the combiner-demodulator to each amplifier-converter on the other line of the cable used for the IF signal. Because of signal path variations, shading, and reflections, the incoming signals are subject to random phase and amplitude variations. The combiner operation performed within the combiner-demodulator removes the phase variations from each input signal. It then measures the amplitudes of the signals for optimum combining and sums the signals. After being combined, the signal is demodulated and coupled from a receiver transfer switchboard to a telegraph demultiplex terminal.

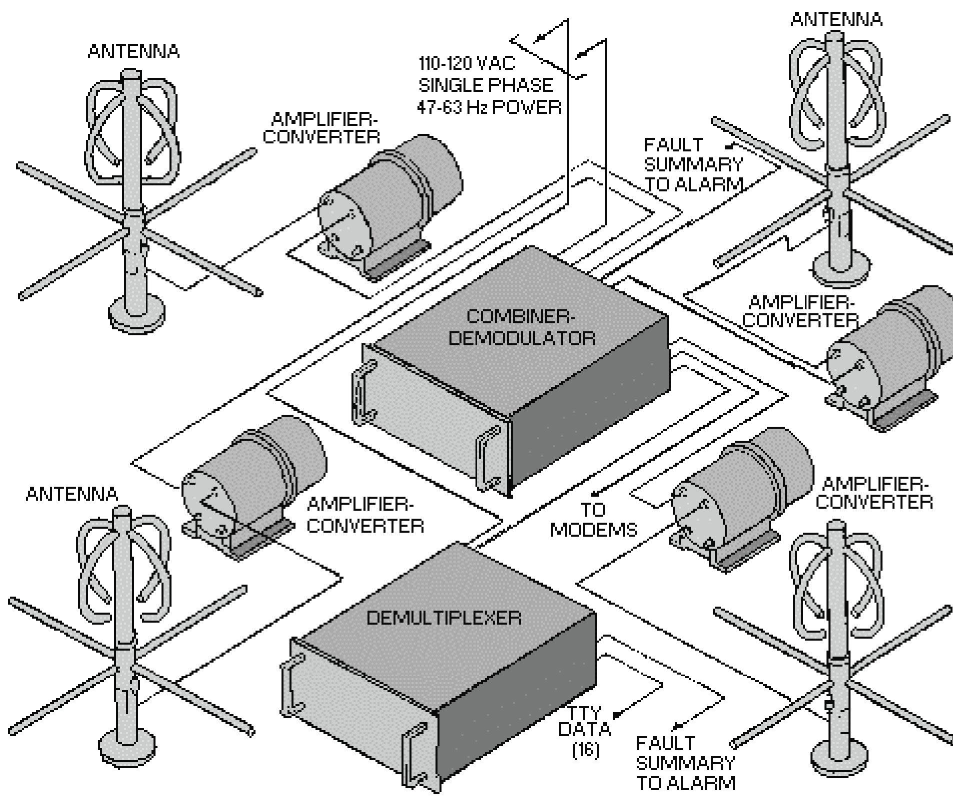

Figure 4-13.—Typical shipboard receive only system.

Q10. What is the function of shipboard receive-only equipment?

Q11. What types of modulation are shipboard receive-only equipment designed to receive?

SATELLITE ACQUISITION AND TRACKING

An essential operation in communicating by satellite is the acquisition (locating) of the satellite by the earth terminal antenna and the subsequent tracking of the satellite. Initial acquisition depends upon an exact knowledge of the position of the satellite. In combination with the geographic location of the earth terminal, knowing the position of the satellite enables you to compute accurate antenna pointing information. The degree of difficulty in locating and tracking a satellite is determined largely by what type orbit the satellite is in.

The locating and tracking of a synchronous satellite is relatively simple. This is because the satellite appears to be stationary. Locating a near-synchronous satellite is also relatively simple because of the slow relative motion of the satellite However, the movement of a near-synchronous satellite is enough that accurate tracking is required to keep the narrow beam antenna pointed toward the satellite. Satellites in medium altitude circular orbits or in elliptical orbits are more difficult to acquire and to track because of the rapid changes in position.

Orbital Prediction

To acquire and track a satellite in space, the earth terminal antennas must be provided with very accurate pointing information. Antenna pointing information is based upon the orbital prediction of the satellite. This information is derived from an EPHEMERIS table. This table provides the coordinates of a satellite or a celestial body at specific times during a given period. After you know the ephemeris data of a satellite, you can predict for any given location the apparent track of the satellite as viewed from that location.

The constants defining an orbit are initially obtained by the process of tracking. At the time of launch, the rocket is tracked by radar from lift-off to orbit and then until it passes out of sight. Tracking data obtained in this way is sufficient for making rough predictions of the orbit. These predictions are made rapidly with a computer and sent to tracking stations all over the world. These other tracking stations watch for the satellite during its first trip and record additional data. During the first week of orbiting, tracking stations all around the world are obtaining progressively more accurate data concerning the Satellite. This data is put into a computer where corrections of earlier estimates of the orbit are made.

Once the initial predictions are complete and the satellite link becomes operational, very little change in these calculations is made. The orbits of a satellite will change slightly over a period of time; however, these changes are so gradual that predictions will be accurate enough to be used for weeks or even months without further corrections. When the orbits are known precisely, an ephemeris can be calculated for each satellite of the system.

Antenna Pointing

Antenna pointing instructions for each satellite must be computed separately for each ground station location. A satellite that bears due south of station A at an elevation of 25 degrees may simultaneously bear due southeast of station B at an elevation of 30 degrees. Antenna pointing instructions are determined by taking into consideration the orbital prediction and the latitude and longitude of each ground station.

To establish radio contact with a satellite, the ground station needs to know the bearing and elevation of a satellite. This allows the antenna to be properly pointed.

Acquisition

The acquisition of satellite signals by a ground station equipped with large antennas and operated at microwave frequencies places severe requirements on the system. Several factors must be considered. These factors are discussed below:

SPATIAL-TIME FACTOR.—Very accurate antenna pointing information is available to earth terminals from the satellite control facility located in Sunnyvale, California. Because of equipment limitations, a small search about the predicted location of the satellite must often be conducted to make initial contact. Either a manual or automatic scan is made around a small area close to the point where the satellite appearance is predicted.

FREQUENCY CONTROL.—The frequency of a radio signal received from a satellite is not generally the exact assigned down-link frequency. This variation depends upon the type of orbit of the satellite. The greatest frequency variations in signals from satellites occur in medium altitude circular or elliptical orbits. The smallest frequency variations occur in signals from satellites in near-synchronous or synchronous orbits.

Tracking

When a particular satellite has been acquired, the earth terminal antenna will track that satellite for as long as it is used as a communications relay. Several methods of tracking are in actual use; however, we will explain PROGRAMMED TRACKING and AUTOMATIC TRACKING.

PROGRAMMED TRACKING.—In programmed tracking the known orbital parameters of the satellite are fed into computation equipment to generate antenna pointing angles. The antenna pointing angles are fed as commands to the antenna positioning servomechanisms. (You may want to review servos in NEETS, Module 15, *Principles of Synchros, Servos, and Gyros*.) These point the antenna in the required direction. The amount of data and computations involved in using programmed tracking is extensive. These are a result of the antenna mount flexing and atmospheric and ionospheric bending of radio waves. Because of these uncertainties, programmed tracking is not used extensively.

AUTOMATIC TRACKING.—In automatic tracking, the equipment generates antenna pointing information by comparing the direction of the antenna axis with the direction from which an actual satellite signal is received. Automatic tracking systems track the apparent position of a satellite. The direction of arrival of the radio signal and the real position of the satellite is not required. The automatic tracking system uses a servomechanism to move the antenna. Once the satellite has been located, the servomechanism generates its own pointing data. This eliminates the requirement for continuous data input and computation.

SATELLITE OUTAGE TIME.—The satellite outage time specifications allow for stewing (moving) the earth terminal antennas, acquiring the satellite signal, and checking for circuit continuity at HAND OVER. (Hand over is the period of time for one earth terminal to yield control to another as a satellite moves out of its area of coverage.) This hand over period represents an outage time. If the control terminal is unable to hand over to another terminal within a specified time, other arrangements are made. For example, control may be retained or transferred to another terminal within the coverage area. There are several reasons why a terminal may be unable to assume control on time; these reasons may combine to increase the outage time. The difference of drift velocities of the satellites leads to bunching within a coverage area. This causes gaps in coverage and increases outage times. When two or more satellites simultaneously occupy the same space of the terminal antennas, they will interfere with each other. This prevents reliable communications. Other factors leading to increased outage times are SATELLITE-SUN CONJUNCTION (increased noise while the satellite passes near the sun), SATELLITE ECLIPSE (absence of power from solar cells), and satellite failures. The distribution of outage times is a complicated function of time and earth-station locations. With careful coverage coordination, maximum communications effectiveness is obtained.

Q12. Why is satellite acquisition and tracking important?

ROLE OF SATELLITE COMMUNICATIONS

In the context of a worldwide military communications network, satellite communications systems are very important. Satellite communications links add capacity to existing communications capabilities and provide additional alternate routings for communications traffic. Satellite links, as one of several kinds of long-distance links, interconnect switching centers located strategically around the world. They are part of the defense communication systems (DCS) network. One important aspect of the satellite communications network is that it continues in operation under conditions that sometimes render other methods of communications inoperable. Because of this, satellites make a significant contribution to improved reliability of Navy communications.

ADVANTAGES OF SATELLITE COMMUNICATIONS

Satellite communications have unique advantages over conventional long distance transmissions. Satellite links are unaffected by the propagation variations that interfere with hf radio. They are also free from the high attenuation of wire or cable facilities and are capable of spanning long distances. The numerous repeater stations required for line-of-sight or troposcatter links are no longer needed. They furnish the reliability and flexibility of service that is needed to support a military operation.

Capacity

The present military communications satellite system is capable of communications between backpack, airborne, and shipboard terminals. The system is capable of handling thousands of communications channels.

Reliability

Communications satellite frequencies are not dependent upon reflection or refraction and are affected only slightly by atmospheric phenomena. The reliability of satellite communications systems is limited only by the equipment reliability and the skill of operating and maintenance personnel.

Vulnerability

Destruction of an orbiting vehicle by an enemy is possible. However, destruction of a single communications satellite would be quite difficult and expensive. The cost would be excessive compared to the tactical advantage gained. It would be particularly difficult to destroy an entire multiple-satellite system such as the twenty-six random-orbit satellite system currently in use. The earth terminals offer a more attractive target for physical destruction. These can be protected by the same measures that are taken to protect other vital installations.

A high degree of freedom from jamming damage is provided by the highly directional antennas at the earth terminals. The wide bandwidth system that can accommodate sophisticated anti-jam modulation techniques also lessens vulnerability.

Flexibility

Most operational military satellite earth terminals are housed in transportable vans. These can be loaded into cargo planes and flown to remote areas. With trained crews these terminals can be put into operation in a matter of hours. Worldwide communications can be established quickly to remote areas nearly anywhere in the free world.

SATELLITE LIMITATIONS

Limitations of a satellite communications system are determined by the technical characteristics of the satellite and its orbital parameters. Active communications satellite systems are limited by two things. Satellite transmitter power on the down links and receiver sensitivity on the up links. Some early communications satellites have been limited by low-gain antennas.

Power

The amount of power available in an active satellite is limited by the weight restrictions imposed on the satellite. Early communications satellites were limited to a few hundred pounds because of launch-vehicle payload restraints. The only feasible power source is the inefficient solar cell. (Total power generation in the earlier satellites was less than 50 watts.) As you can see, the rf power output is severely limited; therefore, a relatively weak signal is transmitted by the satellite on the down link. The weak transmitted signal is often reduced by propagation losses. This results in a very weak signal being available at the earth terminals. The level of signals received from a satellite is comparable to the combination of external atmospheric noise and internal noise of standard receivers. Special techniques must be used to extract the desired information from the received signal. Large, high-gain antennas and special types of preamplifiers solve this problem but add complexity and size to the earth terminal. (The smallest terminal in the defense communication systems network has effectively an 18-foot antenna and weighs 19,500 pounds.) Development of more efficient power sources and relaxation of weight restrictions have permitted improved satellite performance and increased capacity.

Receiver Sensitivity

Powerful transmitters with highly directional antennas are used at earth stations. Even with these large transmitters, a lot of signal loss occurs at the satellite. The satellite antenna receives only a small amount of the transmitted signal power. A relatively weak signal is received at the satellite receiver. This presents little problem as the strength of the signal received on the up link is not as critical as that received on the down link. The down-link signal is critical because the signal transmitted from the satellite is very low in power. Development of high-gain antennas and highly sensitive receivers have helped to solve the down-link problem.

Availability

The availability of a satellite to act as a relay station between two earth terminals depends on the locations of the earth terminals and the orbit of the satellite. All satellites, except those in a synchronous orbit, will be in view of any given pair of earth stations only part of the time. The length of time that a nonsynchronous satellite in a circular orbit will be in the ZONE OF MUTUAL VISIBILITY (the satellite can be seen from both terminals) depends upon the height at which the satellite is circling. Elliptical orbits cause the satellite zone of mutual visibility between any two earth terminals to vary from orbit to orbit. These times of mutual visibility are predictable. Figure 4-14 illustrates the zone of mutual visibility.

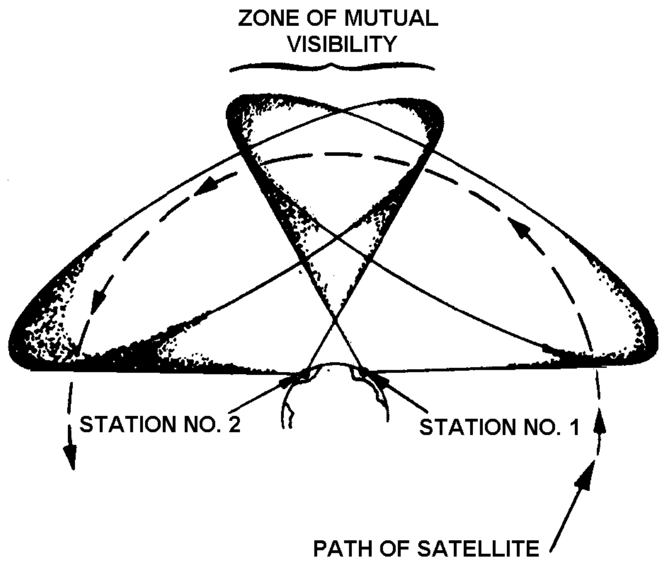

Figure 4-14.—Zone of mutual visibility.

Q13. What are the two limitations to an active satellite communications system?

FUTURE SATELLITE COMMUNICATIONS

Satellite communications are becoming well established in the Navy. In October 1983 the Department of the Navy established the Naval Space Command, which assumed operational responsibility for Navy space systems plus coordination responsibility with other operational activities. Most ships have satellite communications capability. New systems have been installed on ships and are fully compatible with other electronic systems and equipment. Communications via satellite has increased existing Navy communications capabilities for the command and control of naval forces. Satellite communications has not replaced all existing means of radio communications. However, it is a major step in modernizing Navy communications. It has relieved the Navy of its total dependence on hf radio transmission and reduced the need for many hf ground stations overseas.

A recent step in the advancement of satellite communications was the start of the DSCS Phase III. The first Phase III satellite was launched into orbit by the space shuttle in the summer of 1984. Seven satellites will be placed in space during this phase. Figure 4-15 shows a Phase III satellite being tested in a simulated space environment, Figure 4-16 shows the Phase III satellite as it appears in space. Phase III will develop the use of 40-watt, solid-state amplifiers to replace the currently used traveling-wave tube (twt). It will also be used to develop new type filters. These filters will provide increased channel bandwidth, which will provide additional communications capacity.

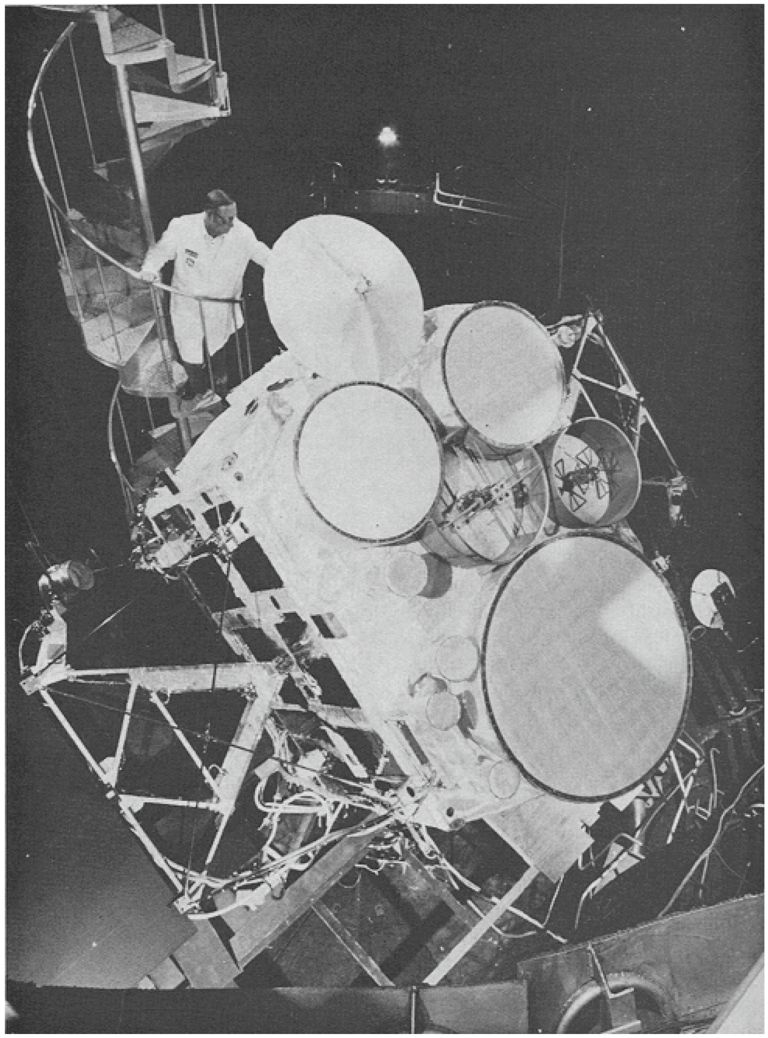

Figure 4-15.—DSCS Phase III satellite being tested.

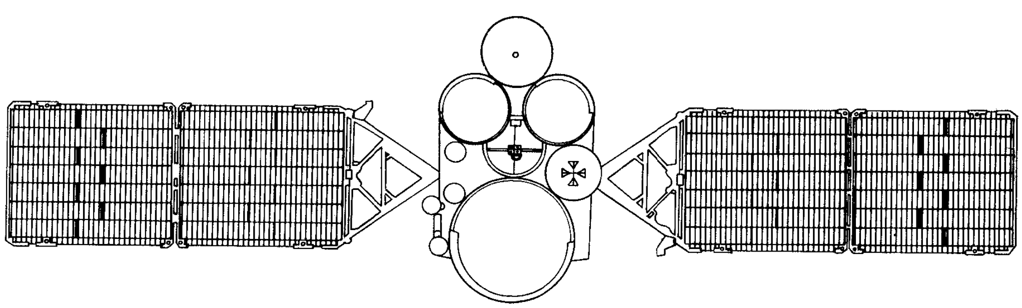

Figure 4-16.—DSCS Phase III satellite as it appears in space.

The survivability of reliable communications for the command and control of our strategic nuclear forces is paramount. Space systems perform many missions more effectively than earthbound systems.

Spaceborne communications increase the effectiveness of military operations. The Department of Defense is engaged in the development of new communications techniques and systems, including some that are space based. As the use of space continues its march forward, vital new opportunities for national defense will continue to materialize. This will improve the survivability of our strategic communications against nuclear and electronic attack.

More information on satellite communications can be found in Navy publication NTP 2, *Navy Satellite Operations*. This publication was written to concisely explain the role of the Navy in the Defense Communications Satellite Program. It also issues procedures for effective, coordinated use of available satellite resources.

SUMMARY

Now that you have completed this chapter, a short review of what you have learned will be helpful. The following review will refresh your memory of satellite communications, equipment, and theory.

A **PASSIVE SATELLITE** is one that reflects radio signals back to earth.

An **ACTIVE SATELLITE** is one that amplifies the received signal and retransmits it back to earth.

REPEATER is another name for an active satellite.

The **UP LINK** is the frequency used to transmit a signal from earth to a satellite.

The **DOWN LINK** is the frequency used to transmit an amplified signal from the satellite back to earth.

A **SYNCHRONOUS ORBIT** is one in which the satellite moves or rotates at the same speed as the earth.

An **ASYNCHRONOUS ORBIT** is one where the satellite does not rotate or move at the same speed as the earth.

A **NEAR SYNCHRONOUS ORBIT** is one in which the satellite rotates close to but not exactly at the same speed as the earth.

PERIGEE is the point in the orbit of a satellite closest to the earth.

APOGEE is the point in the orbit of a satellite the greatest distance from the earth.

The **ANGLE OF INCLINATION** is the angular difference between the equatorial plane of the earth and the plane of orbit of the satellite.

INCLINED ORBITS are orbits where there is some amount of inclination. These include equatorial and polar orbits.

An **EQUATORIAL ORBIT** is an orbit that occurs when the plane of a satellite coincides with the plane of the earth at the equator.

A **POLAR ORBIT** is an orbit that has an angle of inclination of or near 90 degrees.

A **MEDIUM ALTITUDE ORBIT** is an orbit from 2,000 to 12,000 miles above the earth. The rotation rate of the earth and satellite are quite different, and the satellite moves quickly across the sky.

An **ECLIPSE** is when the satellite is not in view or in direct line of sight with the sun. This happens when the earth is between them.

An **EPHEMERIS** is a table showing the precalculated position of a satellite at any given time.

PROGRAMMED TRACKING uses known satellite orbital parameters to generate antenna pointing angles.

AUTOMATIC TRACKING is done by the equipment comparing the direction of the antenna axis and the direction of the received signal.

HAND OVER is the period of time for one earth terminal to yield control to another as a satellite moves out of its area of coverage.

SATELLITE-SUN CONJUNCTION is when the satellite and sun are close together and the noise from the sun prevents or hampers communications.

A **SATELLITE ECLIPSE** is an eclipse where the rays of the sun don't reach the satellite. This prevents recharging of the solar cells of the satellite and decreases the power to the transmitter.

The **ZONE OF MUTUAL VISIBILITY** is where the satellite can be seen by both the up- and down-link earth terminals.

ANSWERS TO QUESTIONS Q1. THROUGH Q13.

A1. Passive and active.

A2. Earth terminals.

A3. Approximately one-half.

A4. The extreme polar regions.

A5. The lack of suitable power sources.

A6. To allow maximum solar cell exposure to the sun and satellite antenna exposure to earth terminals.

A7. Large, high-gain parabolic antennas.

A8. To overcome satellite transmitter low power and permit extraction of the desired information from the received signal.

A9. Up to 20 kilowatts.

A10. To receive fleet multichannel tty broadcasts.

A11. Fm or psk.

A12. To ensure earth terminal antennas are always pointed towards the satellite.

A13. Satellite down-link transmitter power and up-link receiver sensitivity.

CHAPTER 5

INTRODUCTION TO MISCELLANEOUS COMMUNICATIONS SYSTEMS AND EQUIPMENT

LEARNING OBJECTIVES

Upon completion of this chapter you will be able to:

1. Describe the basic operation of communications systems that operate at medium frequencies and below.
2. Describe the basic microwave line-of-sight communications system.
3. Describe the basic tropospheric scatter communications system.
4. Describe the objective/purpose of the naval tactical data system (NTDS).
5. Describe the naval tactical data system (NTDS) data transmission subsystems in terms of links.
6. Explain the various applications of portable communications equipment.
7. Define the term laser.
8. Describe the basic theory of operation of lasers
9. Describe the possible applications of lasers in communications.

INTRODUCTION

In the previous four chapters we've looked at communications equipment and systems that were used in several frequency ranges. Some have had many applications. In this chapter you will look at systems used in some portions of the rf spectrum that have not been covered in detail. We will also discuss the naval tactical data system (NTDS), which operates in the high-frequency and ultrahigh-frequency regions. Various portable communications equipments used in the military and an introduction to the laser and its uses in communications are included. Some of the applications presented are fairly new to the military community.

SYSTEMS

As discussed in chapter 1, the frequency range from elf to shf is from below 300 hertz up to 30 gigahertz. The first area we will cover is the lower frequency bands (medium frequency [mf] and below). You will then get a look at the microwave region and the high-frequency and ultrahigh-frequency range as it pertains to the naval tactical data system (NTDS).

MEDIUM FREQUENCY AND BELOW

Most of the receivers and transmitters that you will see used in the mf portions of the rf spectrum and below are very similar in design. In chapter 1 we discussed the operational uses of the equipment; now let's look at the equipment itself.

Equipment items covered in this and other chapters are meant to be merely representative of equipment that may be encountered in naval communications. No attempt will be made to include all of the possible equipment or equipment configurations.

Transmit Equipment

You should realize the transmitters used in bands of medium frequency and below are similar to those you studied in chapter 2. In other words, a transmitter used in one frequency range is basically the same as one used in another range. However, there are some differences. Two of the differences are component size and the use of a technique called DOUBLING UP.

The components used in bands of medium frequency and below are much larger physically than the ones previously discussed. This is because of the higher operating voltage and current levels required to produce the very high-powered rf outputs needed for the uses covered in chapter 1. A given resistor used in an hf application may be rated at 1/2 watt, whereas the same resistor used in a lower frequency application would probably be rated in tens or even hundreds of watts.

A block diagram of a doubled-up transmitter is shown in figure 5-1. Remember, bands of medium frequencies and below are used almost exclusively for broadcast and are on the air continuously. Doubling up increases reliability. As you can see, two transmitters are located in the same equipment cabinet. This allows you to quickly transfer circuits if one should fail. This dual installation also allows both amplifiers to be used together to double the output power. When you use this application, you sacrifice the doubling-up capability of only the power amplifier. All the other components are still available as backups. Let's go through figure 5-1 and describe the block functions.

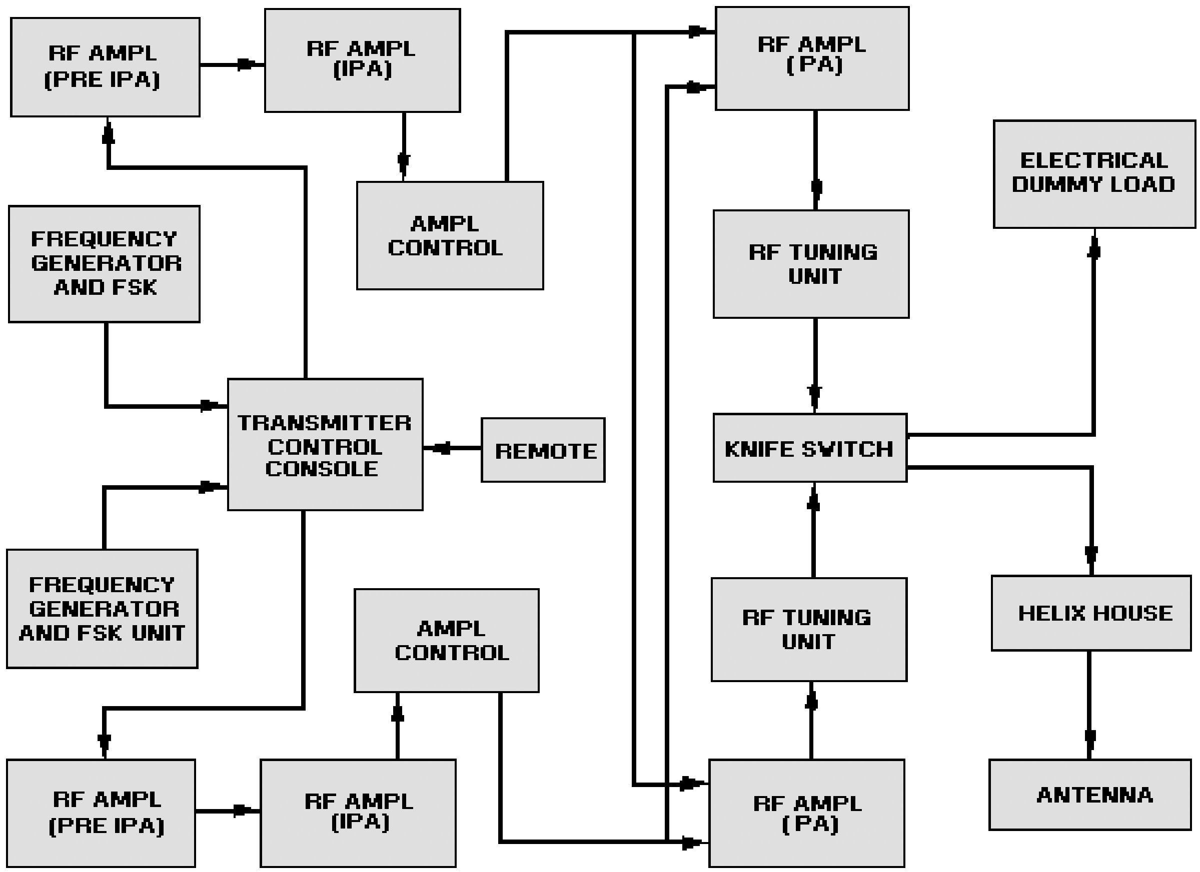

Figure 5-1.—Doubled-up transmitter block diagram.

The frequency generator part of the frequency generator and fsk block is an oscillator. It provides the carrier frequencies for the cw mode. The fsk part is a FREQUENCY SYNTHESIZER (a frequency source of high accuracy). It makes both the mark and space frequencies from a very stable clock oscillator. The keying pulses determine which fsk frequency the keyer chooses to transmit. This signal is then sent to the transmitter control console where it is distributed to the first rf amplifier. This amplifier is referred to as the preliminary intermediate-power amplifier (pre-ipa). The pre-ipa uses linear, untuned, push-pull, rf amplifiers to provide amplified rf to drive other rf amplifiers. The pre-ipa output goes to the intermediate power amplifier (ipa).

The ipa receives the pre-ipa output, amplifies the signal, and drives other selected power amplifiers. The ipa is a single-stage, untuned, linear, push-pull, rf circuit that uses water and forced-air cooled tubes.

Signals are then sent through the amplifier control, where they are used for signal monitoring purposes before being applied to the final rf amplifier (pa). The pa amplifies the signal to the final desired power level. The pa also contains variometers (variable inductors) for coupling. This coupled output is fed to the rf tuning unit.

The rf tuning unit consists of variable oil-filled capacitors and a fixed inductor for frequency tuning. The signal is then sent to a knife switch. This switch simply routes the signal to the DUMMY LOAD or the antenna by way of the HELIX HOUSE. (A dummy load is a nonradiating device the absorbs the rf and has the impedance characteristics of the antenna.) The dummy load is impedance matched to the pa. It allows testing of the pa without putting a signal on the air. When the equipment is in an operating mode, the dummy load is not used. The helix house is a small building physically separated from the transmitter location. It contains antenna loading, coupling, and tuning circuits. The main components consist of a HELIX (large coil) and variable inductors. The signal is fed from the helix directly to the antenna. Sometimes two antennas are used.

Antenna designs vary with the amount and type of land available, desired signal coverage, and bandwidth requirements. Figure 5-2 shows a simplified transmit antenna. The Navy uses TOP-HAT (flat-top) capacitive loading with one or more radiating elements. Typical top hat antennas consist of two or more lengths of wire parallel to each other and to the ground, each fed at or near its mid point. The lengths of wire are usually supported by vertical towers. These antennas may take many shapes. The matching network shown is in the helix house. Figure 5-3 shows the installation at the naval communications unit in Cutler, Maine. The Navy has several of these types of installations. They are used primarily for fleet broadcasts and have power outputs in the .25- to 2-megahertz range. You should notice the transmitter, the location of the helix houses, and the dual antennas. You should also notice the transmission line tunnel. It is underground and over a half-mile long. Figure 5-4, view (A) and view (B), shows another antenna configuration. This array of monopoles (quarter-wave, vertically polarized stubs) is referred to as a TRIATIC antenna. A triatic antenna is a special form of a rhombic-arranged monopole array. This type of array is designed to transmit from a particular location. Triatics are all basically the same but have some design differences at each site. The physical differences compensate for differences in terrain. Now that we have looked at the transmit side, let's look at the receive side.

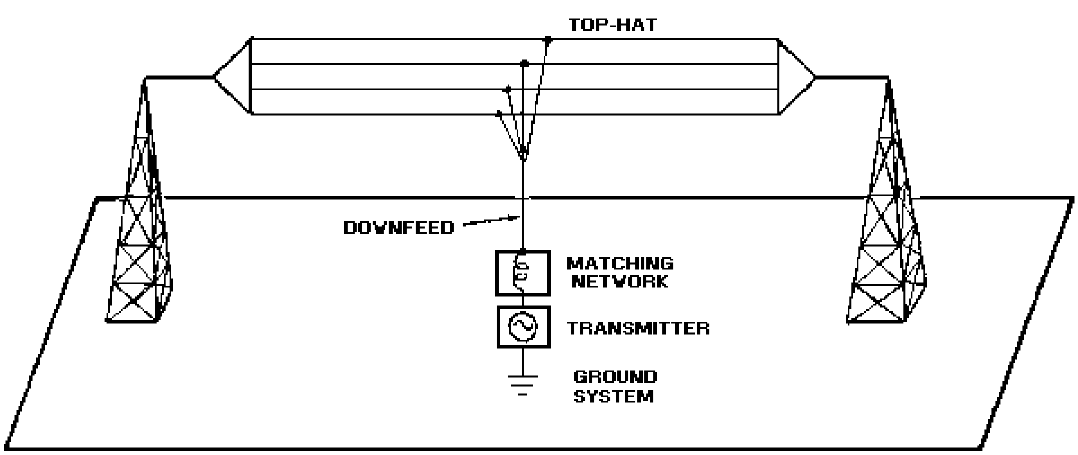

Figure 5-2.—Simplified vlf transmitting antenna.

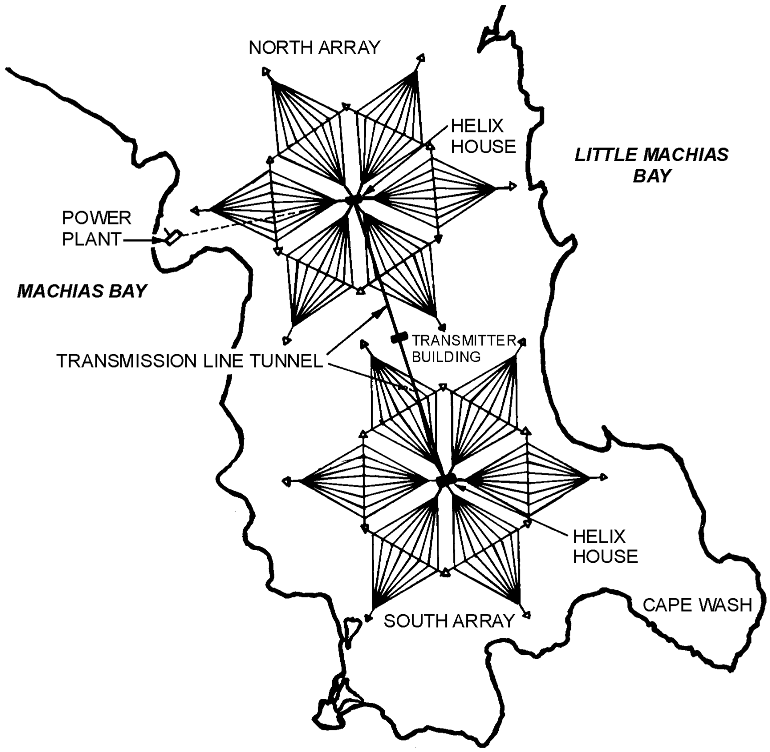

Figure 5-3.—Cutler, Maine antenna installation.

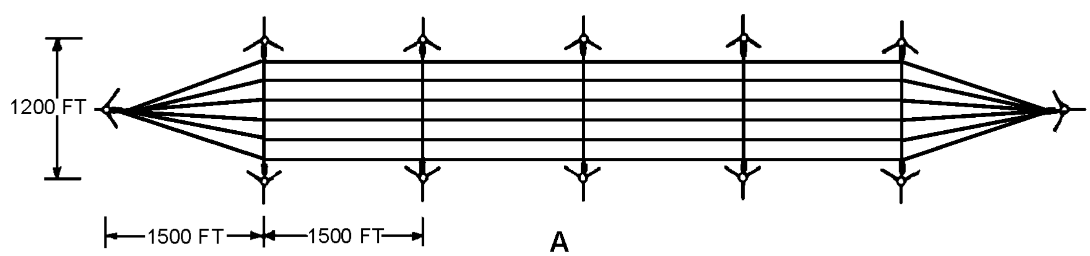

Figure 5-4A.—Triatic type antenna.

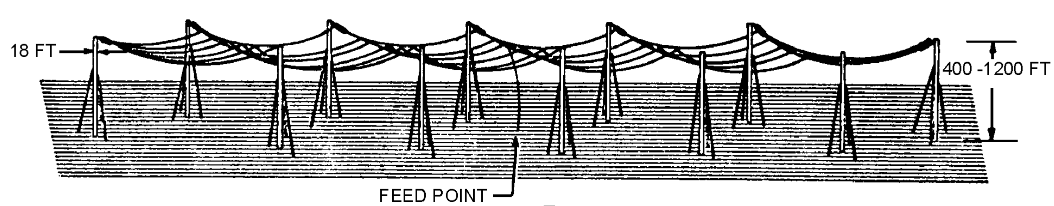

Figure 5-4B.—Triatic type antenna.

Receive Equipment

The receiver you will study here is fundamentally the same as those we covered in chapter 2. A receiver used in this frequency range is about the same electrically as one used in any other range. Figure 5-5 shows the receiver we will discuss. It is a highly sensitive, special purpose receiver because it is capable of splitting-out multiplex signals for detection and reproduction. This receiver covers the frequency range of 3 kilohertz to 810 kilohertz in five bands. It will receive most types of signals, including AM, cw, ssb, fm, and fsk. All operator controls are on the front panel, and a speaker and headset jack permit monitoring.

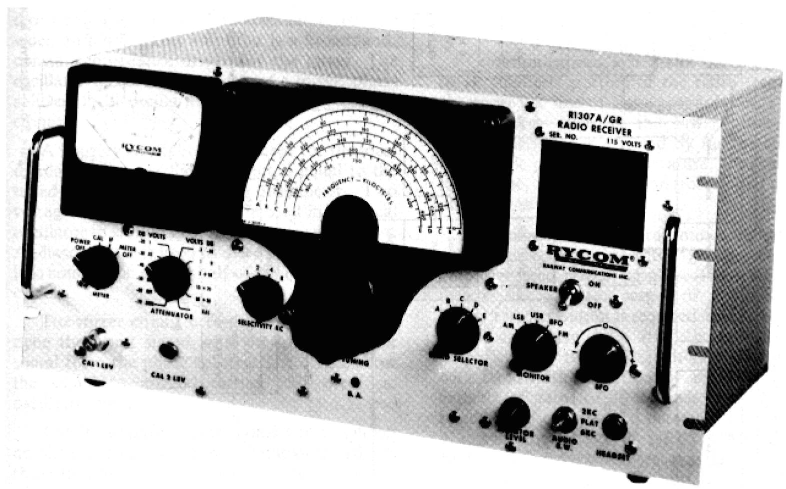

Figure 5-5.—Typical vlf to mf receiver.

Our receiver has five basic stages excluding the power supply. With the exception of a video amplifier in place of an rf amplifier, the circuits perform the functions normally associated with a typical receiver. Figure 5-6 is a block diagram showing the signal paths of the receiver. The input stage consists of a low-pass filter, an attenuator, a calibration oscillator, and a video amplifier. The low-pass filter passes input frequencies below 900 kilohertz. These frequencies are passed to the attenuator, which sets the signal to the proper level to drive the mixer. This minimizes noise and distortion. The calibration oscillator produces a 250-kilohertz output. It is used to calibrate the receiver level and to check for tuning dial accuracy. The input signal is direct-coupled from the attenuator to the video amplifier. This amplifier is a broadband, constant-impedance driver for the mixer. The oscillator-mixer stage consists of a mixer, phase splitter, local oscillator, and frequency control circuits.

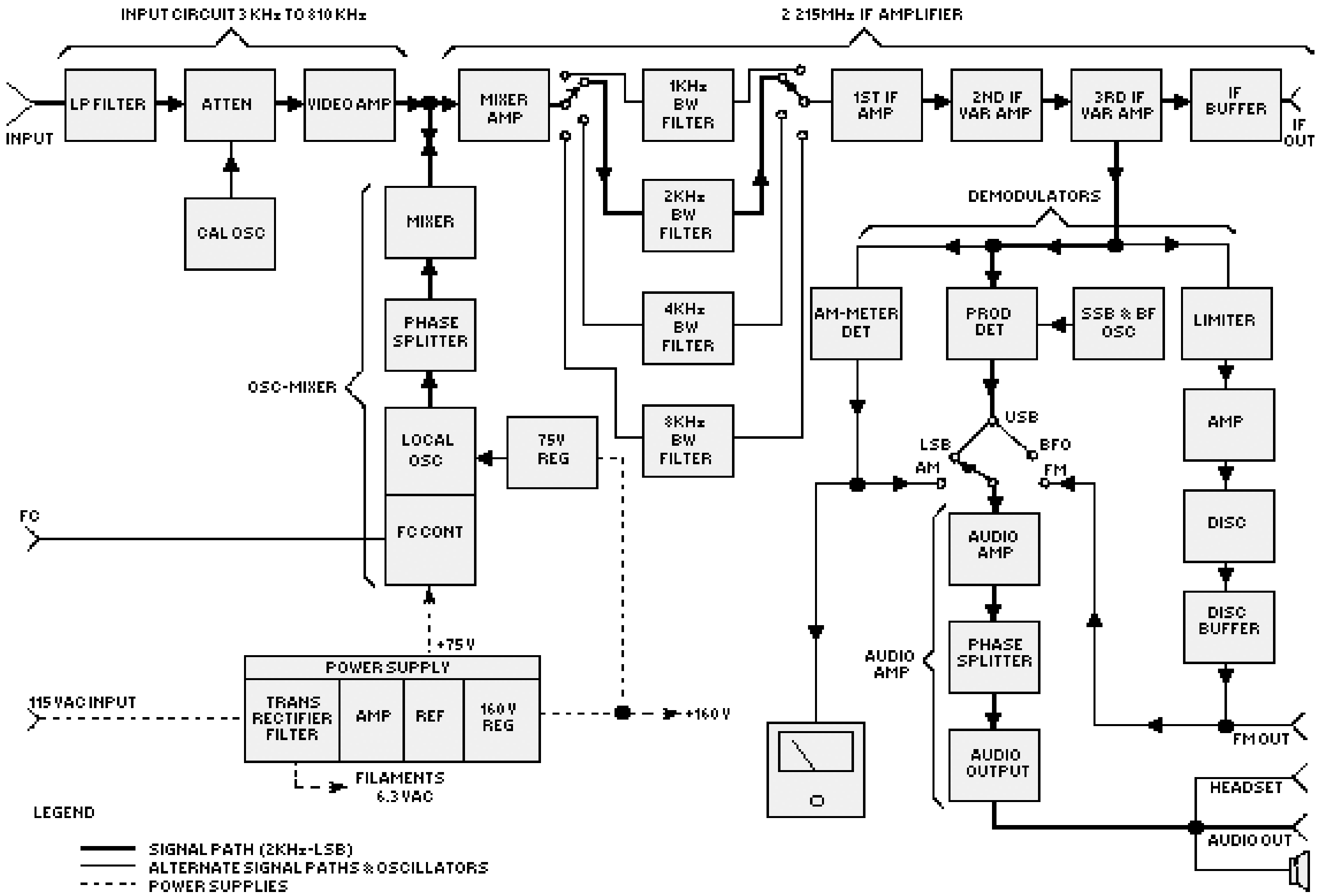

Figure 5-6.—Receiver block diagram.

A Hartley configuration is used for the local oscillator. The oscillator output is equal to the tuned frequency plus 2.215 megahertz. Two voltage-variable capacitors are used in the local oscillator to stabilize small frequency variations. A phase splitter is used to drive the mixer diodes into conduction during half of the local oscillator cycle.

The mixer circuit uses the diodes to heterodyne the input signal with the local oscillator signal from the phase splitter. The diodes short the signal to ground during half the local oscillator cycle.

The IF amplifier stages consist of the mixer amplifier, four selectable bandwidth filters, three IF amplifiers, and an IF buffer amplifier.

The output of the mixer is directly coupled to the mixer amplifier. The IF signal is then directed through one of four bandwidth filters to the first IF amplifier. The signal proceeds to the second and third IF amplifiers for amplification before demodulation. An IF buffer amplifier is used to pass the IF to the IF OUT jack and to isolate this jack from the rest of the circuitry.

Three demodulators are used in this receiver. They are the AM detector, product detector, and fm detector. The AM detector is used to demodulate AM signals. The product detector demodulates ssb, cw, and fsk signals, and the fm detector demodulates fm signals only. An output from the fm detector is provided to the FM OUT jack. This fm output may be used for recording or detailed analysis.

The output from the selected demodulator is amplified by the audio amplifier and presented simultaneously to the HEADSET jack, AUDIO OUT terminals, and the speaker.

You should note that this receiver, as with most others, requires no other special equipment. It uses a standard df loop or a whip antenna. If it is installed in a submarine, a trailed, (towed) long-wire antenna may be used.

MICROWAVE

Communications systems in the 1 gigahertz to 10 gigahertz portion of the radio frequency spectrum use line-of-sight propagation. Propagation takes place in the lower atmosphere (troposphere). It is affected by factors such as barometric pressure, temperature, water vapor, turbulence, and stratification (forming of atmospheric layers).

A typical microwave transmitter includes an exciter group, a modulator group, a power amplifier, and power supplies. The transmitter usually has a power output of about 1 watt. When a higher output is required (about 5 watts), a traveling-wave tube (twt) is used as the amplifier. (A twt is a high-gain, low-noise, wide-bandwidth microwave amplifier. It is capable of gains of 40 decibels or more, with bandwidths of over an octave. The twt was discussed in chapter 2 of NEETS, Module 11, *Microwave Principles*.) A typical microwave receiver contains an rf-IF group, local oscillator, demodulator, and amplifier. Both transmitters and receivers contain special circuits because of the high operating frequencies and critical frequency stability requirements.

Line-of-Sight System

A line-of-sight (los) microwave system consists of one or more point-to-point hops as shown in figure 5-7. Each hop is designed so that it can be integrated into a worldwide communications network. Los systems have many characteristics. In these systems, propagation is only affected by changes in the troposphere. The distance between microwave system hop points ranges from 50 to 150 kilometers (31 to 95 statute miles). These systems are capable of handling up to 600 4-kilohertz voice channels and can also transmit television. These signals can usually be transmitted with less than 10 watts of power. Both the transmit and receive antennas are horn-driven paraboloids that provide high gain and narrow beam widths. In some applications, as shown in figure 5-8, plane reflectors are used with the paraboloids. These systems are very reliable. They are designed to operate over 99 percent of the time. These systems are well adapted to multichannel communications and closed circuit television.

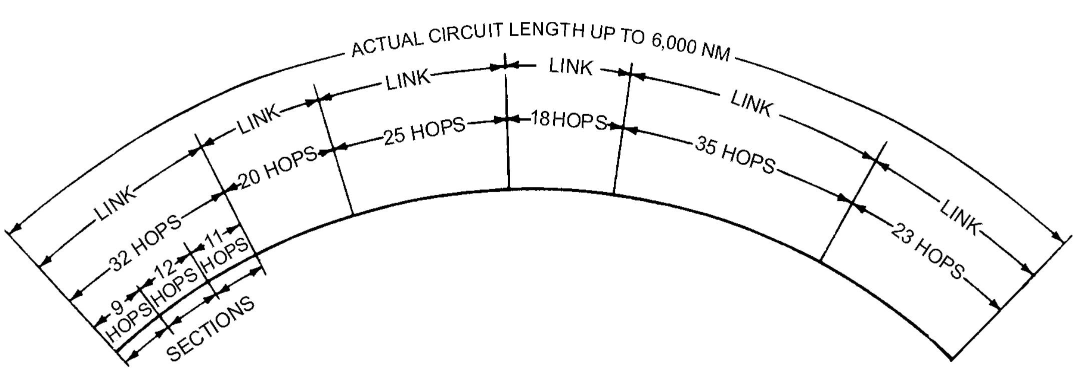

Figure 5-7.—Typical hop-link and section allocation.

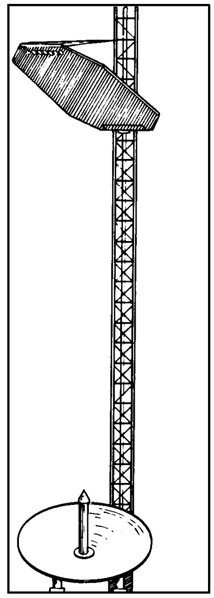

Figure 5-8.—Parabolic antenna and passive reflector combination.

Now let us take a look at another system. It is called the tropospheric-scatter microwave system. But first, you may want to review tropospheric propagation in NEETS, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas.*

Tropospheric Scatter System

A tropospheric-scatter (tropo-scatter) microwave system gets results similar to those of the line-of-sight system. It does it in a different way. The los system uses towers to relay information.

The tropo system uses the turbulence in the layer between the troposphere and the stratosphere to bounce signals back to earth. This method provides several hops and communications beyond los. The propagation reliability and communications capability is the same. The transmission range is up to 800 kilometers (500 statute miles). Transmitter output power may be up to 75 kilowatts depending on the operational requirements. The antennas are horn-driven paraboloids and may be as large as 50 to 60 feet in diameter. Figure 5-9 shows a typical tropospheric-scanner antenna. Remember that hf has a hop distance (skywave) of about 1,400 miles; the distance of one hop for a line-of-sight system is between 31 and 95 miles. The tropospheric-scatter system conveniently fills the gap between these distances.

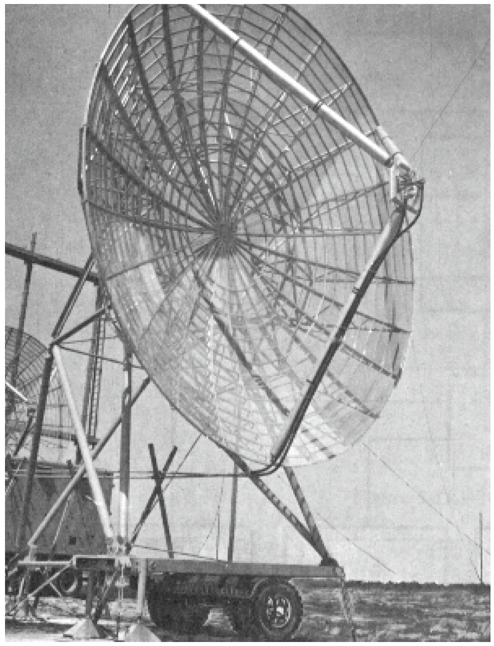

Figure 5-9.—Mobile 30-foot tropospheric-scanner antenna.

Both of these systems are used ashore. You're now going to get a look at a shipboard data information exchange system.

Q1. What is a dummy load?

Q2. What is the function of a product detector?

Q3. What is the frequency range of the mf band?

Q4. Microwave systems use what portion of the atmosphere?

Q5. What is the voice channel capacity of an los communications system?

Q6. What is the one-hop transmission range of a tropospheric-scatter system?

NAVAL TACTICAL DATA SYSTEM

In recent years, the Navy has introduced several new highly technical and effective combat weapons systems. However, these weapons systems did not solve the basic combat command problems that confront our Navy. In combat, a fleet continues to be involved in close-range offense and defense. During close-range combat, the shipboard combat information center (CIC) is involved in complex tactical situations. These situations require intelligent and highly important decisions. Each decision has to be made in a short period of time. You will find the speed at which these combat situations must be solved is inconceivable to someone thinking in terms of typical CIC operations of the recent past. Therefore, the NTDS was developed by the U.S. Navy as a command tool for commanders in tactical combat situations.

Objectives

The naval tactical data system (NTDS) is based on the interaction of humans and machines. The NTDS helps coordinate fleet air defense, antisubmarine warfare, and surface defense operations. Through automation, the NTDS provides commanders with a broad picture of the current tactical situation. It also assists them in directing their operations in time to intercept and destroy all potential enemy threats. The use of digital computers and digital data processing techniques reduces reaction time and increases force effectiveness.

NTDS uses a variety of equipment. This equipment includes transmitters, receivers, cryptographic equipment, high-speed digital computers, magnetic tapes, disks, and a variety of displays. Figure 5-10 shows the NTDS equipment grouping and how it interfaces with the weapons and sensor systems of a ship. Figure 5-11 shows the NTDS system inputs and outputs. As you can see, large amounts and various types of information are provided to or taken from the NTDS. Now that you have seen the types of information associated with the NTDS, let's look at how this information is transmitted and used.

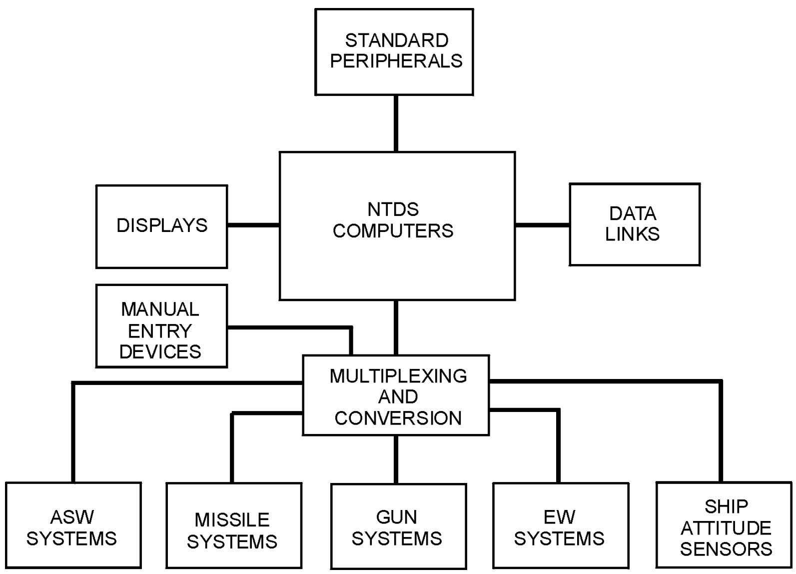

Figure 5-10.—NTDS equipment grouping.

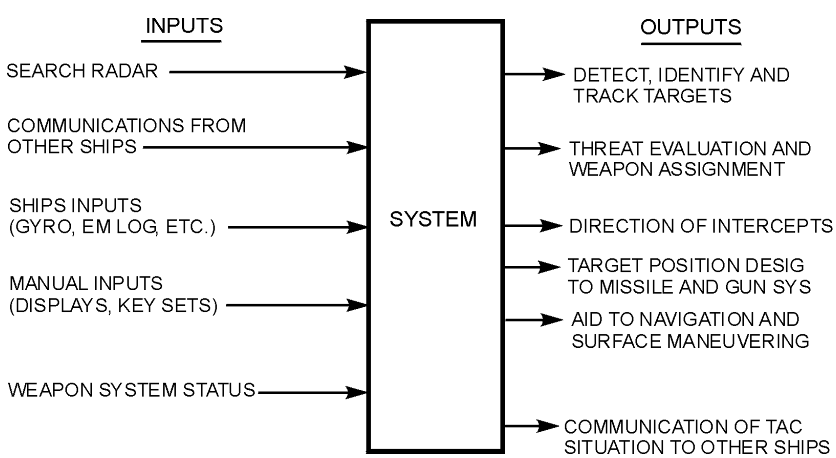

Figure 5-11.—NTDS system inputs/outputs.

NTDS Data Transmission Subsystems

NTDS uses three separate data transmission links to maintain tactical data communications between tactical units. Figure 5-12 illustrates these links. Each link is able to transfer data rapidly to other ships, aircraft, and shore facilities without the delay of human interface (link 14 receive is an exception to this). The data processing subsystem formats the messages for each of the data links. These messages are based on shipboard inputs (from displays, sensors, and other data links).

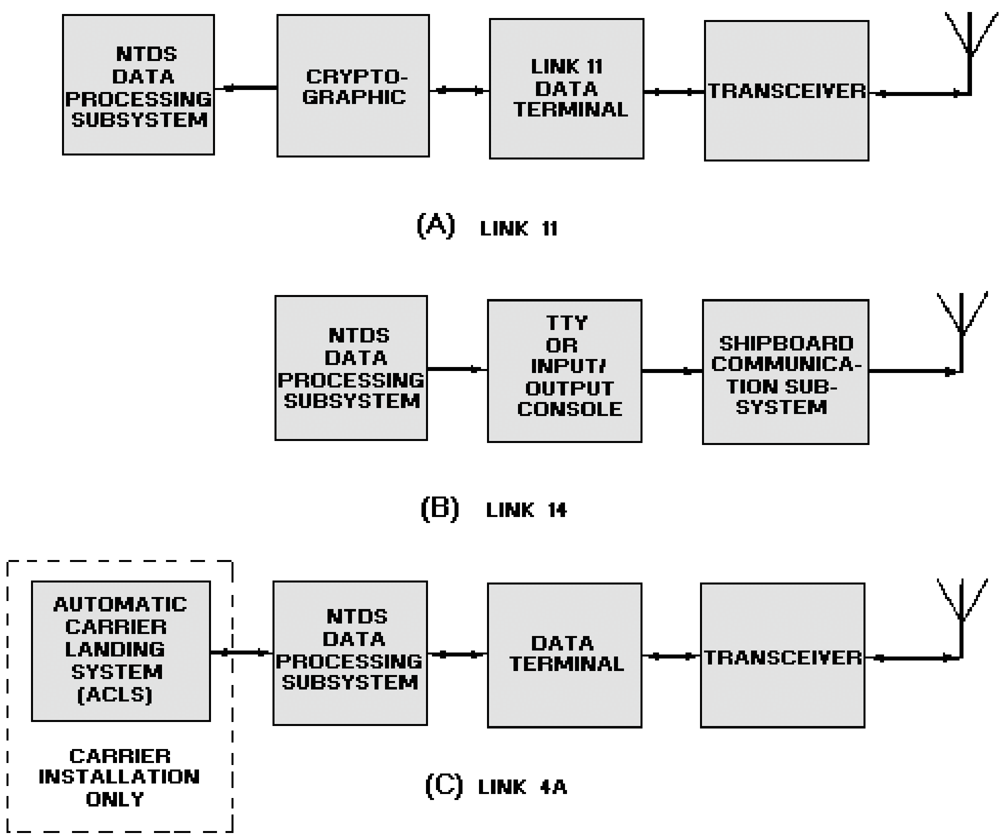

Figure 5-12.—NTDS communications links.

The automatic data communications links provide the operational commander with a high-speed, accurate mode of tactical communications. Link 11 provides high-speed, computer-to-computer transfer of tactical information, command orders, and unit status to all tactical data systems. View A shows you this configuration. The type of tactical information currently transferred is surface, subsurface, air, and EW track information. Data is provided on friendly, hostile, and unknown identity tracks. This broadcast originates through console button actions by the console operators.

Link 14 provides a means of transmitting track information to those units not capable of participating in the link 11 network. View B shows this network. This is a one-way broadcast of information.

Link 4A permits the computer to take control of the autopilot in an equipped aircraft. Also this link can control a plane under other situations. It may control a flight out to a strike area and return it to base without the need for pilot action. The pilot also has the option of overriding the link. The pilot may use the visual display to aid in understanding the intercept controller, or to totally ignore the link 4A transmission. View C shows this link used in conjunction with the automatic carrier landing system (ACLS).

Figure 5-13 is a drawing of an intersystem communications employment diagram. It shows the overall possibilities and flexibility of the NTDS. The new terms shown are defined below:

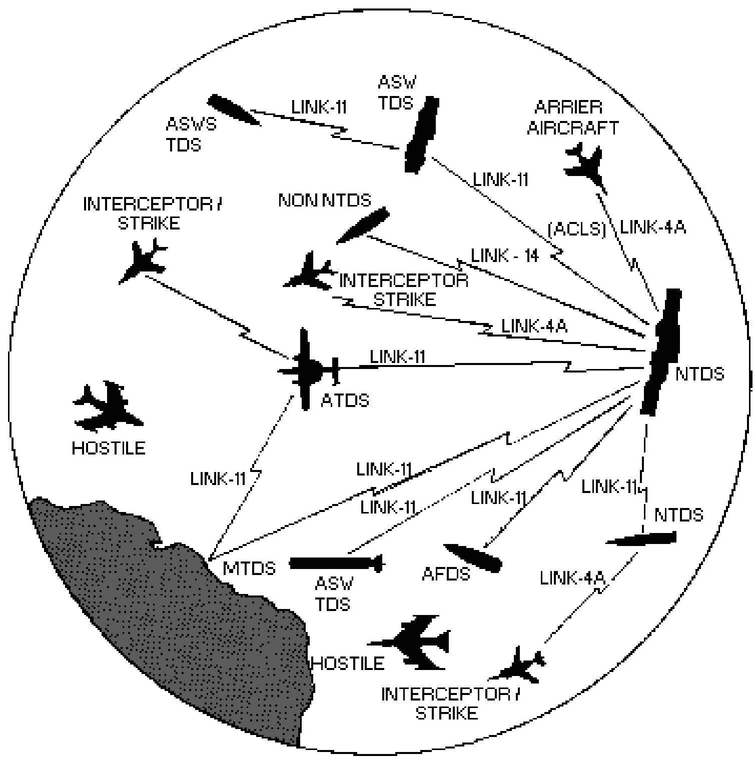

Figure 5-13.—Intersystem communications employment.

- MTDS-Marine tactical data system
- AFDS-Amphibious flagship data system
- ATDS-Airborne tactical data system
- ASWTDS-Antisubmarine warfare tactical data system

Now that we've looked at a complex and stationary system, let's study some fundamental portable equipment.

Q7. What is the primary advantage of NTDS over conventional systems?

Q8. What are the three NTDS data transmission subsystems?

PORTABLE EQUIPMENT

Portable and pack radio sets must be lightweight, compact, and self-contained. Usually, these sets are powered by a battery or a hand generator, have low output power, and are either transceivers or transmitter-receivers. A transceiver consists of a transmitter and a receiver that share common circuits and are housed in the same case or cabinet. A transmitter-receiver is the combination of two separate pieces of equipment that are used together. Navy ships carry a variety of these radio sets for emergency and amphibious communications. The numbers and types of equipment vary according to the individual ship.

EMERGENCY EQUIPMENT

One piece of emergency equipment is shown in figure 5-14. It is a rugged emergency transmitter carried aboard ships and aircraft for use in lifeboats and life rafts. The transmitter operates on the international distress frequency (500 kilohertz) and the survival craft communications frequency (8,364 kilohertz).

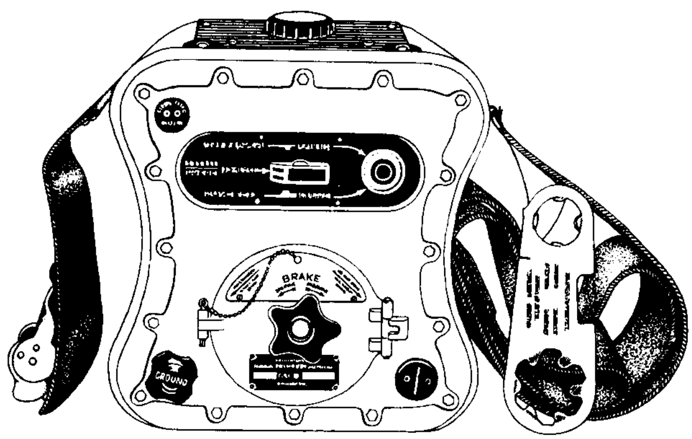

Figure 5-14.—Typical emergency lifeboat transmitter.

The complete radio transmitter, including the power supply, is contained in an aluminum cabinet that is airtight and waterproof. The cabinet is shaped to fit between the legs of the operator and has a strap for securing it in the operating position.

The only operating controls are a three-position selector switch and a push-button telegraph key. A hand crank screws into a socket in the top of the cabinet. The generator, automatic keying, and automatic frequency changing are all operated by turning the hand crank. While the hand crank is being turned, the set automatically transmits the distress signal SOS in Morse code. The code consists of six groups of SOS followed by a 20-second dash. It is transmitted alternately on 500 kilohertz and 8,364 kilohertz. The frequency automatically changes every 50 seconds. These signals are intended for reception by two groups of stations, each having distinct rescue functions. Direction-finding stations cooperating in long-range rescue operations normally use 8,364 kilohertz, whereas aircraft or ships locally engaged in search and rescue missions use 500 kilohertz.

Besides the automatic feature, you can key the transmitter manually on 500 kilohertz only. This is done by means of a push-button telegraph key.

Additional items (not shown) packaged with the transmitter include the antenna, a box kite, and balloons for supporting the antenna. Hydrogen-generating chemicals for inflating the balloon and a signal lamp that can be powered by the hand-crank generator are also included.

The equipment floats and is painted brilliant orange-yellow to provide good visibility against dark backgrounds.

A transceiver is shown in figure 5-15. It is portable, battery powered, and has two channels. It provides homing information and two-way voice communications between life rafts and searching ships and aircraft. This transceiver is a microminiature, solid-state, hand-held radio that operates on the 121.5-megahertz and the 243-megahertz guard channels. The transceiver has four operating controls. These are the volume (VOL) control, the two-position FREQUENCY SELECTOR, the PUSH-TO-TALK/ CODE button, and the three-position MODE switch.

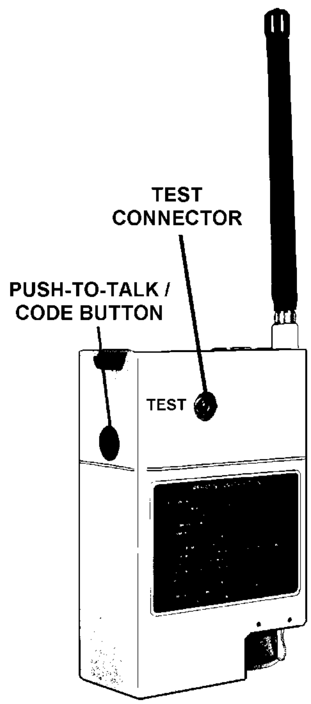

Figure 5-15.—Emergency portable transceiver.

The antenna is a rubber covered, omnidirectional, flexible whip antenna that is 7.74 inches long. The batteries supplied with the radio set are lithium D cells. Each cell is fused to protect against damage from external short circuits. Two cells are installed in the transceiver and four are packaged as spares.

OPERATIONAL EQUIPMENT

An operational transceiver is shown in figure 5-16. It is watertight, lightweight, portable, and operates in the vhf and uhf range. You can use any of 1,750 channels, spaced 200 kilohertz apart, in the 225-400 megahertz range. Its mode of operation is AM voice and it supplies an average output power of 3 watts. It was designed mainly for manpack (backpack) use, but it may also be used at a fixed station or in vehicles when certain accessories are added. When not in use, the equipment is disassembled and stowed in a special aluminum case similar to an ordinary suitcase.

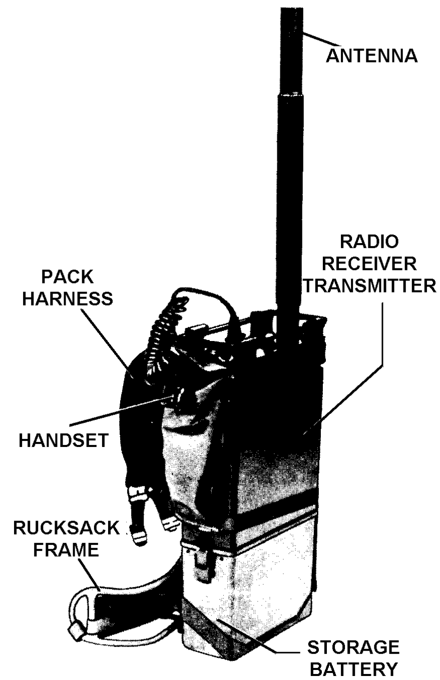

Figure 5-16.—Typical vhf/uhf backpack transceiver.

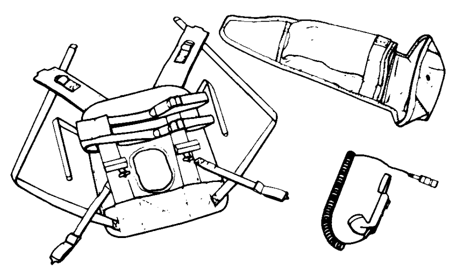
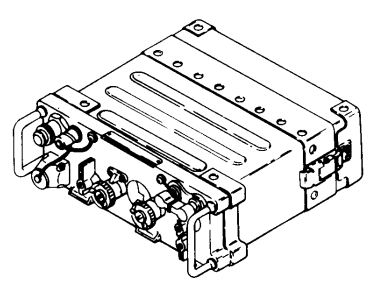
Figure 5-17 shows a typical vhf miniaturized manpack radio set. View A shows the pack frame, the handset, and the canvas accessory pouch. The pouch contains two antennas (one flexible steel band-type whip and one collapsible rigid whip). The handset fits in the pouch when not in use. View B shows the transmitter-receiver.



A



B

Figure 5-17.—Vhf receiver-transmitter.

Now that you have learned about portable equipment, let's look at one of the newest areas of communications. You are going to learn the fundamentals of how a laser works and how it may be used in the field of communications.

Q9. What are the three main design considerations of portable equipment?

LASERS

The word LASER is an acronym for light amplification by stimulated emission of radiation. The laser is widely used in industry, and experimental work is being done with it in communications. You will find a laser is similar to uhf and microwave power sources and could replace either of them in point-to-point communications.

THEORY OF OPERATION

Lasers take energy at (or near) the visible light spectrum and convert it to a very narrow and intense beam in the same region. A close relative of the laser is the light emitting diode (LED). The LED takes dc or low frequency ac power and converts the energy into visible light.

The principle of the laser is somewhat similar to that of a very high-Q cavity resonator. Chapter 1 of NEETS, Module 11, *Microwave Principles*, explains cavity resonators. The laser is shock-excited by a spark transmitter. This transmitter is called a spark transmitter because it uses the discharge of a capacitor through an inductor and a spark gap as a source of rf. While the input energy of the laser covers a wide band of frequencies, the output is on one frequency. Energy outputs of the laser are either INCOHERENT or COHERENT. For example, if you turn on a transmitter with no modulation, you will get coherent radiation. When you connect a noise source to an antenna, the result is incoherent radiation.

Lasers can be either cw or pulsed. Actually, lasers are little different from conventional oscillators. However, the way lasers convert energy from one form to another is quite different. In conventional oscillators, dc power from the collector is converted to rf energy. The frequency is for the most part independent of the molecular or atomic structure of the generator. This is not true for the laser. Laser conversion takes place directly within the molecular structure of a crystal or gas. The external circuits have little effect on actual output frequency. The fact that the light from an LED is always the same color results from similar conditions. In a laser, incoherent light excites the electrons in the atoms to higher energy levels than they normally would have. The new energy states are unstable and the electrons drop down to lower energy levels. Energy is then released in the form of light.

Figure 5-18 shows the ends of the crystal or glass tube laser with light waves reflecting back and forth between two mirrored surfaces. One mirror is only partially reflective, and light energy is transmitted through it to form the light beam. You will find that power sources for lasers include flash tubes or, in the case of diode-type lasers, dc power supplies.

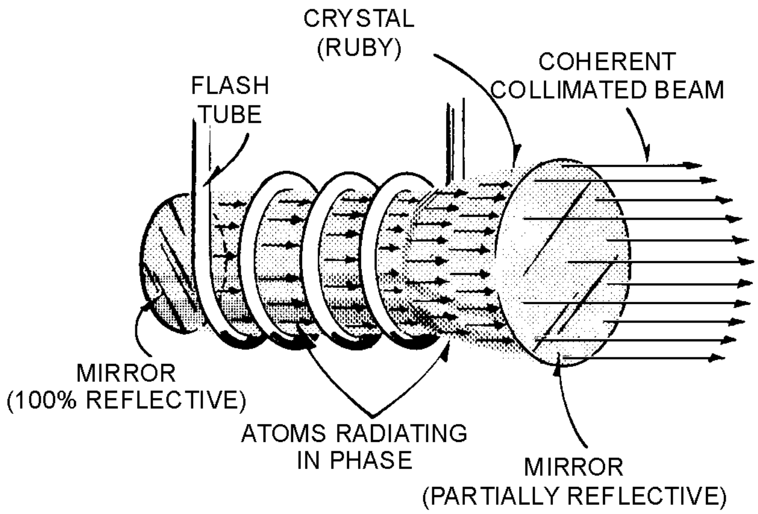


Figure 5-18.—Simple laser.

COMMUNICATIONS APPLICATIONS

High-energy lasers have very small power losses. As a result, a laser with a 2- or 3-inch initial beam can be used to communicate directly with a distant planet. However, from a communications standpoint, they do have some drawbacks. While laser energy is capable of being formed into a very narrow beam, it is still subject to the same difficulties as any other form of light transmission. Fog and other adverse weather conditions can absorb the light. Small atmospheric temperature variations can cause deflection and scattering. An optical waveguide was designed to help overcome this problem. It consists of a thin dielectric fiber clothed by another dielectric coating several wavelengths thick. It has been successfully used to move the beam over considerable distances and around bends. The use of optical waveguides is known as FIBER OPTICS. A number of fibers can be paralleled to reduce the attenuation through the waveguide. This technique has resulted in an inexpensive telephone system with a bandwidth greater than that of previous methods. Researchers are attempting to develop a laser that will operate in the blue-green portion of the visible spectrum. Water offers little attenuation to the blue-green band of frequencies. Because of this, blue-green communications lasers could possibly penetrate the ocean to great depths.

This could give us a very secure undersea communications link.

Q10. Lasers operate in what portion of the frequency spectrum?

Q11. What are the two types of lasers?

Q12. What are the effects of adverse weather on the laser beam?

SUMMARY

Now that you have completed this chapter, a review of what you have learned is in order. The following summary will refresh your memory of new terms.

DOUBLING UP is a type of two-equipment installation where one unit can be substituted for another in the event of failure.

FREQUENCY SYNTHESIZER is a frequency source of high accuracy.

DUMMY LOAD is a nonradiating device that absorbs the rf and has the impedance characteristics of the antenna.

HELIX HOUSE is a building at a transmitter site that contains antenna loading, coupling, and tuning circuits.

A **HELIX** is a large coil of wire. It acts as a coil and is used with variable inductors for impedance matching of high-power transmitters.

TOP-HAT antennas are center-fed and capacitively loaded.

TRIATIC is a special type of monopole antenna array.

LASER is an acronym for light amplification by stimulated emission of radiation.

COHERENT refers to radiation on one frequency or nearly so.

INCOHERENT refers to radiation on a broad band of frequencies.

FIBER OPTICS are conductors or optical waveguides that readily pass light.

MTDS is an abbreviation for the marine tactical data system.

AFDS is an abbreviation for the amphibious flagship data system.

ATDS is an abbreviation for the airborne tactical data system.

ASWTDS is an abbreviation for the antisubmarine warfare tactical data system.

ANSWERS TO QUESTIONS Q1. THROUGH Q12.

A1. An impedance-matched device capable of absorbing all of a transmitters power.

A2. It demodulates ssb, cw, and fsk signals.

A3. 300 kilohertz to 3 megahertz.

A4. Troposphere.

A5. Up to 600 4-kilohertz channels.

A6. Up to 800 kilometers (500 statute miles).

A7. Speed.

A8. Links 4A, 11, and 14.

A9. They must be lightweight, compact, and self-contained.

A10. At or near visible light.

A11. Cw or pulsed.

A12. It absorbs it.

APPENDIX I

GLOSSARY

ACTIVE SATELLITE—A satellite that amplifies the received signal and retransmits it back to earth.

AFDS—An abbreviation for the amphibious flagship data system.

ANGLE OF INCLINATION—The angular difference between the equatorial plane of the earth and the plane of orbit of the satellite.

ANTENNA COUPLER—A device used for impedance matching between an antenna and a transmitter or receiver.

APOGEE—The point in the orbit of a satellite the greatest distance from the earth.

ASSEMBLY—A number of parts or subassemblies, or any combination thereof, joined together to perform a specific function.

ASWTDS—An abbreviation for the antisubmarine warfare tactical data system.

ASYNCHRONOUS ORBIT—One where the satellite does not rotate or move at the same speed as the earth.

ATDS—An abbreviation for the airborne tactical data system.

AUDIO FREQUENCY TONE SHIFT—A system that uses amplitude modulation to change dc mark and space impulses into audio impulses.

AUTOMATIC TRACKING—Tracking done by the equipment comparing the direction of the antenna axis and the direction of the received signal.

AUTOMATIC VOLUME/GAIN CONTROL—A circuit used to limit variations in the output signal strength of a receiver.

BALANCED PHASE DETECTOR—A circuit that controls the oscillator frequency (afc).

BAUD—A measurement of speed based on the number of code elements or units per second.

BEAT-FREQUENCY OSCILLATOR—An additional oscillator used in a receiver when receiving a cw signal. It provides an audible tone.

BITS-PER-SECOND—Bit is an acronym of the words binary digit. One bit is equal to one signal unit or element.

BLACK—The reference color of equipment that passes unclassified information. It normally refers to patch panels.

CODE—In teletypewriter operation, code is a combination of mark and space conditions representing symbols, figures, or letters.

COHERENT—Radiation on one frequency.

COMPARATOR—An equipment that compares incoming signals and selects the strongest to be fed to a teletypewriter through a patch panel. This is used in diversity operation.

CONVERTER—An equipment that changes the audio output of a receiver to dc pulses. These pulses are fed to a tty to indicate marks and spaces.

DETECTION—The separation of low-frequency (audio) intelligence from the high (radio) frequency carrier.

DOUBLING UP—This is a type of two-equipment installation where one unit can be substituted for another in the event of failure.

DOWN LINK—The frequency used to transmit an amplified signal from the satellite back to earth.

DUMMY LOAD—A nonradiating device that absorbs the rf and has the impedance characteristics of the antenna.

ECLIPSE—This occurs when the satellite is not in view or in direct line of sight with the sun. This happens when the earth is between them.

ELECTROMAGNETIC INTERFERENCE—A term used to describe the degradation of a receiver or system.

EPHEMERIS—A table showing the precalculated position of a satellite at any given time.

EQUATORIAL ORBIT—An orbit that occurs when the plane of a satellite coincides with the plane of the earth at the equator.

EXTREMELY HIGH FREQUENCY—The band of frequencies from 30 gigahertz to 300 gigahertz.

EXTREMELY LOW FREQUENCY—The band of frequencies up to 300 hertz.

FACSIMILE—The method for transmitting and receiving still images. These images can be maps, photographs, and handwritten or printed text.

FADING—The variations in signal strength at the antenna of a receiver.

FIBER OPTICS—Conductors or optical waveguides that readily pass light.

FIDELITY—The ability of a receiver to accurately reproduce, at its output, the signal at its input.

FORWARD AGC—The type of agc that causes an amplifier to be driven towards saturation.

FRAMING—The process of synchronizing a facsimile receiver to a transmitter. This allows proper picture reproduction.

FREQUENCY-DIVISION MULTIPLEXING—Multiplexing that transmits and receives the full 360 degrees of each sine wave.

FREQUENCY SYNTHESIS—A process that uses hetrodyning and frequency selection to produce a signal.

FREQUENCY SYNTHESIZER—A frequency source of high accuracy.

GANGED TUNING—The process used to tune two or more circuits with a single control.

GROUP—A collection of units, assemblies, subassemblies, and parts. It is a subdivision of a set or system but is not capable of performing a complete operational function.

HAND OVER—The operation where one earth terminal yields control to another as a satellite moves out of its area of coverage.

HARMONIC—An exact multiple of the fundamental frequency. Even harmonics are 2, 4, and so on, times the fundamental. Odd are 3, 5, and so on, times the fundamental frequency.

HELIX—A large coil of wire. It acts as a coil and is used with variable inductors for impedance matching of high-power transmitters.

HELIX HOUSE—A building at a transmitter site that contains antenna loading, coupling, and tuning circuits.

HETERODYNING—The mixing of the incoming signal with the local oscillator frequency. This produces the two fundamentals and the sum and difference frequencies.

HIGH FREQUENCY—The band of frequencies from 3 megahertz to 30 megahertz.

IMAGE FREQUENCY—An undesired frequency capable of producing the desired frequency through heterodyning.

INCLINED ORBIT—Orbits where there is some amount of inclination. These include equatorial and polar orbits.

INCOHERENT—This refers to radiation on a broad band of frequencies.

INTELLIGENCE—Any signal that conveys information (voice, teletypewriter, facsimile).

KEYER—A device that changes dc pulses to mark and space modulation for teletypewriter transmissions.

LASER—An acronym for light amplification by stimulated emission of radiation.

LISSAJOUS PATTERN—A combined, simultaneous display of the amplitude and phase relationships of two input signals on a CRT.

LOW FREQUENCY—The band of frequencies from 30 kilohertz to 300 kilohertz.

MARKING—The state where a circuit is closed and current flows in teletypewriter operation.

MEDIUM ALTITUDE ORBIT—An orbit from 2,000 to 12,000 miles above the earth. The rotation rate of the earth and satellite are quite different, and the satellite moves quickly across the sky.

MEDIUM FREQUENCY—The band of frequencies from 300 kilohertz to 3 megahertz.

MTDS—An abbreviation for the marine tactical data system.

MULTICOUPLERS—Couplers patch receivers or transmitters to antennas. They also filter out harmonics and spurious responses, and impedance-match the equipment.

MULTIPLEXING—A method for simultaneous transmission of two or more signals over a common carrier wave.

NEAR SYNCHRONOUS ORBIT—An orbit in which the satellite rotates close to but not exactly at the same speed as the earth.

NEUTRAL—The teletypewriter operation where current flow represents a mark and no flow represents a space.

NOISE SILENCER, NOISE SUPPRESSOR, OR NOISE LIMITER—Circuits that clip the peaks of the noise spikes in a receiver.

NONSYNCHRONOUS—The teletypewriter operation where both transmitter and receiver do not operate continuously

ORDER-WIRE CIRCUIT—A circuit between operators used for operations control and coordination.

PAGE PRINTER—A high-speed printer that prints teletypewriter characters one at a time in a full-page format.

PASSIVE SATELLITE—A satellite that reflects radio signals back to earth.

PATCH PANEL—A panel used to tie a receiver or transmitter to its associated equipment.

PART—A part is one component or two or more components joined together. It is not normally subject to disassembly without destruction.

PERFORATOR—A device that stores a teletypewriter message on a paper tape. It may be stored for later transmission.

PERIGEE—The point in the orbit of a satellite closest to the earth.

PERMANENT MAGNET SPEAKER—A speaker with a permanent magnet mounted on soft iron pole pieces.

POLAR—The teletypewriter operation where current flow of one polarity represents a mark and current of the opposite polarity represents a space.

POLAR ORBIT—An orbit that has an angle of inclination of or near 90 degrees.

PROGRAMMED TRACKING—The method that uses known satellite orbital parameters to generate antenna pointing angles.

RADIO COMMUNICATIONS—The term describing teletypewriter, voice, telegraphic, and facsimile communications.

RADIO FREQUENCY CARRIER SHIFT—The system that uses a keyer to shift a radio frequency signal above or below an assigned frequency. These shifts correspond to marks and spaces.

RADIO SET CONTROL UNIT—Equipment used to remotely control certain transmitter and receiver functions.

RECEIVER—Equipment that converts electromagnetic energy into a visible or an audible form.

RECEIVER TRANSFER SWITCHBOARD—Equipment used to transfer receiver audio outputs to remote control station audio circuits.

RECEPTION—The instant when an electromagnetic wave passes through a receiver antenna and induces a voltage in that antenna.

RED—The reference color of equipment that passes classified information. It normally refers to patch panels.

REPEATER—Another name for an active satellite.

REPERFORATOR—Equipment that converts the incoming tty signal and stores it on paper tape.

REPRODUCTION—The process of converting electrical signals to sound waves. This sound is speech, music, and so on.

REVERSE AGC—The type of agc that causes an amplifier to be driven toward cut-off.

RUNNING OPEN—The teletypewriter condition where the type hammer constantly strikes the type box but does not print or move across the page.

SATELLITE ECLIPSE—An eclipse where the rays of the sun don't reach the satellite. This prevents recharging of the solar cells of the satellite and decreases the power to the transmitter.

SATELLITE-SUN CONJUNCTION—A period when the satellite and sun are close together and the noise from the sun prevents or hampers communications.

SCANNING—The process of subdividing a picture in an orderly manner into segments. This is used in facsimile transmission.

SELECTIVITY—The ability of a receiver to select the desired signal and reject unwanted signals.

SENSITIVITY—The ability of a receiver to reproduce very weak signals. The greater the receiver sensitivity, the weaker the signal that will be reproduced.

SET—A unit or units and the assemblies, subassemblies, and parts connected or associated together to perform a specific function.

SPACING—The condition in teletypewriter operation where a circuit is open and no current flows.

SQUELCH—A circuit that cuts off the output of a receiver when there is no input.

START—The first unit of a teletypewriter signal. It is always a space.

STOP—The last unit of a teletypewriter signal. It is always a mark.

SUBASSEMBLY—Consists of two or more parts that form a portion of an assembly or a unit.

SUBHARMONIC—An exact submultiple of the fundamental frequency. Even subharmonics are one-half, one-quarter, and so on. Odd subharmonics are one-third, one-fifth, and so on of the fundamental frequency.

SUPERHIGH FREQUENCY—The band of frequencies from 3 gigahertz to 30 gigahertz.

SUPPRESSION—The process of eliminating an undesired portion of a signal.

SYNCHRONOUS—A type of teletypewriter operation where both transmitter and receiver operate continuously.

SYNCHRONOUS ORBIT—An orbit in which the satellite moves or rotates at the same speed as the earth.

SYSTEM—A combination of sets, units, assemblies, subassemblies, and parts joined together to form a specific operational function or several functions.

TELECOMMUNICATIONS—The transmission, emission, or reception of signs, signals, writings, images, or sounds. This is done by visual, oral, wire, radio, or other electromagnetic means.

TELETYPEWRITER—A machine that can transmit and or receive letters, numbers, or symbols. It may have a keyboard similar to a typewriter.

TEMPEST—A term normally used to describe compromising emanations. These emanations are unintentionally radiated signals that could disclose classified information.

TIME-DIVISION MULTIPLEXING—The process that periodically samples the full 360 degrees of each sine wave. The sample can be of a received signal or of a signal to be transmitted.

TONE-TERMINAL SET—Equipment that converts tty dc pulses into audio tones for modulation of a transmitter in audio-frequency-tone shift transmissions.

TOP-HAT—An antenna that is center-fed and capacitively loaded.

TRANSITION—The time it takes to shift from a mark to a space condition or from a space to a mark condition.

TRANSMITTER—Equipment that generates and amplifies an rf carrier, modulates the rf carrier with intelligence, and radiates the signal into space.

TRANSMITTER DISTRIBUTOR—A device that reads Baudot code from paper tape and allows a message to be printed on a page printer.

TRANSMITTER TRANSFER SWITCHBOARD—Equipment that selectively transfers remote control station functions and signals to transmitters.

TRIATIC—A special type of monopole antenna array.

ULTRAHIGH FREQUENCY—The band of frequencies from 300 megahertz to 3 gigahertz.

UNIT—An assembly or any combination of parts, subassemblies, and assemblies mounted together. Normally capable of independent operation.

UP LINK—The frequency used to transmit a signal from earth to a satellite.

VERY HIGH FREQUENCY—The band of frequencies from 30 megahertz to 300 megahertz.

VERY LOW FREQUENCY—The band of frequencies from 3 kilohertz to 30 kilohertz.

WORDS-PER-MINUTE—An approximate rate of speed. It means the number of five letter words with a space between them that can be transmitted or received in a one-minute period.

ZONE OF MUTUAL VISIBILITY—The area where the satellite can be seen by both the up- and down-link earth terminals.

Assignment Questions

<u>Information</u>: The text pages that you are to study are provided at the beginning of the assignment questions.

ASSIGNMENT 1

Textbook assignment: Chapter 1, "Introduction to Radio-Frequency Communications," pages 1-1 through 1-20. Chapter 2, "Introduction to Communications Theory," pages 2-1 through 2-37.

1-1. For naval communications to be effective, all involved must be top performers. Reliable, secure, and timely receiving and transmitting of information is the goal. Which of the following requirement standards are used to determine whether or not this goal has been met?

1. Wartime
2. Peacetime
3. Cold war less 10 percent
4. Nuclear war less 25 percent

1-2. What are the two types of electrical communications?

1. Radio and wire
2. Television and wire
3. Telegraph and radio
4. Television and radio

1-3. Which of the following terms includes intelligence produced by wire, radio, visual means, oral means or electromagnetic systems?

1. Telecommunications
2. Radiotelegraph
3. Electrolysis
4. Photocopy

1-4. Radiotelegraph (cw) is valuable when communicating to, from, and among widely separated naval units. What is the main advantage of the cw mode?

1. Cost
2. Speed
3. Security
4. Reliability

1-5. Tactical communications is usually considered as line-of-sight. What maximum distance is normally within the line-of-sight range?

1. 5 miles
2. 25 miles
3. 50 miles
4. 250 miles

1-6. You want to transmit high-speed automatic page or tape copy across an ocean area. Which of the following methods should you choose?

1. Facsimile
2. Radiotelegraph
3. Radiotelephone
4. Radioteletypewriter

1-7. What method is normally used to transmit graphs electronically?

1. Facsimile
2. Radio teletypewriter
3. Frequency-shift keying
4. Audio-frequency-tone shifting

1-8. When you use subdivisions to assign reference designators to equipment, what is the designator of (a) the largest and (b) the smallest?

1. (a) System (b) set
2. (a) Set (b) unit
3. (a) Unit (b) assembly
4. (a) System (b) part

1-9. When using the reference designator 1A6A4J6, what level does the number 1 refer to?

1. Subassembly
2. Assembly
3. Group
4. Unit

1-10. What is the total number of frequency bands the military is currently using for communications?

1. 5
2. 7
3. 9
4. 11

1-11. Extremely low-frequency transmissions are primarily directed at which of the following users?

1. Shore installations
2. Surface ships
3. Submarines
4. Aircraft

1-12. Vlf transmitters are used primarily for which of the following purposes?

1. Navigation and fleet communications
2. Frequency standards and time signals
3. Astronomy and oscillator calibration
4. Aircraft control and space vehicle tracking

1-13. Navy use of the low-frequency band is mainly for which, if any, of the following broadcasts?

1. Ship to shore
2. Fleet multichannel
3. Space vehicle telemetry
4. None of the above

1-14. For which of the following reasons does the Navy use only the upper and lower ends of the mf band?

1. They are the most reliable
2. They produce the best propagation
3. The commercial fm band occupies the middle
4. The commercial AM band occupies the middle

1-15. Hf communications over long-distance trunks, or links between fixed terminals are examples of which of the following types of systems?

1. Fleet broadcast
2. Point-to-point
3. Ground-to-air
4. Ship-to-shore

1-16. Sending a message on several frequencies at once is an example of which of the following transmission types?

1. Time-diversity
2. Phase-diversity
3. Distance-diversity
4. Frequency-diversity

1-17. What type of diversity uses physically separated transmit or receive antennas to improve communications?

1. Time
2. Phase
3. Space
4. Frequency

1-18. Normally the transmission range of vhf is limited to line of sight. What technique is used to increase this range?

1. Tropospheric scatter
2. Atmospheric diversity
3. Ionospheric maneuvering
4. Each of the above

1-19. A complex of links make up a major communications system. The naval communications system is further broken down into what two groups?

1. Strategic and local
2. World-wide and local
3. Strategic and tactical
4. Tactical and world-wide

1-20. Communications links have many modes of operation. One terminal in a link has its equipment setup in simplex. The other terminal is using two channels or frequencies in a configuration that allows sending and receiving of different messages at the same time. These two terminals working together make up what mode of operation?

1. Full duplex
2. Half duplex
3. Quasiduplex
4. Semiduplex

1-21. What communications link mode of operation provides telecommunications capability between stations at the same time in both directions?

1. Half duplex
2. Semiduplex
3. Broadcast
4. Duplex

1-22. Aid in restoring downed fleet communications channels is furnished on a not-to-interfere basis by which of the following networks?

1. AUTOSEVOCOM
2. NORATS
3. HICOM
4. DSSCS

1-23. Which of the following switched networks extends tactical voice to shore-based operational commands?

1. NORATS
2. AUTOVON
3. AUTODIN
4. AUTOSEVOCOM

1-24. Of the following transmitter types, which are used for basic communications?

1. Cw, AM, fm, and ssb
2. Fsk, cw, AM, and tty
3. Cw, ssb, voice and fm
4. Voice, tty, fsk, and AM

1-25. Cw transmissions have narrow bandwidths and a high degree of intelligibility under severe noise conditions. What is the primary Navy use for cw?

1. Radioteletypewriter
2. Radiotelegraphy
3. Facsimile
4. Voice

1-26. A cw transmitter must contain which of the following components?

1. A traveling-wave tube
2. A demodulator
3. A combiner
4. A keyer

1-27. In a cw transmitter, a buffer stage performs which of the following functions?

1. Current divider
2. Voltage divider
3. Current amplifier
4. Voltage amplifier

1-28. There are differences between low- and high-power transmitters. The main difference is the high power transmitter contains a larger number of which of the following types of amplifiers?

1. Oscillator
2. Final power
3. Intermediate power
4. Intermediate frequency

1-29. In an AM transmitter, audio frequencies are converted into corresponding electrical energy by which of the following components?

1. An oscillator
2. A microphone
3. A modulator
4. A headset

1-30. In an fm transmitter, a varicap performs which of the following functions?

1. It amplifies the outgoing signal
2. It varies the oscillator frequency
3. It demodulates the outgoing signal
4. It multiplies the oscillator frequency

1-31. If an oscillator has a fundamental frequency of 3,550 megahertz, what is the frequency of the third harmonic?

1. 5,325 megahertz
2. 7,100 megahertz
3. 9,875 megahertz
4. 10,650 megahertz

1-32. If the fundamental frequency of an rf carrier is 1,000 kilohertz, what is the frequency of the fourth subharmonic?

1. 500 kilohertz
2. 333 kilohertz
3. 250 kilohertz
4. 200 kilohertz

1-33. Oscillator output frequencies are raised to usable values by frequency multipliers. To raise an oscillator frequency from 20 megahertz to 120 megahertz, what combination of frequency multipliers would be used?

1. Two doublers
2. A doubler and a tripler
3. A doubler and a quadruplet
4. A tripler and a quadruplet

1-34. When an AM signal leaves the antenna of a transmitter, which of the following frequency components does the signal contain?

1. The carrier
2. The upper sideband
3. The lower sideband
4. All of the above

1-35. In a single-sideband transmitter, selection of the desired sideband and suppression of the other is done by which of the following components?

1. Mixer
2. Filter
3. Detector
4. Oscillator

1-36. When compared to a conventional AM signal, an ssb signal provides which of the following advantages?

1. Improved frequency stability
2. Increased receiver gain
3. Reduced distortion
4. Reduced bandwidth

1-37. For ship-to-shore teletypewriter circuits, which of the following types of multiplexing is/are used?

1. Time and/or phase
2. Time and/or frequency
3. Phase and/or modulation
4. Frequency and/or modulation

1-38. Operators of transmitters and receivers use a circuit to coordinate the service of messages and to make frequency changes. What is the name of this circuit?

1. Order-wire circuit
2. Documentation circuit
3. Synchronization circuit
4. Operator-eyes-only circuit

1-39. A transmitted electromagnetic wave enters an antenna, induces a voltage into it, and passes that voltage to a receiver. What is this chain of events called?

1. Reproduction
2. Selection
3. Detection
4. Reception

1-40. When a receiver picks one frequency out from all other frequencies, it's performing which of the following basic functions?

1. Selection
2. Reception
3. Detection
4. Reproduction

1-41. When a receiver separates the audio frequencies from the radio-frequency carrier it is performing which of the following basic functions?

1. Reception
2. Selection
3. Detection
4. Reproduction

1-42. The receiver action of converting electrical energy to a usable format, such as sound, is an example of which of the following basic functions?

1. Reception
2. Selection
3. Detection
4. Reproduction

1-43. Which of the following measurements provides an indication of the ability of a receiver to reproduce weak signals?

1. Bandwidth
2. Sensitivity
3. Selectivity
4. Frequency response

1-44. Overall sensitivity of a receiver is limited by which of the following factors?

1. Noise
2. Bandwidth
3. Output power
4. Frequency response

1-45. How is a receiver's ability to reject unwanted signals and receive desired signals determined?

1. Noise
2. Fidelity
3. Selectivity
4. Sensitivity

1-46. When high fidelity is your prime consideration you should select a receiver that has been designed with which of the following features?

1. High gain
2. High output power
3. Broadband frequency selection circuits
4. Narrowband frequency selection circuits

1-47. The IF frequency in a receiver is produced by which of the following methods?

1. Modulation
2. Heterodyning
3. Frequency synthesis
4. Frequency multiplication

1-48. The process of heterodyning takes place in which of the following receiver circuits?

1. Mixer
2. Comparator
3. Oscillator
4. Second IF amplifier

1-49. Of the following frequencies, which one is a typical value of IF for AM communications receivers?

1. 455 kilohertz
2. 554 kilohertz
3. 455 megahertz
4. 554 megahertz

1-50. Two or more circuits within a receiver are varied by a single control through the use of which of the following processes?

1. Ganged tuning
2. Frequency synthesis
3. Automatic gain control
4. Automatic frequency control

1-51. There are electrical differences between AM and fm receivers. An fm receiver contains which of the following circuits?

1. Comparator
2. Discriminator
3. Limiter
4. Both 2 and 3 above

1-52. An fm signal has which of the following characteristics when compared to an AM signal?

1. More noise
2. Less static
3. A higher power output
4. A lower operating frequency

1-53. Ssb transmissions have which of the following characteristics when compared to AM transmissions?

1. Wide bandpass frequencies
2. Concentrated power
3. Less modulation
4. High fidelity

1-54. Single sideband receivers use a special oscillator. The output of that oscillator is fed directly to the detector circuit. What type of oscillator is used?

1. Local
2. High frequency
3. Variable frequency
4. Carrier reinsertion

1-55. A transmitter has a suppressed carrier frequency of 4 megahertz and is radiating only an upper sideband signal. When the intelligence is a 1-kilohertz tone, which of the following sideband frequencies will be transmitted?

1. 3,999 kilohertz
2. 4,000 kilohertz
3. 4,001 kilohertz
4. Both 2 and 3 above

1-56. Manual gain lets you adjust a receiver for maximum sensitivity and amplify weak input signals. Which of the following internal sections of the receiver are varied by this control?

1. Oscillator
2. Audio frequency
3. Radio frequency
4. Intermediate frequency

1-57. Manual volume control of a receiver internally varies the input to which of the following circuits?

1. Detector
2. Audio amplifier
3. Frequency converter
4. Radio frequency amplifier

1-58. Changes in receiver input strength due to changing atmospheric conditions is described by which of the following terms?

1. Gain
2. Fading
3. Ducting
4. Trapping

1-59. The rf amplifier connected to your receiving antenna has a voltage gain of 240. When the antenna is receiving a signal of 8 microvolts, what will be the maximum output voltage of the rf amplifier?

1. 1.92 millivolts
2. 2.91 microvolts
3. 30 microvolts
4. 33 millivolts

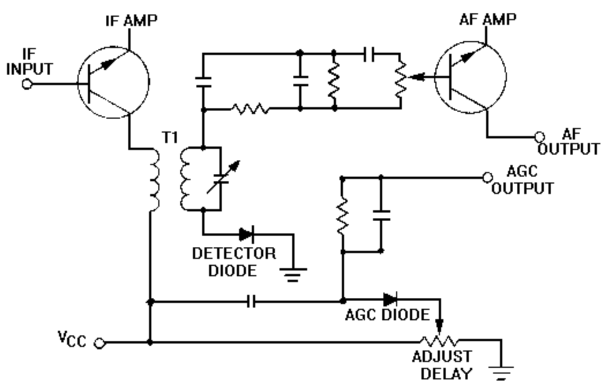

Figure 1A.

IN ANSWERING QUESTIONS 1-60 AND 1-61, REFER TO FIGURE 1A.

1-60. If the agc diode shorts, which of the following actions would result?

1. There would be no aqc
2. There would be no delay
3. The agc diode would be reverse biased
4. The polarity of the agc would be reversed

1-61. The amount of agc feedback depends on attaining an established received signal strength. If the established signal strength is set for 50 microvolts, and the input signal measures 44 microvolts, approximately which, if any, of the following values of agc is developed?

1. 44 microvolts
2. 50 microvolts
3. 94 microvolts
4. None of the above

1-62. To automatically compensate for input signal strength variations within a receiver, which of the following types of circuits are added?

1. Afc
2. Nfc
3. Agc
4. Nsu

1-63. AgC circuitry within a receiver uses a portion of which of the following detector voltage components as a feedback signal to preceding stages?

1. Dc
2. Ac
3. IF
4. Audio

1-64. Which of the following types of agc voltage drives an amplifier toward cutoff?

1. Saturation
2. Delayed
3. Reverse
4. Forward

1-65. What is the purpose of the squelch circuit in a receiver?

1. To attenuate very strong signals in order to prevent their overdriving the remaining stages in the receiver
2. To suppress receiver noise output when no input signal is being received
3. To suppress the electronic "whine" of the rf amplification stage
4. To reject signals of other than the desired frequency should the receiver drift off frequency

1-66. How does a receiver accomplish the squelch function?

1. By proportional blocking of the rf amplifier stage output
2. By blocking the detector or audio amplifier when there is no signal
3. By switching an inductive/capacitive filter into the output of the last rf amplifier
4. By switching in a matched-frequency stage which passes matching frequencies and rejects all others

1-67. A quartz crystal filter is used in a communications receiver to improve which of the following characteristics?

1. Fidelity
2. Sensitivity
3. Selectivity
4. Reproduction

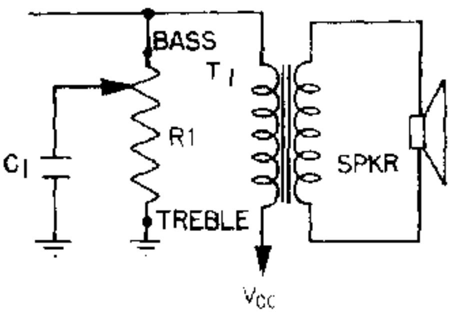

Figure 1B.

IN ANSWERING QUESTION 1-68, REFER TO FIGURE 1B.

1-68. When the wiper of R1 is placed in the full treble position, which of the following actions occur?

1. Bass response is improved
2. High frequency shunting is reduced
3. Higher frequencies are shunted to ground
4. The capacitor and resistor are placed in parallel

1-69. Automatic frequency control circuits are used in a receiver for which of the following purposes?

1. To adjust IF amplifier gain
2. To correct for oscillator frequency drift
3. To extend the frequency range of the receiver
4. To automatically tune the receiver to the desired frequency

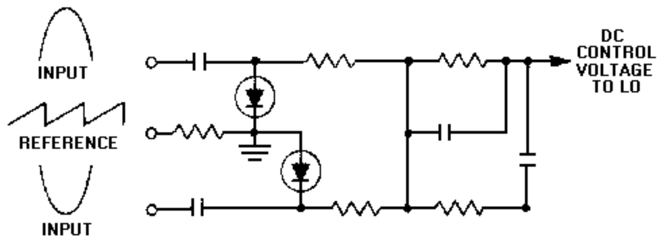

Figure 1C.

IN ANSWERING QUESTIONS 1-70 AND 1-71, REFER TO FIGURE 1C.

1-70. What is the phase relationship between the input signals fed to the diodes?

1. In phase
2. 90 degrees out of phase
3. 180 degrees out of phase
4. 270 degrees out of phase

1-71. A change in oscillator frequency will change which of the following input relationships between the sawtooth reference voltage and the incoming signal?

1. Phase
2. Voltage
3. Current
4. Amplitude

1-72. How is the long term stability and accuracy required of modern communications receivers attained?

1. Through the use of a single, crystal-controlled oscillator, as the local oscillator
2. Through the use of an electron-coupled oscillator, as the local oscillator
3. Through a process of automatic frequency control
4. Through a process known as frequency synthesis

1-73. When using the frequency synthesis process, a signal of the desired accuracy and stability is produced by which, if any, of the following methods?

1. Automatic frequency control, that is, by sensing the difference between the oscillator frequency and the desired frequency and automatically compensating for this difference
2. Using a crystal-controlled oscillator to produce a stable high frequency, and through the process of frequency division selecting a subharmonic of this frequency as the desired frequency
3. The heterodyning and selection of frequencies which are not harmonically related to each other
4. None of the above

1-74. Permanent magnet speakers respond quite well to which of the following audio frequency ranges?

1. Low
2. High
3. Mid band
4. Each of the above

1-75. For which of the following reasons do most standard Navy headphones respond poorly to low frequencies?

1. Small diaphragm size
2. Diaphragm inflexibility
3. Both 1 and 2 above
4. Input signal filtering

ASSIGNMENT 2

Textbook assignment: Chapter 3, "Fundamental Systems Equipment," pages 3-1 through 3-47.

2-1. In a basic communications voice system, which of the following functions occur in the handset during the receive process?

1. Correction voltages are fed to the local oscillator
2. Phasing voltages are received from the master oscillator
3. Voice energy is transformed into electronic impulses
4. Electrical energy is converted to acoustical energy

2-2. Radio set control units are often used aboard ship to remotely control transmitters and receivers. Under standard operating conditions what is the maximum number of units that can be paralleled with a single transmitter and receiver group?

1. One
2. Two
3. Eight
4. Four

2-3. When you are using a transmitter transfer switchboard, what is the maximum number of transmitters that may be connected to a single remote control station?

1. One
2. Two
3. Eight
4. Four

THIS SPACE LEFT BLANK INTENTIONALLY.

2-4. You are using a radio set control unit to remotely control 1 of 8 transmitters. Operating knob number 1 on transmitter transfer switchboard number 1 is used to select transmitters 1 through 6. If you want to control transmitter number 7, what switch position must be selected?

1. 1
2. Any of 1-6
3. X
4. OFF

2-5. On a receiver transfer switchboard, each switch position is connected to what maximum number of receivers?

1. One
2. Two
3. Three
4. Four

IN ANSWERING QUESTIONS 2-6 THROUGH 2-13, REFER TO THE RADIO TRANSMITTING SET DISCUSSED IN CHAPTER 3.

2-6. The impedance matching of equipment to transmission line is accomplished by which of the following equipment groups?

1. A radio transmitter
2. An antenna coupler
3. An rf amplifier
4. A power supply

2-7. The output power of the transmitter unit drives which of the following units?

1. The rf amplifier
2. The power supply
3. The antenna coupler
4. The antenna coupler control

2-8. The rf amplifier receives digital tuning information that is generated in which of the following units?

1. The receiver
2. The transmitter
3. The coupler control
4. The radio set control

2-9. In some installations tuning must be done without the use of rf power, as rf is suppressed except during brief transmission periods. Under these conditions, which of the following methods of tuning should be used?

1. Silent
2. Anti-jam
3. Automatic
4. Semiautomatic

2-10. Operator controlled tuning of the antenna coupler group by the use of front panel controls is possible during which of the following modes of operation?

1. Silent and manual
2. Manual and automatic
3. Semiautomatic and silent
4. Automatic and semiautomatic

2-11. Once tuned, the antenna coupler is able to handle which of the following maximum amounts of power?

1. 500 watts average
2. 2,000 watts average
3. 250 watts peak envelope
4. 1,000 watts peak envelope

2-12. The antenna coupler is pressurized with dry nitrogen for which of the following reasons?

1. To prevent corona
2. To prevent arcing
3. To aid in internal heat transfer
4. Each of the above

2-13. You are using the cw mode of the radio transmitter unit. The 500-kilohertz local carrier is directly inserted into which of the following circuits?

1. The rf amplifiers
2. The IF amplifiers
3. The modulator
4. The detector

IN ANSWERING QUESTIONS 2-14 THROUGH 2-16, REFER TO THE RADIO RECEIVER DISCUSSED IN CHAPTER 3.

2-14. Adjacent-channel selectivity and image-frequency suppression have been improved in this receiver by the addition of which of the following features?

1. Digital tuning
2. Triple conversion
3. Front panel readout
4. Very accurate frequency standard

2-15. The full accuracy of the frequency standard is sacrificed when which of the following types of tuning is used?

1. Vernier
2. Automatic
3. 1-kilohertz incremental
4. 100- or 500-hertz incremental

2-16. The receiver demodulates and provides audio outputs for which of the following types of received signals?

1. Fm, AM, and fsk
2. AM, cw, and isb
3. Cw, fm, and isb
4. Lsb, usb, and fm

2-17. A receiving antenna patch panel serves which of the following functions?

1. Terminates lines leading to receivers
2. Terminates incoming antenna transmission lines
3. Both 1 and 2 above
4. Physically connects transmitters to receivers

2-18. Transmitting antenna patch panels are interlocked with the transmitter for which of the following reasons?

1. Safety
2. Ease of operation
3. Ease of maintenance
4. Both 2 and 3 above

2-19. A transmit multicoupler provides which of the following functions?

1. Receiver isolation
2. Transmitter tuning
3. Additional amplification
4. Isolation between transmitters

2-20. In a manual telegraph circuit, the only two conditions are marking and spacing. Marking is characterized by which of the following descriptions?

1. The key is open
2. Current is flowing
3. Current is not flowing
4. The armature is retracted by a spring

2-21. A teletypewriter code signal consists of 7 units. Of the following functions, which describes the middle 5 units?

1. Provides channel data
2. Carries the intelligence
3. Signals stop information
4. Signals start information

2-22. Which of the following terms describe the time between a space and mark or mark and space condition in a teletypewriter?

1. Movement
2. Variation
3. Transition
4. Character interval

2-23. The time interval between words when using the Morse code is equal to which of the following durations?

1. 1 dot
2. 7 dots
3. 3 dashes
4. 5 dashes

2-24. When you are using the five-unit code in teletypewriter operation, what is the maximum number of combinations available that will print letters, figures, function signs, and numerals?

1. 30
2. 32
3. 60
4. 74

2-25. When you are using the teletypewriter five-unit code, which of the following signals are used to increase the printing capacity of the equipment?

1. Inverter
2. Combiner
3. Case-shift
4. Type-adjust

2-26. Which, if any, of the following modes of teletypewriter operation is more often used in high-speed data systems?

1. Start-stop
2. Synchronous
3. Asynchronous
4. None of the above

2-27. In teletypewriter operation, what term defines the length of time required to transmit one letter, figure, function sign or numeral?

1. Baud rate
2. Bit speed
3. Code length
4. Character interval

2-28. Synchronous teletypewriter systems are characterized by which of the following features when compared to asynchronous systems?

1. Internal timing signals are always used
2. Only the start-stop element must be transmitted
3. Only the intelligence elements must be transmitted
4. Signal quality determines receiver line signal condition

2-29. When you are referring to the unit of teletypewriter signaling speed, the reciprocal of the time (in seconds) of the shortest signal element is described by which of the following terms?

1. Unit code
2. Baud rate
3. Bits per second
4. Words per minute

2-30. The teletypewriter condition where current flow represents a mark and no current flow represents a space occurs in which of the following types of operation?

1. Polar
2. Arctic
3. Biased
4. Neutral

2-31. You are using neutral keying and the teletypewriter type hammer continually strikes the type box but there is no printing or type box movement across the page. What is the name of this condition?

1. Debugging
2. Running open
3. Baudot blanking
4. Decoding at random

2-32. Of the following equipment which one changes teletypewriter dc pulses to mark and space modulation for the transmitter carrier wave?

1. A comparator
2. A modulator
3. A converter
4. A keyer

2-33. To change an rf signal to do pulses for teletypewriter operation, you must use a receiver and what other piece of equipment?

1. A keyer
2. A converter
3. A comparator
4. A demodulator

2-34. A tone-modulated radio teletypewriter system uses what modulation method to change dc mark and space impulses into audio electrical impulses?

1. Amplitude
2. Frequency
3. Phase
4. Pulse

2-35. In a basic tone-modulated radio teletypewriter system, separation of the audio signal from the carrier is accomplished by what process?

1. Conversion
2. Modulation
3. Selection
4. Detection

2-36. In a radio-frequency-carrier shift system, what equipment is the source of radio-frequency excitation voltages?

1. The inverter
2. The converter
3. The comparator
4. The transmitter keyer

2-37. The keyer in a radio-frequency-carrier shift system is normally adjusted for which of the following maximum frequency spreads?

1. 425 hertz
2. 500 hertz
3. 750 hertz
4. 850 hertz

2-38. Of the following teletypewriter equipment, which one is used to store incoming teletypewriter messages on tapes for future transmission on a transmitter distributor?

1. A keyboard
2. A page printer
3. A typing reperforator
4. A communication patching panel

2-39. Teletypewriter patch panels perform which of the following functions?

1. They provide a means for connecting the teletypewriter equipment in various combinations
2. They provide a means for permanently connecting commonly used combinations of equipment
3. They provide a central point for connecting the dc supply voltage to the teletypewriter circuits
4. Each of the above

2-40. You are working with a teletypewriter patch panel. What color signifies that secure information is being passed?

1. Red
2. Gray
3. Black
4. Green

2-41. In any switching operation between plugs and jacks of a teletypewriter panel, if the cord plug is pulled from the set (machine) jack before the plug is removed from the looping jack, which of the following conditions will occur?

1. A dangerous dc voltage will be produced on the exposed plug
2. All teletypewriter messages in the channel will be interrupted
3. Both 1 and 2 above
4. Classified information will be Compromised

2-42. Cryptographic equipment performs which, if any, of the following functions?

1. Encodes and decodes messages
2. Reduces mean-time between messages
3. Acts as an additional power amplifier
4. None of the above

2-43. In the radio-frequency-carrier shift system, translation of an rf signal to an audio signal is done by which of the following equipment?

1. A converter
2. A comparator
3. A radio receiver
4. An antenna filter

2-44. A comparator compares signal strength during which of the following types of receiver operation?

1. Single
2. Space diversity
3. Frequency diversity
4. Both 2 and 3 above

2-45. In an afts transmit system, the conversion of dc signals into audio tone-shift signals is done by which of the following pieces of equipment?

1. Cryptographic
2. Tone terminal set
3. Converter/comparator
4. Modulator/demodulator

2-46. The process of simultaneous transmission of several intelligible signals on the same frequency during the same period of time is called

1. duplexing
2. simplexing
3. complexing
4. multiplexing

2-47. What are the two methods of multiplexing?

1. Time-division and frequency-multiplication
2. Time-division and frequency-division
3. Time-multiplication and frequency-multiplication
4. Time-multiplication and frequency-division

2-48. In time-division multiplexing, assume that a 4,000-hertz tone is applied to each of six channels in a telegraph transmitter and that each channel is to be sampled at a rate of 2. 5 times during each cycle of the 4,000-hertz tone. At what speed, in revolutions per second, must the rotating switch turn to accomplish this sampling rate?

1. 3,000
2. 4,000
3. 7,200
4. 10,000

2-49. In time-division multiplexing, what drawback is encountered if an excessive number of frequency channels is used?

1. Static is increased
2. Bandwidth is increased
3. Switching becomes unreliable
4. Reception becomes unintelligible

2-50. How many times per cycle is a practical time-division multiplex system optimumly sampled?

1. 1.5
2. 2.0
3. 2.4
4. 3.1

2-51. Frequency-division multiplexing systems transmit and receive during a maximum of how many degrees of a sinewave?

1. 90
2. 180
3. 270
4. 360

2-52. By using frequency-division multiplexing, tty circuits may carry a maximum of how many single, 3,000-hertz channels?

1. 12
2. 16
3. 18
4. 24

2-53. In a 16-channel tty-multiplexing system, the maximum difference between a mark and a space, for any give channel, is how many hertz?

1. 85
2. 382.5
3. 425
4. 467.5

2-54. Weather charts and photographs are examples of materials transmitted by

1. aw telegraphy
2. FAX (facsimile)
3. landline teletypewriter
4. rttv (radio teletypewriter)

2-55. Which of the following facsimile transceiver operations consists of subdividing the picture in an orderly manner and into a large number of segments?

1. Scanning
2. Recording
3. Receiving
4. Transmitting

2-56. The scanning operation is accomplished in the facsimile transmitter by a

1. scanning drum and a phototube arrangement
2. scanning drum and aperture tube
3. spiral drum and amplifier
4. phototube amplifier

2-57. The purpose of the phototube in facsimile equipment is to

1. illuminate a segment of the picture
2. produce the carrier signal for the exciter lamp
3. maintain the output voltage at a predetermined fixed value
4. transform varying amounts of light into electrical signals

2-58. Which of the following means is used to synchronize the receiving drum with the transmitting drum in a radio facsimile system?

1. The drums are mechanically linked
2. Each drum is started by an accurate clock
3. Both drums are operated by synchronous motors
4. Both drums are stepped around a precise number of steps by a relay

2-59. In a facsimile system, which of the following methods is used to accomplish framing at the receiver unit?

1. A synchronous clutch mechanism is actuated
2. A primary time/frequency standard is switched in
3. A series of phasing pulses are transmitted prior to image transmission
4. A synchronous motor at both the transmitter and receiver is engaged

2-60. Of the following terms, which one is primarily concerned with compromising emanations?

1. Tempest
2. Radiation hazard
3. Quality monitoring
4. Electromagnetic interference

2-61. Of the following fundamental requirements of a military communications system, which one, if any, is most important?

1. Speed
2. Security
3. Reliability
4. None of the above

2-62. What one assumption may be made regarding all military radio transmissions?

1. They are secure
2. They have been encrypted
3. They have been decrypted
4. They have been intercepted

2-63. Scheduled maintenance in support of QMCS is designed to alert you to which of the following problems?

1. Safety hazards
2. Equipment failure
3. System degradation
4. Improper operating procedures

2-64. Of the following terms, which one is defined as the ability of an electronic system to perform its individual functions without interference?

1. Electronic countermeasures
2. Electromagnetic interference
3. Electromagnetic compatibility
4. Electronic counter-countermeasures

2-65. The sources of electromagnetic radiations that reduce receiver performance are known by which of the following terms?

1. Electronic countermeasures
2. Electromagnetic interference
3. Electromagnetic compatibility
4. Electronic counter-countermeasures

2-66. Which of the following categories of electromagnetic interference includes interference generated by electrically charged raindrops?

1. Natural
2. Functional
3. Incidental
4. Hull-generated

2-67. Cross modulation is a form of emi where the desired carrier intermodulates with an undesired signal. Which of the following devices should minimize this interference?

1. Filters
2. Preselectors
3. Both 1 and 2 above
4. Preamplifiers

2-68. Shipboard receive systems are designed to include protective circuitry between the antenna and the receiver that prevent which of the following problems?

1. Degradation of overall receiver performance by processing of off-frequency signals
2. Decrease of desired signal amplification
3. Burn out of front-end stages
4. Each of the above

2-69. Of the following body organs, which are considered the most vulnerable to radiation hazards (RADHAZ)?

1. Eyes and testes
2. Heart and lungs
3. Liver and spleen
4. Kidneys and brain

2-70. Which of the following methods of reducing rf burn hazards is the most useful and widespread technique used?

1. Operate receivers only
2. Vary the operating frequency
3. Bond and ground all metallic objects
4. Operate transmitters only at low power

2-71. The greatest hazard from thermal effects appears to come from equipment operated in which of the following frequency ranges?

1. 1 to 3 gigahertz
2. 2 to 30 megahertz
3. 30 to 300 kilohertz
4. 225 to 500 megahertz

2-72. You have been working on a piece of equipment and your eyes have been exposed to high-intensity microwaves. Which of the following types of eye problems may occur?

1. Detached retina
2. Conjunctivitis
3. Cataracts
4. Glaucoma

ASSIGNMENT 3

Textbook assignment: Chapter 4, "Introduction to Satellite Communications," pages 4-1 through 4-21.
Chapter 5, "Introduction to Miscellaneous Systems and Equipment," pages 5-1 through 5-20.

3-1. What artificial satellite is credited with starting the era of space technology?

1. Vela
2. Midas
3. Score
4. Sputnik

3-2. There are two types of communications satellites. What type acts as a repeater for the signal?

1. Active
2. Passive
3. Reflecting
4. Retransmitting

3-3. Transmission of information to a satellite is done on what frequency?

1. Up-link
2. Down-link
3. Transponder
4. Termination

3-4. An earth terminal receives signals on what frequency?

1. Up-link
2. Transmit
3. Down-link
4. Termination

3-5. Of the following orbit parameters, which one describes the basic orbit shape of a communications satellite?

1. Inclined or polar
2. Polar or equatorial
3. Elliptical or circular
4. Synchronous or nonsynchronous

3-6. When the period of an orbit is identical to that of the earth, the orbit is

1. synchronous
2. asynchronous
3. subsynchronous
4. near-synchronous

3-7. What is the parameter in the orbit of a satellite that refers to the point nearest the center of the earth?

1. Apogee
2. Perigee
3. Altitude
4. Inclination

3-8. As a reference, perigee and apogee are measured in which of the following units?

1. Nautical miles
2. Statute miles
3. Light years
4. Kilometers

3-9. A satellite which has a flight path that does not coincide with the equatorial plane of the earth is said to be in what type if orbit?

1. A circular
2. An inclined
3. An elliptical
4. An equatorial

3-10. A satellite orbiting with an angle of inclination of approximately 90 degrees describes which of the following types of orbit?

1. Polar
2. Equatorial
3. Synchronous
4. Asynchronous

3-11. In order to cover most of the earth except the polar regions, what is the minimum number of satellites that mast be orbited?

1. 5
2. 6
3. 3
4. 4

3-12. There were many limitations that caused problems on the first communications satellites. Of the following problems, which one was considered the most severe?

1. The excessive size
2. The excessive weight
3. The too low orbit altitude
4. The lack of a suitable power source

3-13. Which of the following power sources is/are considered a practical choice for satellites?

1. Solar cells only
2. Storage batteries only
3. A combination of solar cells and storage batteries
4. Sunlight and leclanche cells

3-14. What development in satellite communications improved back-up power during eclipses?

1. The installation of a battery back-up
2. The installation of a nuclear power source
3. The continuous exposure of solar cells to the sun
4. The increase in solar cells mounted on the surface of the satellite

3-15. Why is satellite orientation in space so important?

1. Because it is a necessity for back-up power
2. To meet the requirements of spin stabilization
3. To ensure that sunlight converging on the solar cells is converted to electrical power
4. Because it is essential for maximum solar cell exposure to the sun and satellite antenna visibility to earth terminals

3-16. Why are communications satellite earth terminals generally located in areas remote from the actual users?

1. To minimize cost
2. To minimize jamming
3. To minimize rf interference
4. To allow for future expansion

3-17. Which of the following characteristics is a requirement for a satellite earth terminal antenna?

1. It must be omnidirectional
2. It must be of the Franklin collinear type
3. It must have low gain and be highly directional
4. It must be capable of transmitting and receiving signals simultaneously

3-18. One earth terminal antenna uses a cluster of four 10-foot parabolic antennas. This array is effectively a total of how many feet in diameter?

1. 18
2. 20
3. 32
4. 40

3-19. Why do satellite earth terminals require highly sensitive receivers?

1. To overcome the down-link power losses
2. To permit extraction of the desired communications information from the received signal
3. Both 1 and 2 above
4. Because of the signal scatter effect of the antennas

3-20. Which of the following functions is performed by the exciter stage of an earth terminal transmitter?

1. Modulation of the IF carrier
2. Translation of the IF signal to the up-link frequency
3. Amplification of the IF signal to the level required by the receiver
4. Conversion of the down-link frequency to an IF

3-21. Telemetery equipment used in satellite communications systems performs which of the following functions?

1. They monitor the operating conditions within the satellite
2. They provide local control for satellite operations
3. They furnish high-capacity wide-band tty trunks
4. They measure ambient weather conditions

3-22. A typical shipboard receive-only satellite system uses which of the following types of modulation?

1. Pulsed or amplitude
2. Pulsed or frequency
3. Amplitude or phase-shift-key
4. Frequency or phase-shift-key

3-23. Locating a near-synchronous satellite is rather simple for which of the following reasons?

1. It is stationary
2. It is moving north to south
3. It has a slow relative motion
4. It has a fast relative motion

3-24. What is the name of the table that provides coordinates of a satellite at specific times?

1. Bearing location
2. Longitudinal
3. Propagation
4. Ephemeris

3-25. To establish radio contact with a satellite, an earth terminal must know which of the following satellite data?

1. Attitude
2. Elevation
3. Operating speed
4. Angle of inclination

3-26. Satellite down-link frequency variations occur most often from satellites in which of the following orbits?

1. Low altitude elliptical
2. Medium altitude circular
3. High altitude synchronous
4. Superhigh altitude near-synchronous

3-27. Of the following terms, which one describes the period of time required for one earth terminal to yield control of a satellite to another?

1. Slewing
2. Hand over
3. Control shift
4. Terminal continuity

3-28. When compared to hf communications, which of the following advantages are unique to satellite communications links?

1. They are more reliable and flexible
2. They are unaffected by propagation variations affecting hf
3. They do not require repeater stations or troposcatter links
4. Each of the above

3-29. Which of the following factors limits the reliability of active satellite communications system?

1. The reflection or refraction of signals
2. The reliability of the equipment used
3. The skill of the operating and maintenance personnel
4. Both 2 and 3 above

3-30. An increase of invulnerability to jamming of satellite communications systems is seen through the use of which of the following features?

1. Narrow bandwidths
2. Low transmitter output power
3. Antijamming modulation techniques
4. Omnidirectional earth terminal Antennas

3-31. Which of the following statements best describes the advantage of satellite communications in terms of flexibility?

1. The antenna group of any earth terminal can be mounted on the weather deck of a ship
2. Certain earth terminals are housed in vans and can be transported to remote areas
3. Military satellite communications are capable of handling hundreds of voice channels
4. A high degree of protection from jamming is afforded by the highly Directional antennas at earth terminals

3-32. A satellite communications system is limited by which of the following characteristics?

1. The attitude of the satellite repeater
2. The technical design of the satellite
3. The immobility of the satellite
4. The mobility of the satellite

3-33. Active communications satellite systems have two major limitations. What are they?

1. Complex preamplifiers and high gain antennas
2. Up-link transmitter power and earth terminal antenna size
3. Down-link transmitter power and uplink receiver sensitivity
4. Down-link receiver sensitivity and external atmospheric noise

3-34. The rf power output of a satellite communications system is severely limited due to which of the following factors?

1. A lack of adequate jamming capabilities
2. An inefficient solar-cell package aboard the satellite
3. An unstable satellite orientation with respect to the horizon
4. A requirement for large antenna-farm earth-terminal systems

3-35. The availability of a satellite to act as a relay station between two earth terminals depends upon which of the following considerations?

1. The mobility of the satellite
2. The location of the earth terminals
3. The operating frequencies of the satellite
4. The electronic design of the earth terminals

3-36. What determines the length of time that a nonsynchronous satellite in a circular orbit will be in the zone of mutual visibility?

1. Height of the orbit
2. Earth terminal antenna size
3. Down-link transmitter power
4. Up-link receiver sensitivity

3-37. Satellite communications systems are being rapidly developed by the Navy for which of the following reasons?

1. To replace microwave links
2. To relieve dependence on hf communications
3. To reduce procurement and development costs
4. To replace all physically large size equipment

3-38. In an mf transmitter, the frequency generator is used during which of the following modes of operation?

1. AM
2. Fm
3. Cw
4. Fsk

3-39. The pre-ipa and ipa in an mf transmitter are which of the following types?

1. Linear, tuned
2. Linear, untuned
3. Non-linear, tuned
4. Non-linear, untuned

3-40. Of the following communications system components, which one is a device that is nonradiating, absorbs rf, and has the characteristic impedance of the antenna?

1. Helix
2. Dummy load
3. Rf tuning unit
4. Frequency synthesizer

3-41. Which of the following antenna arrays consists of quarter-wave, vertically polarized stubs?

1. Broadside
2. Parasitic
3. Top-hat
4. Triatic

IN ANSWERING QUESTIONS 3-42 THROUGH 3-44, REFER TO THE MEDIUM FREQUENCY AND BELOW RECEIVER COVERED IN CHAPTER 5.

3-42. With one exception, the receiver has the same circuitry as any high frequency receiver. What is the one exception?

1. The components are doubled up
2. The local oscillator is eliminated
3. The radio-frequency amplifier is replaced by a video amplifier
4. The audio-frequency amplifier is replaced by a traveling-wave tube

3-43. The rejection of input frequencies above 900-kilohertz is performed by which of the following circuits?

1. An attenuator
2. A video amplifier
3. A low-pass filter
4. A calibration oscillator

3-44. The demodulation of ssb, cw, and fsk signals is performed by which of the following circuits?

1. An fm detector
2. A phase splitter
3. An audio amplifier
4. A product detector

3-45. Of the following amplifiers, which one has a high gain, low noise, wide bandwidth and is operated in the microwave region?

1. A magnetic
2. An operational
3. A differential
4. A traveling-wave-tube

3-46. In a line-of-sight communications system, propagation is affected by which of the following layers of the atmosphere?

1. Ionosphere
2. Troposphere
3. Stratosphere
4. Thermosphere

3-47. Horn-driven paraboloid antennas have which of the following characteristics?

1. High gain, narrow beam width
2. Low gain, narrow beam width
3. High gain, wide beam width
4. Low gain, wide beam width

3-48. Line-of-sight systems are configured in many ways with regards to channel width and number of channels. A voice system with a channel width of 4-kilohertz has a total of how many channels available for transmission?

1. 200
2. 400
3. 600
4. 800

3-49. A one-hop transmission of a tropo-scatter system can travel what maximum distance?

1. 1200 miles
2. 1000 miles
3. 800 miles
4. 500 miles

3-50. Of the following advantages, which one is primary to the NTDS when compared with conventional data systems?

1. Speed
2. Distance
3. Security
4. Reliability

3-51. The NTDS uses which of the following data transmission links?

1. 14, 11, 4A
2. 14A, 11, 4
3. 14, 11A, 4
4. 14A, 11A, 4A

3-52. Of the following NTDS links, which one(s) is/are only used as a one-way broadcast?

1. 14
2. 4A
3. 11, 14
4. 4A, 11

3-53. Portable radio sets are used primarily for which of the following types of communications?

1. Amphibious
2. Air-to-air
3. Electronic warfare
4. Anti-submarine warfare

3-54. When designing portable and pack radios, which of the following characteristics is the prime consideration?

1. Must be solar powered
2. Must be heavy and rugged
3. Must have high output power
4. Must be light-weight and compact

IN ANSWERING QUESTIONS 3-55 THROUGH 3-58, REFER TO THE EMERGENCY LIFEBOAT TRANSMITTER COVERED IN CHAPTER 5.

3-55. Search and rescue stations are divided into groups that have distinct rescue functions. Emergency lifeboat transmissions are designed for reception by a total of how many of these groups?

1. 5
2. 2
3. 3
4. 4

3-56. What are the operating frequencies of the transmitter?

1. 8,364 kHz and 500 MHz
2. 500 MHz and 8,864 kHz
3. 500 kHz and 8,364 kHz
4. 500 kHz and 8,864 kHz

3-57. What is the primary source of power for the transmitter?

1. External ac
2. Wind generator
3. Internal battery
4. Handcrank generator

3-58. When in the automatic mode of operation, the transmitter transmits (a) while changing frequency every (b) seconds?

1. (a) The SOS distress signal
   (b) 50
2. (a) Voice messages
   (b) 20
3. (a) Voice messages
   (b) 50
4. (a) The SOS distress signal
   (b) 20

3-59. What is the maximum number of channels available when you are using the emergency portable transceiver covered in chapter 5?

1. 5
2. 2
3. 3
4. 4

3-60. A laser operates in which of the following areas of the light spectrum?

1. Red
2. Infrared
3. Ultraviolet
4. At or near visible light

3-61. The principle of the laser is much like that of, which of the following electronic components?

1. Hall generator
2. Reflex klystron
3. Traveling-wave-tube
4. Very high-Q cavity resonator

3-62. Which of the following components is a close relative of the laser?

1. Thyristor
2. Photo transistor
3. Light emitting diode
4. Photovoltaic transducer

3-63. Laser transmissions during adverse weather conditions experience which of the following problems?

1. Absorption
2. Refraction
3. Reflection
4. Diffraction

PREFACE

About this course:

This is a self-study course. By studying this course, you can improve your professional/military knowledge, as well as prepare for the Navywide advancement-in-rate examination. It contains subject matter about day-to-day occupational knowledge and skill requirements and includes text, tables, and illustrations to help you understand the information. An additional important feature of this course is its reference to useful information in other publications. The well-prepared Sailor will take the time to look up the additional information.

Training series information:

This is Module 18 of a series.

History of the course:

Sep 1998: *Original edition released. Prepared by FTMC Frank E. Sloan and FTCM Gilbert J. Coté*

Jan 2004: *Administrative update released. Reviewed by ETC(SW) Jack Weatherford. No change in technical content.*

TABLE OF CONTENTS

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

CHAPTER 1

RADAR FUNDAMENTALS

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions are based on the objectives. By successfully completing the OCC/ECC, you indicate that you have met the objectives and have learned the information. The learning objectives are listed below.

1. Define range, bearing, and altitude as they relate to a radar system.
2. Discuss how pulse width, peak power, and beam width affect radar performance.
3. Describe the factors that contribute to or detract from radar accuracy.
4. Using a block diagram, describe the basic function, principles of operation, and interrelationships of the basic units of a radar system.
5. Explain the various ways in which radar systems are classified, including the standard Army/Navy classification system.
6. Explain the basic operation of cw, pulse, and Doppler radar systems.

INTRODUCTION TO RADAR FUNDAMENTALS

The term RADAR is common in today's everyday language. You probably use it yourself when referring to a method of recording the speed of a moving object. The term *Radar* is an acronym made up of the words radio detection and ranging. The term is used to refer to electronic equipment that detect the presence, direction, height, and distance of objects by using reflected electromagnetic energy. Electromagnetic energy of the frequency used for radar is unaffected by darkness and also penetrates weather to some degree, depending on frequency. It permits radar systems to determine the positions of ships, planes, and land masses that are invisible to the naked eye because of distance, darkness, or weather.

The development of radar into the highly complex systems in use today represents the accumulated developments of many people and nations. The general principles of radar have been known for a long time, but many electronics discoveries were necessary before a useful radar system could be developed. World War II provided a strong incentive to develop practical radar, and early versions were in use soon after the war began. Radar technology has improved in the years since the war. We now have radar systems that are smaller, more efficient, and better than those early versions.

Modern radar systems are used for early detection of surface or air objects and provide extremely accurate information on distance, direction, height, and speed of the objects. Radar is also used to guide missiles to targets and direct the firing of gun systems. Other types of radar provide long-distance surveillance and navigation information.

BASIC RADAR CONCEPTS

The electronics principle on which radar operates is very similar to the principle of sound-wave reflection. If you shout in the direction of a sound-reflecting object (like a rocky canyon or cave), you will hear an echo. If you know the speed of sound in air, you can then estimate the distance and general direction of the object. The time required for a return echo can be roughly converted to distance if the speed of sound is known. Radar uses electromagnetic energy pulses in much the same way, as shown in figure 1-1. The radio-frequency (rf) energy is transmitted to and reflects from the reflecting object. A small portion of the energy is reflected and returns to the radar set. This returned energy is called an ECHO, just as it is in sound terminology. Radar sets use the echo to determine the direction and distance of the reflecting object.

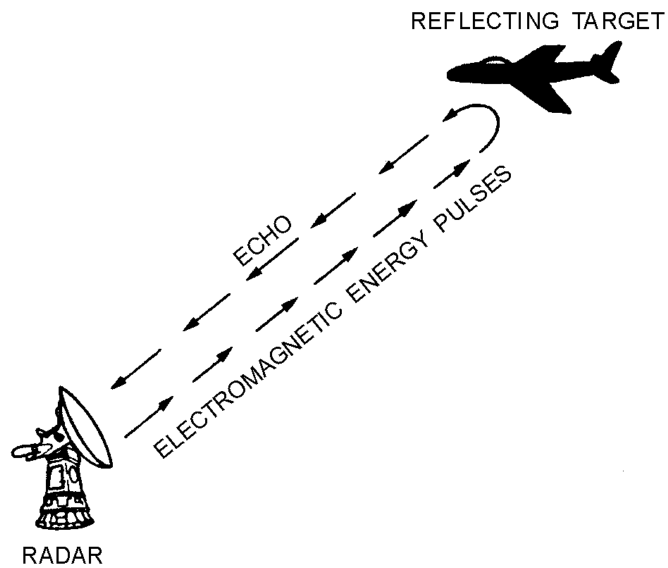

Figure 1-1.—Radar echo.

NOTE: The terms TARGET, RETURN, ECHO, CONTACT, OBJECT, and REFLECTING OBJECT are used interchangeably throughout this module to indicate a surface or airborne object that has been detected by a radar system.

Radar systems also have some characteristics in common with telescopes. Both provide only a limited field of view and require reference coordinate systems to define the positions of detected objects. If you describe the location of an object as you see it through a telescope, you will most likely refer to prominent features of the landscape. Radar requires a more precise reference system. Radar surface angular measurements are normally made in a clockwise direction from TRUE NORTH, as shown in figure 1-2, or from the heading line of a ship or aircraft. The surface of the earth is represented by an imaginary flat plane, tangent (or parallel) to the earth's surface at that location. This plane is referred to as the HORIZONTAL PLANE. All angles in the up direction are measured in a second imaginary plane that is perpendicular to the horizontal plane.

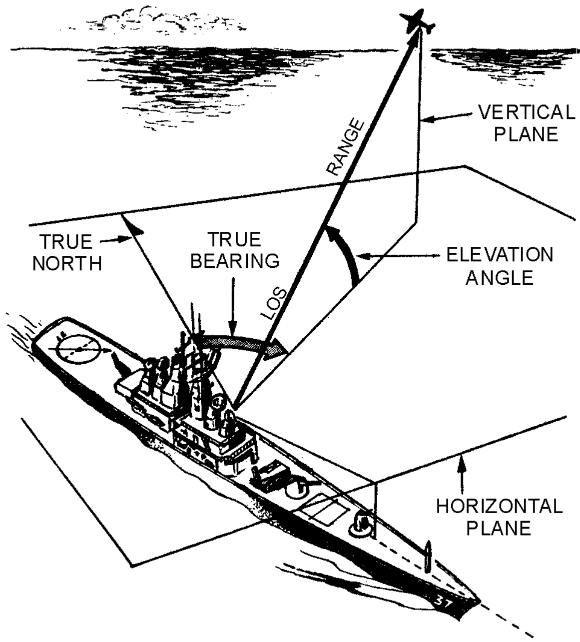

Figure 1-2.—Radar reference coordinates.

This second plane is called the VERTICAL PLANE. The radar location is the center of this coordinate system. The line from the radar set directly to the object is referred to as the LINE OF SIGHT (los). The length of this line is called RANGE. The angle between the horizontal plane and the los is the ELEVATION ANGLE. The angle measured clockwise from true north in the horizontal plane is called the TRUE BEARING or AZIMUTH angle. These three coordinates of range, bearing, and elevation describe the location of an object with respect to the antenna.

Q1. Radar surface-angular measurements are referenced to true north and measured in what plane?

Q2. The distance from a radar set to a target measured along the line of sight is identified by what term?

RANGE

Radar measurement of range, or distance, is made possible because of the properties of radiated electromagnetic energy. This energy normally travels through space in a straight line, at a constant speed, and will vary only slightly because of atmospheric and weather conditions. The effects atmosphere and weather have on this energy will be discussed later in this chapter; however, for this discussion on determining range, these effects will be temporarily ignored.

Electromagnetic energy travels through air at approximately the speed of light, which is 186,000 STATUTE MILES per second. The Navy uses NAUTICAL MILES to calculate distances; 186,000 statute miles is approximately 162,000 nautical miles. While the distance of the statute mile is approximately 5,280 feet, the distance for a nautical mile is approximately 6,080 feet.

Radar timing is usually expressed in microseconds. To relate radar timing to distances traveled by radar energy, you should know that radiated energy from a radar set travels at approximately 984 feet per microsecond. With the knowledge that a nautical mile is approximately 6,080 feet, we can figure the approximate time required for radar energy to travel one nautical mile using the following calculation:

$$\text{time for energy to travel one nautical mile}$$
$$= \frac{6{,}080 \text{ feet}}{984 \text{ feet per microsecond}}$$
$$= 6.18 \text{ microseconds (approx.)}$$

The same answer can be obtained using yards instead of feet. In the following calculation, the 6,080 foot approximation of a nautical mile is converted to 2,027 yards and energy speed is changed from 984 feet to 328 yards per microsecond:

$$\text{time for energy to travel one nautical mile} = \frac{2{,}027 \text{ yards}}{328 \text{ yards per microsecond}}$$
$$= 6.18 \text{ microseconds (approx.)}$$

A pulse-type radar set transmits a short burst of electromagnetic energy. Target range is determined by measuring elapsed time while the pulse travels to and returns from the target. Because two-way travel is involved, a total time of 12.36 (6.18 x 2) microseconds per nautical mile will elapse between the start of the pulse from the antenna and its return to the antenna from a target. This 12.36 microsecond time interval is sometimes referred to as a RADAR MILE, RADAR NAUTICAL MILE, or NAUTICAL RADAR MILE. The range in nautical miles to an object can be found by measuring the elapsed time during a *round trip* of a radar pulse and dividing this quantity by 12.36. In equation form, this is:

$$\text{range} = \frac{\text{elapsed time}}{12.36 \text{ microseconds per nautical mile}}$$

For example, if the elapsed time for an echo is 62 microseconds, then the distance is 5 miles, as shown in the following calculation:

$$\text{range} = \frac{\text{elapsed time}}{12.36 \text{ microseconds per nautical mile}}$$
$$= \frac{62 \text{ microseconds}}{12.36 \text{ microseconds per nautical mile}}$$
$$= 5 \text{ nautical miles (approx.)}$$

NOTE: Unless otherwise stated all distances will be expressed as nautical miles throughout this module.

Minimum Range

Recall from NEETS, Module 11, *Microwave Principles*, that the DUPLEXER alternately switches the antenna between the transmitter and receiver so that only one antenna need be used. This switching is necessary because the high-power pulses of the transmitter would destroy the receiver if energy were allowed to enter the receiver. As you probably already realize, timing of this switching action is critical to the operation of the radar system. What you may not realize is that the minimum range ability of the radar system is also affected by this timing. The two most important times in this action are PULSE WIDTH and RECOVERY TIME.

This timing action must be such that during the transmitted pulse (pulse width), only the transmitter can be connected to the antenna. Immediately after the pulse is transmitted, the antenna must be reconnected to the receiver.

The leading edge of the transmitted pulse causes the duplexer to align the antenna to the transmitter. This action is essentially instantaneous. At the end of the transmitted pulse, the trailing edge of the pulse causes the duplexer to line up the antenna with the receiver; however, this action is not instantaneous. A small amount of time elapses at this point that is referred to as recovery time. Therefore, the total time in which the receiver is unable to receive the reflected pulse is equal to the pulse width plus the recovery time. Note that any reflected pulses from close targets returning before the receiver is connected to the antenna will be undetected. The minimum range, in yards, at which a target can be detected is determined using the following formula (pulse width and recovery time are expressed in microseconds or fractions of microseconds):

$$\text{minimum range} = \frac{\text{pulse width} + \text{recovery time}}{2} \times 328 \text{ yards}$$

or

$$\text{minimum range} = (\text{pulse width} + \text{recovery time}) \times 164 \text{ yds}$$

For example, minimum range for a radar system with a pulse width of 25 microseconds and a recovery time of 0.1 microseconds is figured as follows:

$$\begin{aligned}\text{minimum range} &= (25 + 0.1) \times 164 \text{ yards} \\ &= 25.1 \times 164 \text{ yards} \\ &= 4,116 \text{ yards (approximate)}\end{aligned}$$

Most modern radar systems are designed with such small recovery times that this figure can often be ignored when figuring minimum range.

Maximum Range

The maximum range of a pulse radar system depends upon CARRIER FREQUENCY, PEAK POWER of the transmitted pulse, PULSE-REPETITION FREQUENCY (prf) or PULSE REPETITION RATE (prr), and RECEIVER SENSITIVITY with prf as the primary limiting factor. The peak power of the pulse determines what maximum range the pulse can travel to a target and still return a usable echo. A usable echo is the smallest signal detectable by a receiver system that can be processed and presented on an indicator.

The frequency of the rf energy in the pulse radiated by a radar is referred to as the CARRIER FREQUENCY of the radar system. The carrier frequency is often a limiting factor in the maximum range capability of a radar system because radio frequency energy above 3,000 megahertz is rapidly attenuated by the atmosphere. This decreases the usable range of radio-frequency energy. Therefore, as the carrier frequency is increased, the transmitted power must also be increased to cover the same range. Long-range coverage is more easily achieved at lower frequencies because atmospheric conditions have less effect on low-frequency energy.

Radar systems radiate each pulse at the carrier frequency during transmit time, wait for returning echoes during listening or rest time, and then radiate a second pulse, as shown in figure 1-3. The number of pulses radiated in one second is called the pulse-repetition frequency (prf), or the pulse-repetition rate (prr). The time between the beginning of one pulse and the start of the next pulse is called PULSE-REPETITION TIME (prt) and is equal to the reciprocal of prf as follows:

$$prt = \frac{1}{prf}$$

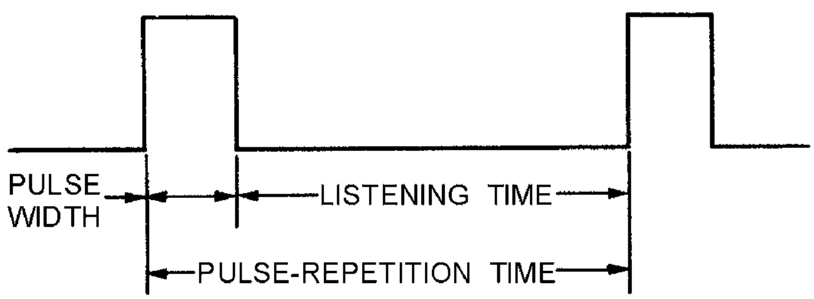

Figure 1-3.—Radar pulse relationships.

AMBIGUOUS RETURNS.—The radar timing system must be reset to zero each time a pulse is radiated. This is to ensure that the range detected is measured from time zero each time. The prt of the radar becomes important in maximum range determination because target return times that exceed the prt of the radar system appear at incorrect locations (ranges) on the radar screen. Returns that appear at these incorrect ranges are referred to as AMBIGUOUS RETURNS or SECOND-SWEEP ECHOES.

Figure 1-4 illustrates a radar system with a 1 millisecond prt. The pulses are shown at the top, and examples of two transmitted pulses hitting targets and returning are shown at the bottom. In the case of target A, the pulse travels round trip in 0.5 millisecond, which equates to a target range of 82,000 yards. Since 0.5 millisecond is less than 1 millisecond, displaying a correct range is no problem. However, target B is 196,800 yards distant from the radar system. In this case, total pulse travel time is 1.2 milliseconds and exceeds the prt limitation of 1 millisecond for this radar. While the first transmitted pulse is traveling to and returning from target B, a second pulse is transmitted and the radar system is reset to 0 again. The first pulse from target B continues its journey back to the radar system, but arrives during the timing period for the second pulse. This results in an inaccurate reading. In this case, the first return pulse from target B arrives 0.2 millisecond into the second timing period. This results in a range of 32,800 yards instead of the actual 196,800 yards. You should see from this example that pulse returns in excess of the prt of the radar system result in ambiguous ranges while pulse returns within the prt limits result in normal (unambiguous) ranges. The maximum unambiguous range for a given radar system can be determined by the following formula:

$$R_{max}\ \text{unambiguous} = \frac{162,000\ \text{miles/second}}{2} \times \text{prt}$$

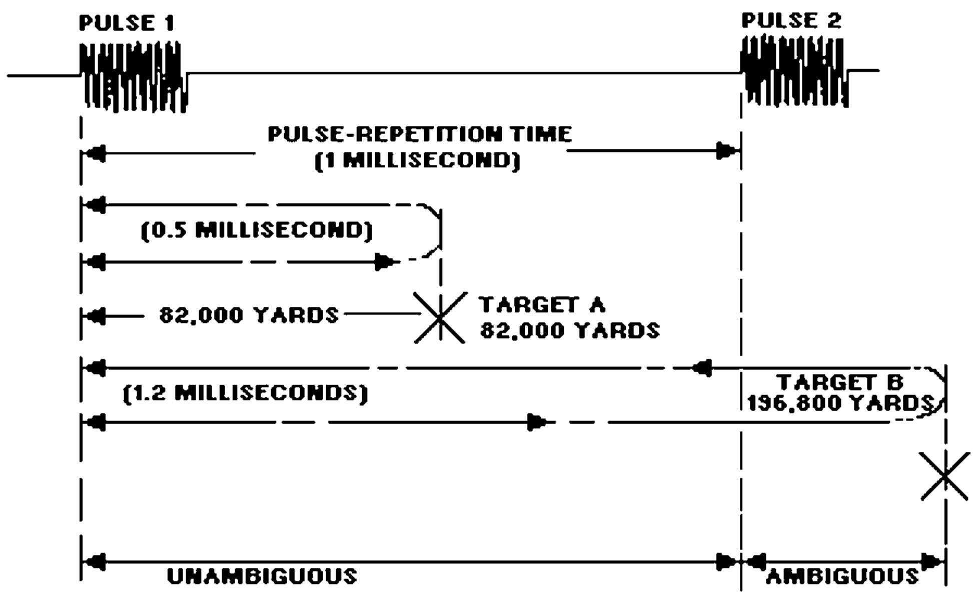

Figure 1-4.—Maximum unambiguous range.

Q3. What is the speed of electromagnetic energy traveling through air?

Q4. How much time is required for electromagnetic energy to travel 1 nautical mile and return to the source?

Q5. In addition to recovery time, what determines the minimum range of a radar set?

PULSE-REPETITION FREQUENCY AND POWER CALCULATIONS.—The energy content of a continuous-wave radar transmission may be easily figured because the transmitter operates continuously. However, pulsed radar transmitters are switched on and off to provide range timing information with each pulse. The resulting waveform for a transmitter was shown in figure 1-3. The amount of energy in this waveform is important because maximum range is directly related to transmitter output power. The more energy the radar system transmits, the greater the target detection range will be. The energy content of the pulse is equal to the PEAK (maximum) POWER LEVEL of the pulse multiplied by the pulse width. However, meters used to measure power in a radar system do so over a period of time that is longer than the pulse width. For this reason, pulse-repetition time is included in the power calculations for transmitters. Power measured over such a period of time is referred to as AVERAGE POWER. Figure 1-5 illustrates the way this average power would be shown as the *total* energy content of the pulse. The shaded area represents the total energy content of the pulse; the crosshatched area represents average power and is equal to peak power spread out over the prt. (Keep in mind, as you look at figure 1-5, that *no energy is actually present between pulses* in a pulsed radar system. The figure is drawn just to show you how average power is calculated.) Pulse-repetition time is used to help figure average power because it defines the total time from the beginning of one pulse to the beginning of the next pulse. Average power is figured as follows:

Where: P_{avg} = average power

P_{pk} = peak power

pw = pulse width

prt = pulse-repetition time

$$P_{avg} = P_{pk} \times \frac{pw}{prt}$$

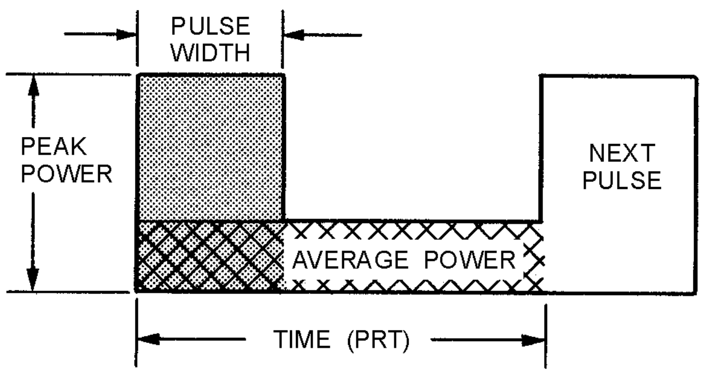

Figure 1-5.—Pulse energy content.

Because 1/prt is equal to prf, the formula may be written as follows:

$$P_{avg} = P_{pk} \times pw \times prf$$

The product of pulse width (pw) and pulse-repetition frequency (prf) in the above formula is called the DUTY CYCLE of a radar system. The duty cycle is a ratio of the *time on* to the *time off* of the transmitter, as shown in figure 1-6. The duty cycle is used to calculate both the peak power and average power of a radar system. The formula for duty cycle is shown below:

$$\text{duty cycle} = pw \times prf$$

NOTE: Pulse repetition frequency (prf) and pulse repetition rate (prr) are interchangeable terms.

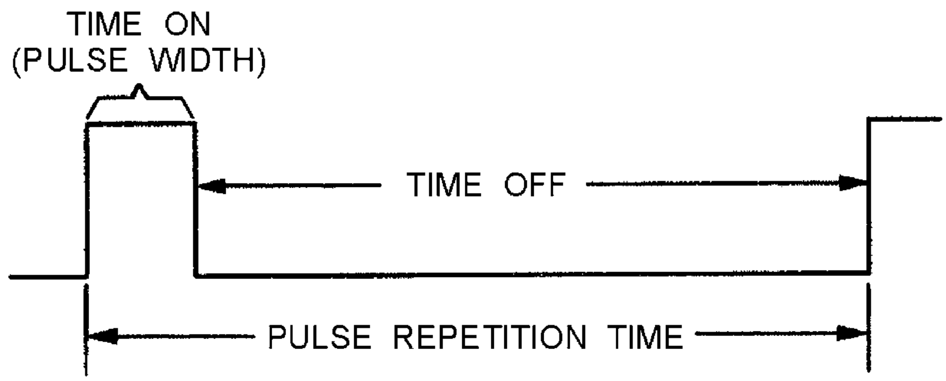

Figure 1-6.—Duty cycle.

Since the duty cycle of a radar is usually known, the most common formula for average power is expressed as:

$$P_{avg} = P_{pk} \times \text{duty cycle}$$

Transposing the above formula gives us a common formula for peak power:

$$P_{pk} = \frac{P_{avg}}{\text{duty cycle}}$$

Peak power must be calculated more often than average power. This is because, as previously mentioned, most measurement instruments measure average power directly. An example is shown below:

Where:

$$P_{avg} = 20,000 \text{ watts}$$
$$pw = 20 \text{ microseconds } (20 \times 10^{-6})$$
$$prf = 1,000 \text{ or } 10^{3} \text{ pulses per second}$$

Before figuring P*p*, you must figure duty cycle as follows:

$$\begin{aligned} \text{duty cycle} &= pw \times prf \\ &= 20 \times 10^{-6} \times 10^{3}\ 20 \times 10^{-3} \\ &= .02 \end{aligned}$$

Now that you have duty cycle, P*p* may be calculated as follows:

$$P_{pk} = \frac{P_{avg}}{\text{duty cycle}}$$

$$= \frac{20,000}{.02}$$

$$= 1,000,000 \text{ or } 10^6 \text{ watts}$$

ANTENNA HEIGHT AND SPEED.—Another factor affecting radar range is antenna height. The high-frequency energy transmitted by a radar system travels in a straight line and does not normally bend to conform to the curvature of the earth. Because of this, the height of both the antenna and the target are factors in detection range. The distance to the horizon (in nautical miles) for a radar system varies with the height of the antenna according to the following formula:

$$\text{radar horizon distance} = 1.25\sqrt{\text{antenna height in feet}}$$
$$\text{(in nautical miles)}$$

For example, assume antenna height to be 64 feet in the following calculations:

$$\begin{aligned}\text{horizon distance} &= 1.25\sqrt{\text{antenna height}}\\ &= 1.25\sqrt{64 \text{ feet}}\\ &= 1.25 \times 8 \text{ feet}\\ &= 10 \text{ nautical miles}\end{aligned}$$

A target at a range greater than the radar horizon will not be detected unless it is high enough to be above the horizon. An example of the antenna- and target-height relationship is shown in figure 1-7.

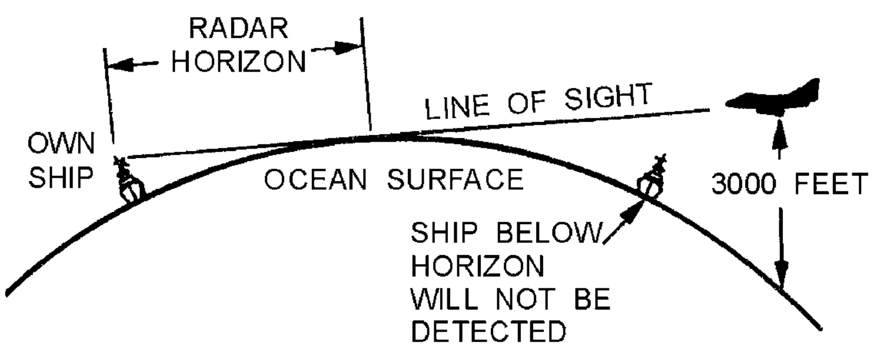

Figure 1-7.—Radar horizon.

The antenna-rotation rate also affects maximum detection range. The slower an antenna rotates, the greater the detection range of a radar system. When the antenna is rotated at 10 revolutions per minute (rpm), the beam of energy strikes each target for just one-half the time it would if the rotation were 5 rpm.

The number of strikes per antenna revolution is referred to as HITS PER SCAN. During each revolution enough pulses must be transmitted to return a usable echo.

NOTE: The more pulses transmitted to a given area (at slower antenna speeds), the greater the number of hits per scan.

As an example, if the antenna rotates at 20 rpm, it completes a revolution in 3 seconds. During this time, a transmitter with a prf of 200 pulses per second (pps) transmits 600 pulses. Since 360 degrees of azimuth must be covered, the following formula shows the number of pulses for each degree of azimuth:

$$\frac{600 \text{ pulses per revolution}}{360 \text{ degrees per revolution}} = 1.67 \text{ pulses per degree}$$

Such a low number of pulses for any given target area greatly increases the likelihood that some targets will be missed entirely; therefore, prf and antenna speed must be matched for maximum efficiency.

Q6. Atmospheric interference with the travel of electromagnetic energy increases with what rf energy characteristic?

Q7. How is prt related to prf?

Q8. What type of radar transmitter power is measured over a period of time?

Q9. What term is used to describe the product of pulse width and pulse-repetition frequency?

BEARING

The TRUE BEARING (referenced to true north) of a radar target is the angle between true north and a line pointed directly at the target. This angle is measured in the horizontal plane and in a clockwise direction from true north. The bearing angle to the radar target may also be measured in a clockwise direction from the centerline of your own ship or aircraft and is referred to as the RELATIVE BEARING. Both true and relative bearing angles are illustrated in figure 1-8.

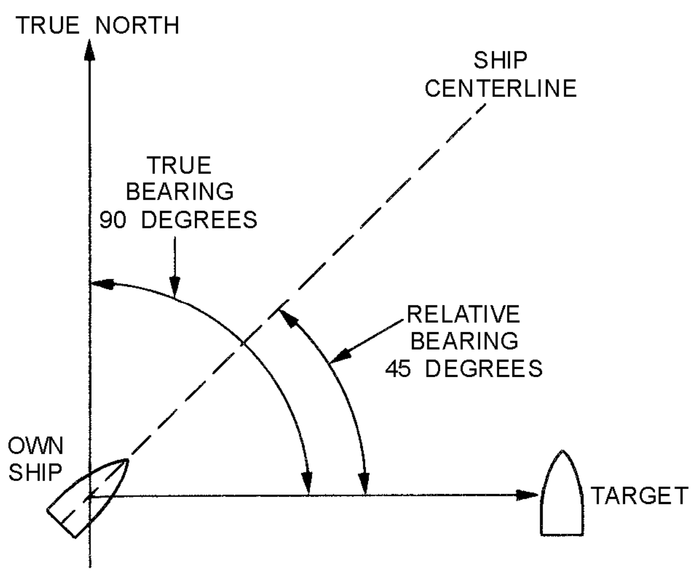

Figure 1-8.—True and relative bearings.

The antennas of most radar systems are designed to radiate energy in a one-directional lobe or beam that can be moved in bearing simply by moving the antenna. As you can see in figure 1-9, the shape of the beam is such that the echo signal strength varies in amplitude as the antenna beam moves across the target. At antenna position **A**, the echo is minimal; at position **B**, where the beam axis is pointing directly at the target, the echo strength is maximum. Thus, the bearing angle of the target can be obtained by moving the antenna to the position at which the echo is strongest. In actual practice, search radar antennas move continuously; the point of maximum echo return is determined by the detection circuitry as the beam passes the target or visually by the operator. Weapons-control and guidance radar systems are positioned to the point of maximum signal return and maintained at that position either manually or by automatic tracking circuits.

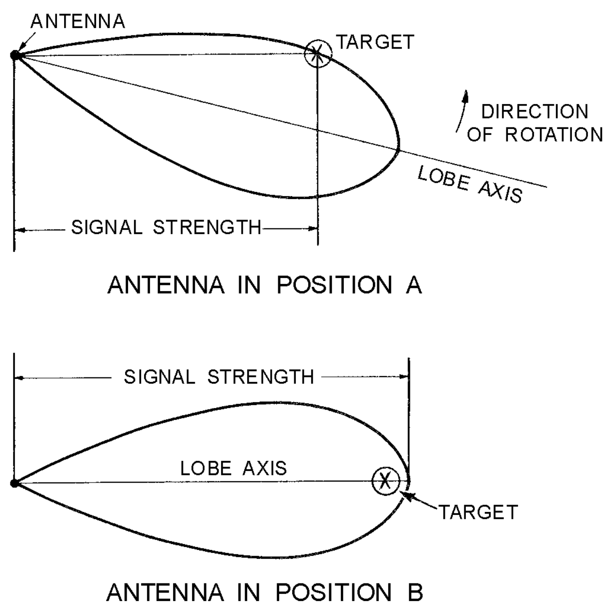

Figure 1-9.—Determination of bearing.

ALTITUDE

Many radar systems are designed to determine only the range and bearing of an object. Such radar systems are called TWO-DIMENSIONAL (2D) radars. In most cases these systems are further described as SEARCH RADAR SYSTEMS and function as early-warning devices that search a fixed volume of space. The range and bearing coordinates provide enough information to place the target in a general area with respect to the radar site and to determine distance, direction of travel, and relative speed. However, when action must be taken against an airborne target, altitude must be known as well. A search radar system that detects altitude as well as range and bearing is called a THREE-DIMENSIONAL (3D) radar.

Altitude- or height-finding search radars use a beam that is very narrow in the vertical plane. The beam is scanned in elevation, either mechanically or electronically, to pinpoint targets. Height-finding radar systems that also determine bearing must have a beam that is very narrow in both the vertical and horizontal planes. An electronic elevation-scanning pattern for a search radar set is illustrated in figure 1-10. Lines originating at the antenna indicate the number of beam positions required for complete elevation coverage. In practice the beams overlap slightly to prevent any gaps in the coverage. Each beam position corresponds to a slight change in either the frequency or phase of the radiated energy. A change in either phase or frequency of the energy causes it to leave the antenna at a different angle. Thus, the frequency or phase can be predetermined to create an orderly scanning pattern that covers the entire vertical plane. Electronic scanning permits automatic compensation for an unstable radar platform (site), such as a ship at sea. Error signals are produced by the roll and pitch of the ship and are used to correct the radar beam to ensure complete elevation coverage.

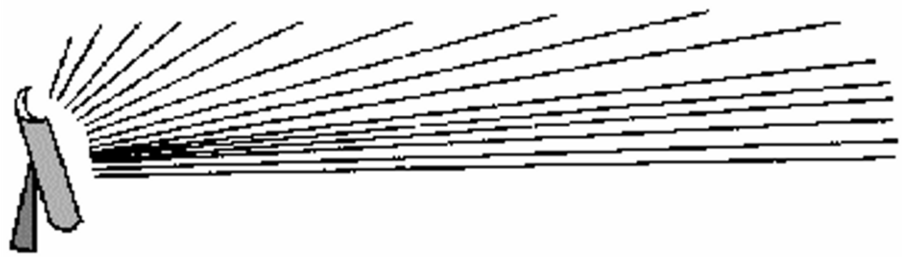

Figure 1-10.—Electronic elevation scan.

Mechanical elevation scanning is achieved by mechanically moving the antenna or radiation source. Weapons-control and tracking radar systems commonly use mechanical elevation scanning techniques. Most electronically scanned radar systems are used as air search radars. Some older air-search radar systems use a mechanical elevation scanning device; however, these are being replaced by electronically scanned radar systems.

Q10. What type of target bearing is referenced to your ship?

Q11. What type of radar detects range, bearing, and height?

Q12. What characteristic(s) of radiated energy is (are) altered to achieve electronic scanning?

TARGET RESOLUTION

The TARGET RESOLUTION of a radar is its ability to distinguish between targets that are very close together in either range or bearing. Weapons-control radar, which requires great precision, should be able to distinguish between targets that are only yards apart. Search radar is usually less precise and only distinguishes between targets that are hundreds of yards or even miles apart. Resolution is usually divided into two categories; RANGE RESOLUTION and BEARING RESOLUTION.

Range Resolution

Range resolution is the ability of a radar system to distinguish between two or more targets on the same bearing but at different ranges. The degree of range resolution depends on the width of the transmitted pulse, the types and sizes of targets, and the efficiency of the receiver and indicator. Pulse width is the primary factor in range resolution. A well-designed radar system, with all other factors at maximum efficiency, should be able to distinguish targets separated by one-half the pulse width time. Therefore, the theoretical range resolution of a radar system can be calculated from the following formula:

$$\text{range resolution (in yards)} = \frac{\text{pw (microseconds)}}{2} \times 328 \text{ yards per microsecond}$$

The above formula is often written as:

$$\text{range resolution} = \text{pw} \times 164 \text{ yards per microsecond}$$

For example, if a radar system has a pulse width of 5 microseconds, the range resolution is calculated as follows:

$$\begin{aligned}\text{range resolution} &= \text{pw} \times 164 \text{ yards per microsecond}\\ &= 5 \times 164 \text{ yards per microsecond}\\ &= 820 \text{ yards}\end{aligned}$$

In the above example, targets on the same bearing would have to be separated by more than 820 yards to show up as two targets on your indicator.

Bearing Resolution

Bearing, or azimuth, resolution is the ability of a radar system to separate objects at the same range but at different bearings. The degree of bearing resolution depends on radar beam width and the range of the targets. Range is a factor in bearing resolution because the radar beam spreads out as range increases. A RADAR BEAM is defined in width in terms of HALF-POWER POINTS. All the points off the centerline of the beam that are at one-half the power level at the center are plotted to define beam width. When the half-power points are connected to the antenna by a curve, such as that shown in figure 1-11, the resulting angular width of the curve is called the ANTENNA BEAM WIDTH. The physical size and shape of the antenna determines beam width. Beam width can vary from about 1 degree up to 60 degrees. In figure 1-11, only the target within the half-power points will reflect a useful echo. Two targets at the same range must be separated by at least one beam width to be distinguished as two objects.

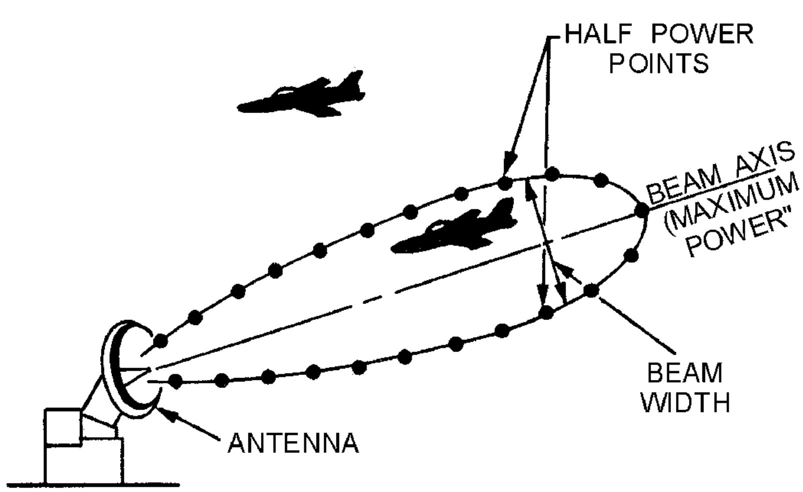

Figure 1-11.—Beam half-power points.

RADAR ACCURACY

Radar accuracy is a measure of the ability of a radar system to determine the correct range, bearing, and, in some cases, height of an object. The degree of accuracy is primarily determined by the resolution of the radar system. Some additional factors affecting accuracy are pulse shape and atmospheric conditions.

Pulse Shape

In the case of a pulse radar, the shape and width of the rf pulse influences minimum range, range accuracy, and maximum range. The ideal pulse shape is a square wave having vertical leading and trailing edges. However, equipments do not usually produce the ideal waveforms.

The factors influencing minimum range are discussed first. Since the receiver cannot receive target reflections while the transmitter is operating, you should be able to see that a narrow pulse is necessary for short ranges. A sloping trailing edge extends the width of the transmitter pulse, although it may add very little to the total power generated. Therefore, along with a narrow pulse, the trailing edge should be as near vertical as possible.

A sloping leading edge also affects minimum range as well as range accuracy since it provides no definite point from which to measure elapsed time on the indicator time base. Using a starting point at the lower edge of the pulse's leading edge would increase minimum range. Using a starting point high up on the slope would reduce the accuracy of range measurements at short ranges which are so vital for accurate solution of the fire-control problem.

Maximum range is influenced by pulse width and pulse repetition frequency (prf). Since a target can reflect only a very small part of the transmitted power, the greater the transmitted power, the greater the strength of the echo that could be received. Thus, a transmitted pulse should quickly rise to its maximum amplitude, remain at this amplitude for the duration of the desired pulse width, and decay instantaneously to zero. Figure 1-12 illustrates the effects of pulse shapes.

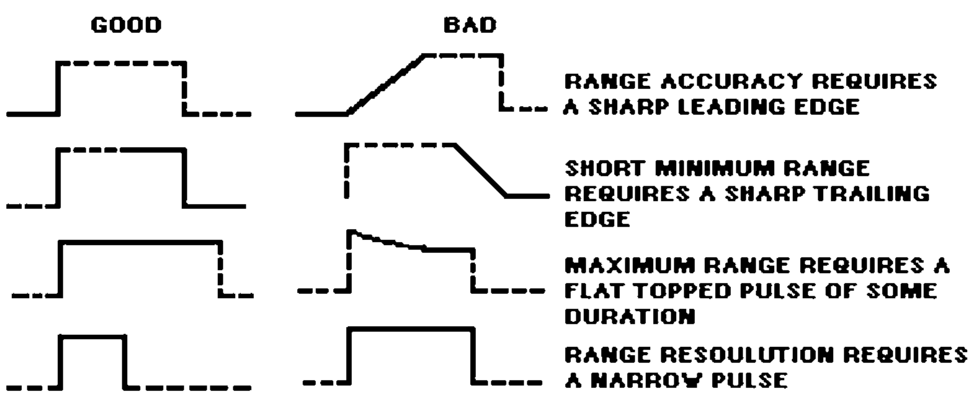

Figure 1-12.—Pulse shapes and effects.

Atmospheric Conditions

Electromagnetic wavefronts travel through empty space in straight lines at the speed of light, but the REFRACTIVE INDEX of the atmosphere affects both the travel path and the speed of the electromagnetic wavefront. The path followed by electromagnetic energy in the atmosphere, whether direct or reflected, usually is slightly curved; and the speed is affected by temperature, atmospheric pressure, and the amount of water vapor present in the atmosphere, which all affect the refractive index. As altitude increases, the combined effects of these influences, under normal atmospheric conditions, cause a small, uniform increase in signal speed. This increase in speed causes the travel path to curve slightly downward, as shown in figure 1-13. The downward curve extends the radar horizon beyond a line tangent to the earth, as illustrated in figure 1-14.

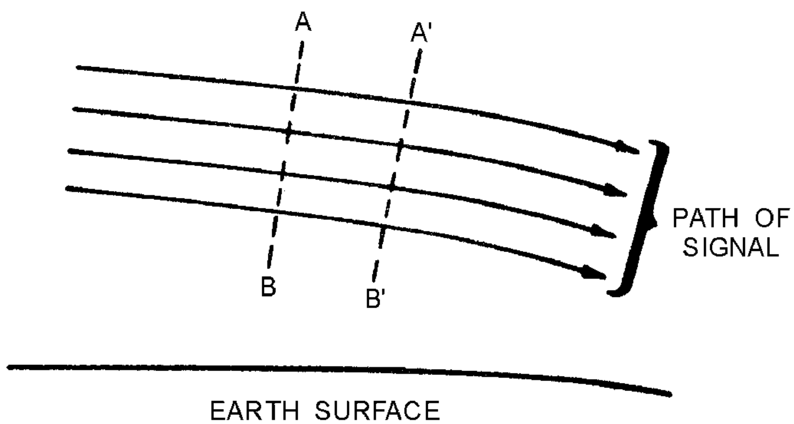

Figure 1-13.—Wavefront path.

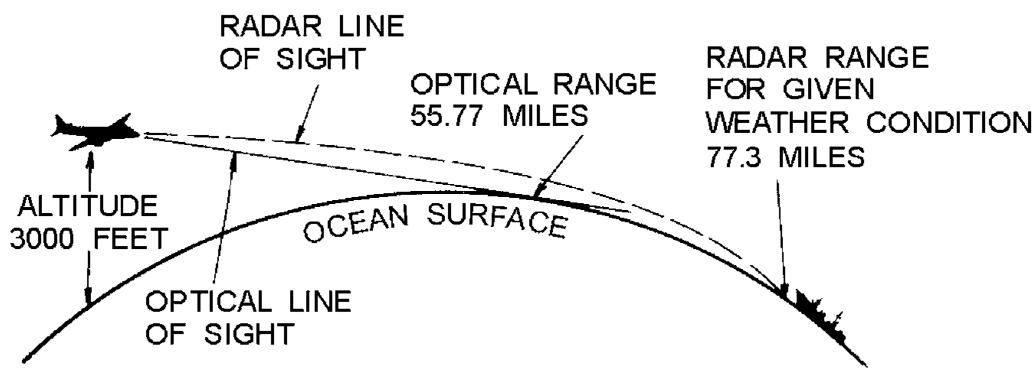

Figure 1-14.—Extension of the radar horizon.

The reason for the downward curve can be illustrated using line **AB** in figure 1-13. Line **AB** represents the surface of a wavefront with point A higher in altitude than point B. As wavefront AB moves to the point represented by A'B', the speed at A and A' is faster than the speed at B and B' since A and A' are at a greater altitude. Therefore, in a given time, the upper part of the wavefront moves farther than the lower part. The wavefront leans slightly forward as it moves. Since the direction of energy propagation is always perpendicular to the surface of a wavefront, the tilted wavefront causes the energy path to curve downward.

REFRACTION is the bending of electromagnetic waves caused by a change in the density of the medium through which the waves are passing. A visible example of electromagnetic refraction is the apparent displacement of underwater objects caused by the bending of light as it passes from the atmosphere into the water. An INDEX OF REFRACTION has been established which indicates the degree of refraction, or bending, caused by different substances. Because the density of the atmosphere changes with altitude, the index of refraction changes gradually with height.

The temperature and moisture content of the atmosphere normally decrease uniformly with an increase in altitude. However, under certain conditions the temperature may first increase with height and then begin to decrease. Such a situation is called a temperature inversion. An even more important deviation from normal may exist over the ocean. Since the atmosphere close to the surface over large bodies of water may contain more than a normal amount of moisture, the moisture content may decrease more rapidly at heights just above the sea. This effect is referred to as MOISTURE LAPSE.

Either temperature inversion or moisture lapse, alone or in combination, can cause a large change in the refraction index of the lowest few-hundred feet of the atmosphere. The result is a greater bending of the radar waves passing through the abnormal condition. The increased bending in such a situation is referred to as DUCTING and may greatly affect radar performance. The radar horizon may be extended or reduced, depending on the direction the radar waves are bent. The effect of ducting on radar waves is illustrated in figure 1-15.

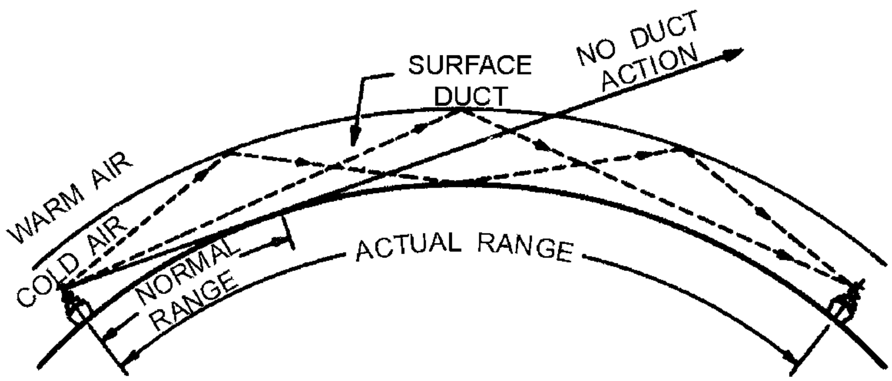

Figure 1-15.—Ducting effect on the radar wave.

Another effect of the atmosphere on radar performance is caused by particles suspended in the air. Water droplets and dust particles diffuse radar energy through absorption, reflection, and scattering so less energy strikes the target. Consequently, the return echo is smaller. The overall effect is a reduction in usable range that varies widely with weather conditions. The higher the frequency of a radar system, the more it is affected by weather conditions such as rain or clouds. In some parts of the world, dust suspended in the air can greatly decrease the normal range of high-frequency radar.

Q13. What term is used to describe the ability of a radar system to distinguish between targets that are close together?

Q14. The degree of bearing resolution for a given radar system depends on what two factors?

Q15. What happens to the speed of electromagnetic energy traveling through air as the altitude increases?

Q16. What term is used to describe a situation in which atmospheric temperature first increases with altitude and then begins to decrease?

RADAR PRINCIPLES OF OPERATION

Radar systems, like other complex electronics systems, are composed of several major subsystems and many individual circuits. This section will introduce you to the major subsystems common to most radar sets. A brief functional description of subsystem principles of operation will be provided. A much more detailed explanation of radar subsystems will be given in chapters 2 and 3. Since most radar systems in use today are some variation of the pulse radar system, the units discussed in this section will be those used in pulse radar. All other types of radar use some variation of these units, and these variations will be explained as necessary.

RADAR COMPONENTS

Pulse radar systems can be functionally divided into the six essential components shown in figure 1-16. These components are briefly described in the following paragraphs and will be explained in detail after that:

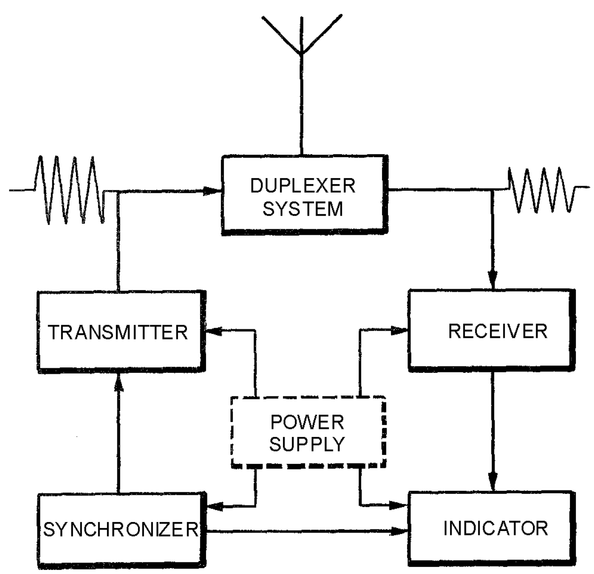

Figure 1-16.—Functional block diagram of a basic radar system.

- The SYNCHRONIZER (also referred to as the TIMER or KEYER) supplies the synchronizing signals that time the transmitted pulses, the indicator, and other associated circuits.
- The TRANSMITTER generates electromagnetic energy in the form of short, powerful pulses.
- The DUPLEXER allows the same antenna to be used for transmitting and receiving.
- The ANTENNA SYSTEM routes the electromagnetic energy from the transmitter, radiates it in a highly directional beam, receives any returning echoes, and routes those echoes to the receiver.
- The RECEIVER amplifies the weak, electromagnetic pulses returned from the reflecting object and reproduces them as video pulses that are sent to the indicator.

- The INDICATOR produces a visual indication of the echo pulses in a manner that, at a minimum, furnishes range and bearing information.

While the physical configurations of radar systems differ, any radar system can be represented by the functional block diagram in figure 1-16. An actual radar set may have several of these functional components within one physical unit, or a single one of these functions may require several physical units. However, the functional block diagram of a basic radar set may be used to analyze the operation of almost any radar set.

In the following paragraphs, a brief description of the operation of each of the major components is given.

Synchronizer (Timer)

The synchronizer ensures that all circuits connected with the radar system operate in a definite timed relationship. It also times the interval between transmitted pulses to ensure that the interval is of the proper length. Timing pulses are used to ensure synchronous circuit operation and are related to the prf. The prf can be set by any stable oscillator, such as a sine-wave oscillator, multivibrator, or a blocking oscillator. That output is then applied to pulse-shaping circuits to produce timing pulses. Associated components can be timed by the output of the synchronizer or by a timing signal from the transmitter as it is turned on.

Transmitter

The transmitter generates powerful pulses of electromagnetic energy at precise intervals. The required power is obtained by using a high-power microwave oscillator, such as a magnetron, or a microwave amplifier, such as a klystron, that is supplied by a low-power rf source. (The construction and operation of microwave components can be reviewed in NEETS, Module 11, *Microwave Principles*.) The high-power generator, whether an oscillator or amplifier, requires operating power in the form of a properly-timed, high-amplitude, rectangular pulse. This pulse is supplied by a transmitter unit called the MODULATOR. When a high-power oscillator is used, the modulator high-voltage pulse switches the oscillator on and off to supply high-power electromagnetic energy. When a microwave power amplifier is used, the modulator pulse activates the amplifier just before the arrival of an electromagnetic pulse from a preceding stage or a frequency-generation source. Normally, because of the extremely high voltage involved, the modulator pulse is supplied to the cathode of the power tube and the plate is at ground potential to shield personnel from shock hazards. The modulator pulse may be more than 100,000 volts in high-power radar transmitters. In any case, radar transmitters produce voltages, currents, and radiation hazards that are extremely dangerous to personnel. Safety precautions must always be strictly observed when working in or around a radar transmitter.

Duplexer

A duplexer is essentially an electronic switch that permits a radar system to use a single antenna to both transmit and receive. The duplexer must connect the antenna to the transmitter and disconnect the antenna from the receiver for the duration of the transmitted pulse. The receiver must be completely isolated from the transmitted pulse to avoid damage to the extremely sensitive receiver input circuitry. After the transmitter pulse has ended, the duplexer must rapidly disconnect the transmitter and connect the receiver to the antenna. As previously mentioned, the switching time is called receiver recovery time, and must be very fast if close-in targets are to be detected. Additionally, the duplexer should absorb very little power during either phase of operation. Low-loss characteristics are particularly important during the receive period of duplexer operation. This is because the received signals are of extremely low amplitude.

Antenna System

The antenna system routes the pulse from the transmitter, radiates it in a directional beam, picks up the returning echo, and passes it to the receiver with a minimum of loss. The antenna system includes the antenna, transmission lines and waveguide from the transmitter to the antenna, and the transmission line and waveguide from the antenna to the receiver. In some publications the duplexer is included as a component of the antenna system.

Receiver

The receiver accepts the weak echo signals from the antenna system, amplifies them, detects the pulse envelope, amplifies the pulses, and then routes them to the indicator. One of the primary functions of the radar receiver is to convert the frequency of the received echo signal to a lower frequency that is easier to amplify. This is because radar frequencies are very high and difficult to amplify. This lower frequency is called the INTERMEDIATE FREQUENCY (IF). The type of receiver that uses this frequency conversion technique is the SUPER HETERODYNE RECEIVER. Superheterodyne receivers used in radar systems must have good stability and extreme sensitivity. Stability is ensured by careful design and the overall sensitivity is greatly increased by the use of many IF stages.

Indicator

The indicator uses the received signals routed from the radar receiver to produce a visual indication of target information. The cathode-ray oscilloscope is an ideal instrument for the presentation of radar data. This is because it not only shows a variation of a single quantity, such as voltage, but also gives an indication of the relative values of two or more quantities. The sweep frequency of the radar indicator is determined by the pulse-repetition frequency of the radar system. Sweep duration is determined by the setting of the range-selector switch. Since the indicator is so similar to an oscilloscope, the term RADAR SCOPE is commonly used when referring to radar indicators.

Q17. What radar subsystem supplies timing signals to coordinate the operation of the complete system?

Q18. When a transmitter uses a high-power oscillator to produce the output pulse, what switches the oscillator on and off?

Q19. What radar component permits the use of a single antenna for both transmitting and receiving?

SCANNING

Radar systems are often identified by the type of SCANNING the system uses. Scanning is the systematic movement of a radar beam in a definite pattern while searching for or tracking a target. The type and method of scanning used depends on the purpose and type of radar and on the antenna size and design. In some cases, the type of scan will change with the particular system mode of operation. For example, in a particular radar system, the search mode scan may be quite different from that of the track mode scan.

Stationary-Lobe Scanning

A SINGLE STATIONARY-LOBE SCANNING SYSTEM is the simplest type of scanning. This method produces a single beam that is stationary in relation to the antenna. The antenna is then mechanically rotated continuously to obtain complete 360-degree azimuth coverage. A stationary lobe, however, cannot satisfactorily track a moving object because it does not provide enough information about the object's movement to operate automatic tracking circuits, such as those in fire-control tracking radar. A two-dimensional search radar, however, does use a single-lobe that is scanned in a 360-degree pattern because automatic tracking circuits are not normally used in 2D radars.

Single-lobe scanning is unsuitable for use as a tracking radar for several reasons. For example, let's assume that a target is somewhere on the lobe axis and the receiver is detecting signals reflected from the target. If these reflected signals begin to decrease in strength, the target likely has flown off the lobe axis. In this case, the beam must be moved to continue tracking. The beam might be moved by an operator tracking the target with an optical sight, but such tracking is slow, inaccurate, and limited by conditions of visibility. An automatic tracking system would require that the beam SCAN, or search, the target area in such a case.

Again, assume that a missile is riding (following) the axis of a single beam. The strength of the signals it receives (by means of a radar receiver in the missile) will gradually decrease as its distance from the transmitter increases. If the signal strength decreases suddenly, the missile will know, from built-in detection circuitry, that it is no longer on the axis of the lobe. But it will *not* know which way to turn to get back on the axis. A simple beam does not contain enough information for missile guidance.

Methods of Beam Scanning

The two basic methods of beam scanning are MECHANICAL and ELECTRONIC. In mechanical scanning, the beam can be moved in various ways: (1) The entire antenna can be moved in the desired pattern; (2) the energy feed source can be moved relative to a fixed reflector; or (3) the reflector can be moved relative to a fixed source. In electronic scanning, the beam is effectively moved by such means as (1) switching between a set of feeder sources, (2) varying the phasing between elements in a multielement array, or (3) comparing the amplitude and phase differences between signals received by a multielement array. A combination of mechanical and electronic scanning is also used in some antenna systems.

MECHANICAL SCANNING.—The most common type of mechanical scanning is the rotation of the antenna through 360 degrees to obtain azimuth coverage. Most search radar sets use this method. A common form of scanning for target tracking or missile beam-rider systems is CONICAL (cone-like) SCANNING. This is generally accomplished mechanically by NUTATING the rf feed point.

Nutation is difficult to describe in words but easy to demonstrate. Hold a pencil in two hands. While holding the eraser end as still as possible, swing the point in a circular motion. This motion of the pencil is referred to as nutation; the pencil point corresponds to the open, or transmitting, end of the waveguide antenna. The important fact to remember is that polarization of the beam is not changed during the scanning cycle. This means that the axis of the moving feeder does not change either horizontal or vertical orientation while the feeder is moving. You might compare the feeder movement to that of a ferris wheel; that is, the vertical orientation of each seat remains the same regardless of the position of the wheel.

Recall that a waveguide is a metal pipe, usually rectangular in cross section, used to conduct the rf energy from the transmitter to the antenna. The open end of the waveguide faces the concave side of the reflector and the rf energy it emits is bounced from the reflector surface.

A conical scan can be generated by nutation of the waveguide. In this process the axis of the waveguide itself is moved through a small conical pattern. In an actual installation of a nutating waveguide, the three-dimensional movement is fast and of small amplitude. To an observer, the waveguide appears merely to be vibrating slightly.

By movement of either the waveguide or the antenna, you can generate a conical scan pattern, as shown in figure 1-17. The axis of the radar lobe is made to sweep out a cone in space; the apex of this cone is, of course, at the radar transmitter antenna or reflector. At any given distance from the antenna, the path of the lobe axis is a circle. Within the useful range of the beam, the inner edge of the lobe always overlaps the axis of scan.

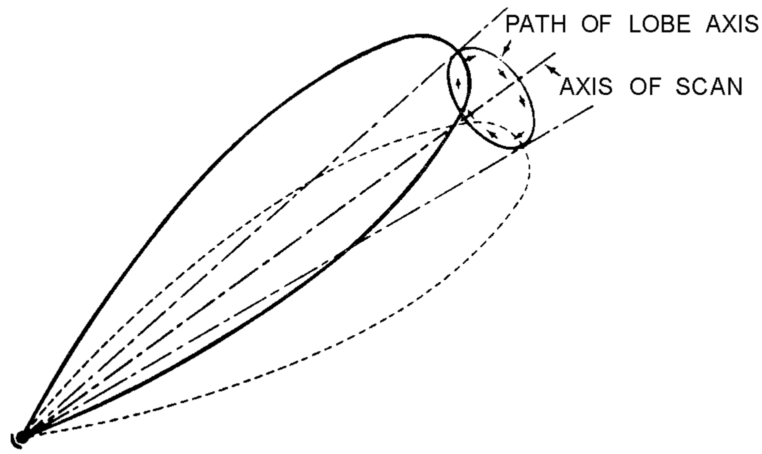

Figure 1-17.—Conical scanning.

Now assume that we use a conically scanned beam for target tracking. If the target is on the scan axis, the strength of the reflected signals remains constant (or changes gradually as the range changes). But if the target is slightly off the axis, the amplitude of the reflected signals will change at the scan rate. For example, if the target is to the left of the scan axis, as shown in figure 1-18, the reflected signals will be of maximum strength as the lobe sweeps through the left part of its cone; the signals will quickly decrease to a minimum as the lobe sweeps through the right part. Information on the instantaneous position of the beam, relative to the scan axis, and on the strength of the reflected signals is fed to a computer. Such a computer in the radar system is referred to as the angle-tracking or angle-servo circuit (also angle-error detector). If the target moves off the scan axis, the computer instantly determines the direction and amount of antenna movement required to continue tracking. The computer output is used to control servomechanisms that move the antenna. In this way, the target is tracked accurately and automatically.

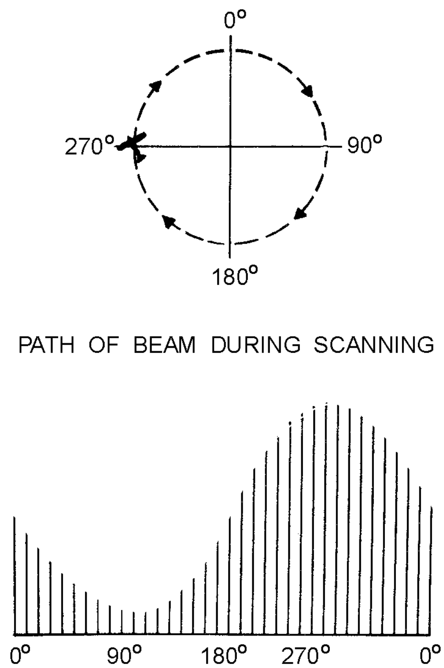

Figure 1-18.—Reflected signal strength.

Q20. What is the simplest type of scanning?

Q21. How does the operator of a single-lobe scanning system determine when the target moves off the lobe axis?

Q22. What are the two basic methods of scanning?

Q23. Rotation of an rf-feed source to produce a conical scan pattern is identified by what term?

ELECTRONIC SCANNING.—Electronic scanning can accomplish lobe motion more rapidly than, and without the inherent maintenance disadvantages of, the mechanical systems. Because electronic scanning cannot generally cover as large an area of space, it is sometimes combined with mechanical scanning in particular applications.

With MONOPULSE (SIMULTANEOUS) LOBING, all range, bearing, and elevation-angle information of a target is obtained from a single pulse. Monopulse scanning is used in fire-control tracking radars.

For target tracking, the radar discussed here produces a narrow circular beam of pulsed-rf energy at a high pulse-repetition rate. Each pulse is divided into four signals which are equal both in amplitude and phase. These four signals are radiated at the same time from each of four feedhorns that are grouped in a cluster. The resulting radiated energy is focused into a beam by a microwave lens. Energy reflected from targets is refocused by the lens back into the feedhorns. The total amount of the energy received by each horn varies, depending on the position of the target relative to the beam axis. This is illustrated in figure 1-19 for four targets at different positions with respect to the beam axis. Note that a phase inversion takes place at the microwave lens similar to the image inversion that takes place in an optical system.

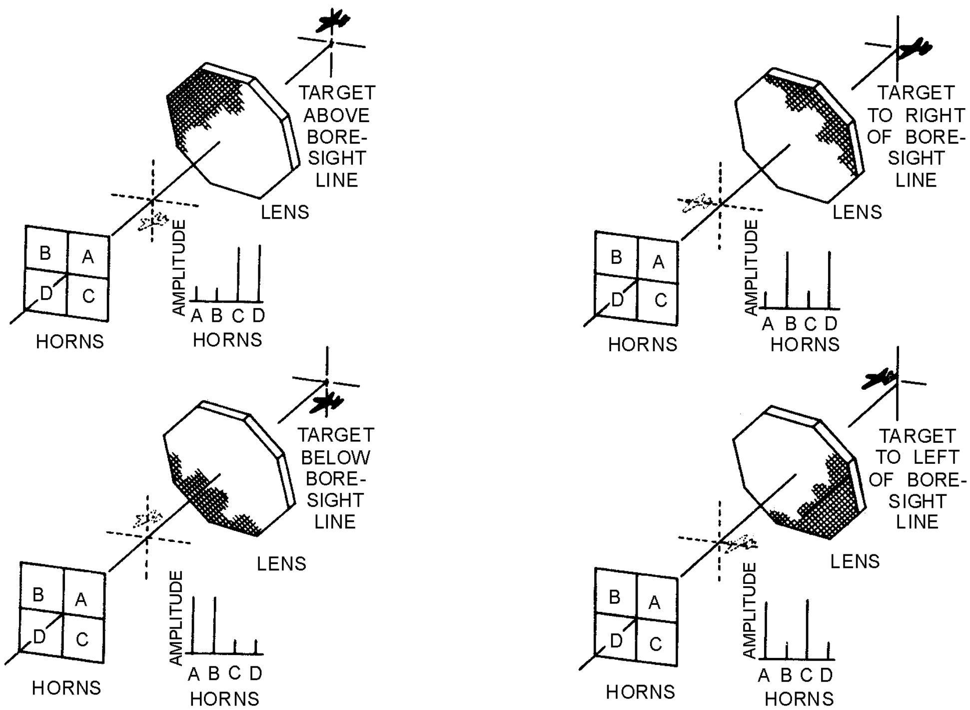

Figure 1-19.—Monopulse scanning.

The amplitude of returned signals received by each horn is continuously compared with those received in the other horns. Error signals are generated which indicate the relative position of the target with respect to the axis of the beam. Angle servo circuits receive these error signals and correct the position of the radar beam to keep the beam axis on target.

The TRAVERSE (BEARING) SIGNAL is made up of signals from horn **A** added to **C** and from horn **B** added to **D**. By waveguide design, the sum of **B** and **D** is made 180 degrees out of phase with the sum of **A** and **C**. These two are combined and the traverse signal is the difference of (**A** + **C**) − (**B** + **D**). Since the horns are positioned as shown in figure 1-19, the relative amplitudes of the horn signals give an indication of the magnitude of the traverse error. The elevation signal consists of the signals from horns **C** and **D** added 180 degrees out of phase with horns **A** and **B** [(**A** + **B**) − (**C** + **D**)]. The sum, or range, signal is composed of signals from all four feedhorns added together in phase. It provides a reference from which target direction from the center of the beam axis is measured. The range signal is also used as a phase reference for the traverse and elevation-error signals.

The traverse and elevation error signals are compared in the radar receiver with the range or reference signal. The output of the receiver may be either positive or negative pulses; the amplitudes of the pulses are proportional to the angle between the beam axis and a line drawn to the target. The polarities of the output pulses indicate whether the target is above or below, to the right or to the left of the beam axis. Of course, if the target is directly on the line of sight, the output of the receiver is zero and no angle-tracking error is produced.

An important advantage of a monopulse-tracking radar over radar using conical scan is that the instantaneous angular measurements are not subject to errors caused by target SCINTILLATION. Scintillation can occur as the target maneuvers or moves and the radar pulses bounce off different areas of the target. This causes random reflectivity and may lead to tracking errors. Monopulse tracking radar is not subject to this type of error because each pulse provides an angular measurement without regard to the rest of the pulse train; no such cross-section fluctuations can affect the measurement. An additional advantage of monopulse tracking is that no mechanical action is required.

ELECTRONIC SCANNING used in search radar systems was explained in general terms earlier in this chapter during the discussion of elevation coverage. This type of electronic scanning is often called FREQUENCY SCANNING. An in-depth explanation of frequency scanning theory can be found in the fire control technician rate training manuals.

RADAR TRANSMISSION METHODS

Radar systems are normally divided into operational categories based on energy transmission methods. Up to this point, we have mentioned only the pulse method of transmission to illustrate basic radar concepts. Although the pulse method is the most common method of transmitting radar energy, two other methods are sometimes used in special applications. These are the continuous-wave (cw) method and the frequency modulation (fm) method. All three basic transmission methods are often further subdivided to designate specific variations or combinations.

CONTINUOUS-WAVE METHOD

When radio-frequency energy transmitted from a fixed point continuously strikes an object that is either moving toward or away from the source of the energy, the *frequency* of the reflected energy is changed. This shift in frequency is known as the DOPPLER EFFECT. The difference in frequency between the transmitted and reflected energy indicates both the presence and the speed of a moving target.

Doppler Effect

A common example of the Doppler effect in action is the changing pitch of the whistle of an approaching train. The whistle appears to change pitch from a high tone, as the train approaches, to a lower tone as it moves away from the observer. As the train approaches, an apparent increase in frequency (an increase in pitch) is heard; as the train moves away, an apparent decrease in frequency (a decrease in pitch) is heard. This pitch variation is known as the Doppler effect.

Let's examine the reason for this apparent change in pitch. Assume that the transmitter emits an audio signal at a frequency of 60 hertz and that the transmitter is traveling at a velocity of 360 feet per second (fps). At the end of 1 second, the transmitter will have moved from point P to point P1 as shown in view A of figure 1-20. The total distance from point P to the observer is 1,080 feet. The velocity of sound is 1,080 feet per second; thus, a sound emitted at point P will reach the observer in 1 second. To find the wavelength of this transmitted signal, you divide the velocity of the signal (1,080 fps) by the frequency (60 hertz). The result is 18 feet, as shown below:

$$\begin{aligned} \text{wavelength} &= \frac{\text{velocity}}{\text{frequency}} \\ &= \frac{1,080 \text{ fps}}{60 \text{ Hz}} \\ &= 18 \text{ feet} \end{aligned}$$

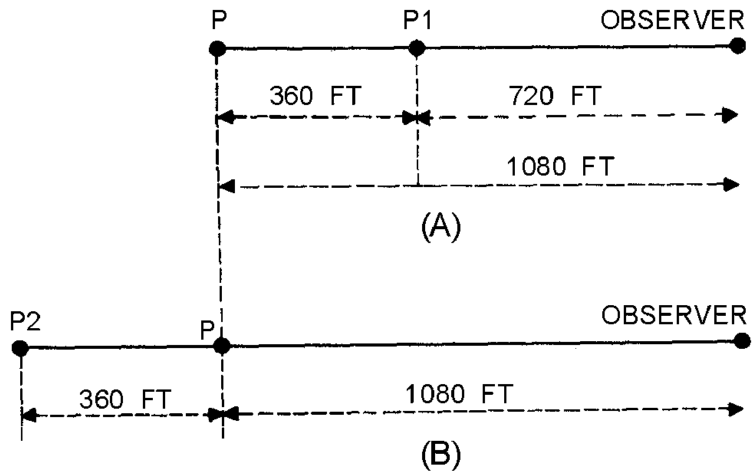

Figure 1-20.—Transmitter moving relative to an observer.

In 1 second the transmitter moves 360 feet and transmits 60 hertz. At the end of 1 second, the first cycle of the transmitted signal reaches the observer, just as the sixtieth cycle is leaving the transmitter at point P1. Under these conditions the 60 hertz emitted is located between the observer and point P1. Notice that this distance is only 720 feet (1,080 minus 360). The 60 hertz is spread over the distance from point P1 to the observer and has a wavelength of just 12 feet (720 divided by 60). To find the new frequency, use the following formula:

$$\begin{aligned} \text{frequency} &= \frac{\text{velocity}}{(\text{wavelength})} \\ &= \frac{1,080}{12} \\ &= 90 \text{ hertz} \end{aligned}$$

The original frequency, 60 hertz, has changed to an apparent frequency of 90 hertz. This new frequency only applies to the observer. Notice that the Doppler frequency variation is directly proportional to the velocity of the approaching transmitter. The faster the transmitter moves toward the observer, the greater the number of waves that will be crowded into the space between the transmitter and the observer.

Suppose the transmitter were stationary and the observer moving. When approaching the transmitter, the observer would encounter waves per unit of time. As a result, the observer would hear a higher pitch than the transmitter would actually emit.

If the transmitter were traveling away from the observer, as shown in view B of figure 1-20, the first cycle would leave the transmitter at point P and the sixtieth at point P2. The first cycle would reach the observer when the transmitter reached P2. You would then have 60 cycles stretched out over 1,080 plus 360 feet, a total of 1,440 feet. The wavelength of these 60 hertz is 1,440/60, or 24 feet. The apparent frequency is 1,080 divided by 24, or 45 hertz.

Uses of CW Doppler System

The continuous-wave, or Doppler, system is used in several ways. In one radar application, the radar set differentiates between the transmitted and reflected wave to determine the speed of the moving object.

The Doppler method is the best means of detecting fast-moving objects that do not require range resolution. As a moving object approaches the transmitter, it encounters and reflects more waves per unit of time. The amount of frequency shift produced is very small in relation to the carrier frequency. This is because the velocity of propagation of the signal is very high compared to the speed of the target. However, because the carrier frequencies used in radar are high, larger frequency shifts (in the audio-frequency range) are produced. The *amount* of shift is proportional to the *speed* of the reflecting object. One-quarter cycle shift at 10,000 megahertz will provide speed measurements accurate to a fraction of a percent.

If an object is moving, its velocity, relative to the radar, can be detected by comparing the transmitter frequency with the echo frequency (which differs because of the Doppler shift). The DIFFERENCE or BEAT FREQUENCY, sometimes called the DOPPLER FREQUENCY (fd), is related to object velocity.

The separation of the background and the radar contact is based on the Doppler frequency that is caused by the reflection of the signal from a moving object. Disadvantages of the Doppler system are that it does not determine the range of the object, nor is it able to differentiate between objects when they lie in the same direction and are traveling at the same speed. Moreover, it does not "see" stationary or slow-moving objects, which a pulse radar system can detect.

To track an object with cw Doppler, you must determine the radar range. Since the Doppler frequency is not directly related to range, another method is needed to determine object range. By using two separate transmitters that operate at two different frequencies (f_1 and f_2), you can determine range by measuring the relative phase difference between the two Doppler frequencies. In such a system, a mixer is used to combine the two transmitted frequencies and to separate the two received frequencies. This permits the use of one transmitting and receiving antenna.

Instead of using two transmitter frequencies, you can find the range by sweeping the transmitter frequency uniformly in time to cover the frequency range from f_1 to f_2. The beat, or difference, frequency between the transmitted and received signals is then a function of range. In this type of radar, the velocity as well as range is measured.

Q24. The Doppler effect causes a change in what aspect of rf energy that strikes a moving object?

Q25. The Doppler variation is directly proportional to what radar contact characteristic?

Q26. The Doppler method of object detection is best for what type objects?

Q27. The beat frequency in a swept-frequency transmitter provides what contact information?

FREQUENCY-MODULATION METHOD

In the frequency-modulation method, the transmitter radiates radio-frequency waves. The frequency of these rf waves is continually increasing and decreasing from a fixed reference frequency. At any instant, the frequency of the returned signal differs from the frequency of the radiated signal. The amount of the difference frequency is determined by the time it took the signal to travel the distance from the transmitter to the object.

An example of a frequency-modulated signal, plotted against time, is shown in figure 1-21. As shown, the 420-megahertz frequency increases linearly to 460 megahertz and then quickly drops to 420 megahertz again. When the frequency drops to 420 megahertz the frequency cycle starts over again.

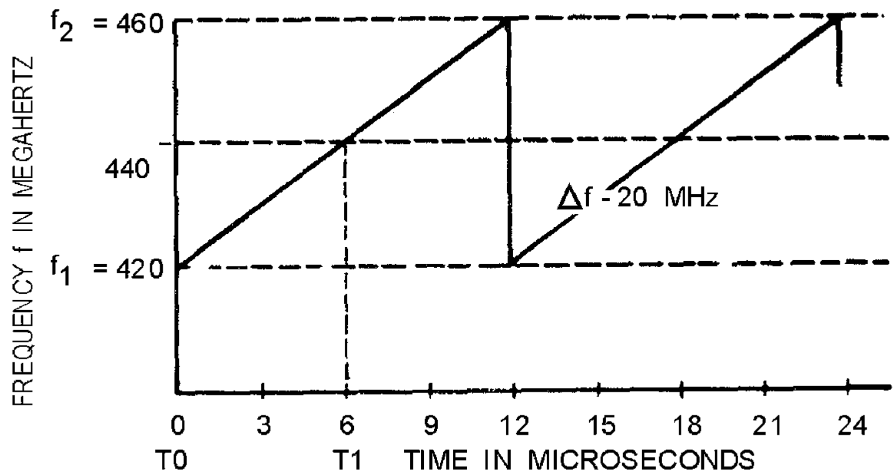

Figure 1-21.—Frequency-modulation chart.

The frequency regularly changes 40 megahertz with respect to time; therefore, its value at any time during its cycle can be used as the basis for computing the time elapsed after the start of the frequency cycle. For example, at T0 the transmitter sends a 420-megahertz signal toward an object. It strikes the object and returns to the receiver at T1, when the transmitter is sending out a new frequency of 440 megahertz. At T1, the 420-megahertz returned signal and the 440-megahertz transmitter signal are fed to the receiver simultaneously. When the two signals are mixed in the receiver, a beat frequency results. The beat frequency varies directly with the distance to the object, increasing as the distance increases. Using this information, you can calibrate a device that measures frequency to indicate range.

This system works well when the detected object is stationary. It is used in aircraft altimeters which give a continuous reading of the height above the earth of the aircraft. The system is not satisfactory for locating moving objects. This is because moving targets produce a frequency shift in the returned signal because of the Doppler effect; this affects the accuracy of the range measurement.

PULSE-MODULATION METHOD

The pulse-modulation method of energy transmission was analyzed to some extent earlier in this chapter. As the previous discussions indicated, radio-frequency energy can also be transmitted in very short bursts, called pulses. These pulses are of extremely short time duration, usually on the order of 0.1 microsecond to approximately 50 microseconds. In this method, the transmitter is turned on for a very short time and the pulse of radio-frequency energy is transmitted, as shown in view A of figure 1-22. The transmitter is then turned off, and the pulse travels outward from the transmitter at the velocity of light (view B). When the pulse strikes an object (view C), it is reflected and begins to travel back toward the radar system, still moving at the same velocity (view D). The pulse is then received by the radar system (view E). The time interval between transmission and reception is computed and converted into a visual indication of range in miles or yards. The radar cycle then starts over again by transmitting another pulse (view F). This method does not depend on the relative frequency of the returned signal or on the motion of the target; therefore, it has an important advantage over cw and fm methods.

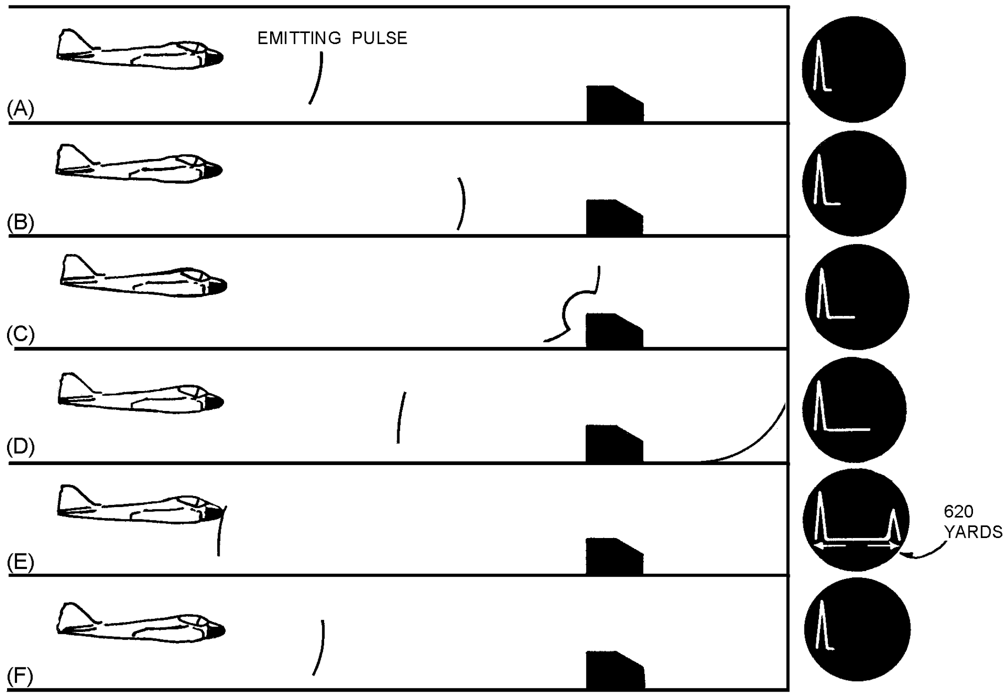

Figure 1-22.—Pulse detection.

PULSE-DOPPLER METHOD

Pulse radar systems may be modified to use the Doppler effect to detect a moving object.

A requirement for any Doppler radar is COHERENCE; that is, some definite phase relationship must exist between the transmitted frequency and the reference frequency, which is used to detect the Doppler shift of the receiver signal. Moving objects are detected by the phase difference between the target signal and background noise components. Phase detection of this type relies on coherence between the transmitter frequency and the receiver reference frequency.

In coherent detection, a stable cw reference oscillator signal, which is locked in phase with the transmitter during each transmitted pulse, is mixed with the echo signal to produce a beat or difference signal. Since the reference oscillator and the transmitter are locked in phase, the echoes are effectively compared with the transmitter in frequency and phase.

The phase relationships of the echoes from fixed objects to the transmitter is constant and the amplitude of the beat signal remains constant. A beat signal of varying amplitude indicates a moving object. This is because the phase difference between the reference oscillator signal and the echo signal changes as the range to the reflecting object changes. The constant amplitude beat signal is filtered out in the receiver. The beat signal of varying amplitude is sent to the radar indicator scope for display.

Q28. What factor determines the difference between the transmitted frequency and the received frequency in an fm transmitter?

Q29. What type of objects are most easily detected by an fm system?

Q30. What transmission method does NOT depend on relative frequency or target motion?

Q31. What transmission method uses a stable cw reference oscillator, which is locked in phase with the transmitter frequency?

RADAR CLASSIFICATION AND USE

Radar systems, like cars, come in a variety of sizes and have different performance specifications. Some radar systems are used for air-traffic control at airports and others are used for long-range surveillance and early-warning systems. A radar system is the heart of a missile guidance system. Small portable radar systems that can be maintained and operated by one person are available as well as systems that occupy several large rooms.

MILITARY CLASSIFICATION OF RADAR SYSTEMS

The large number of radar systems used by the military has forced the development of a joint-services classification system for accurate identification. The Federal Aviation Agency (FAA) also makes extensive use of radar systems for commercial aircraft in-flight and landing control, but does not use the military classification system.

Radar systems are usually classified according to specific function and installation vehicle. Some common examples are listed below:

FUNCTION	INSTALLATION VEHICLE
Search	Ground or land based
Track	Airborne
Height-finder	Shipboard

The joint-service standardized classification system further divides these broad categories for more precise identification. Table 1-1 is a listing of equipment identification indicators. Use of the table to identify a particular radar system is illustrated in figure 1-23. Note that for simplicity, only a portion of the table has been used in the illustration.

Table 1-1.—Table of Equipment Indicators

TABLE OF EQUIPMENT INDICATORS			Miscellaneous Identification
Installation (1st letter)	Type of Equipment (2d letter)	Purpose (3rd letter)	
A—Piloted aircraft	A—invisible light, heat radiation	B—Bombing	X, Y, Z—Changes in voltage, phase, or frequency
B—Underwater mobile, submarine	C—Carrier	C—Communications (receiving and transmitting	T—Training
D—Pilotless carrier	D—Radiac	D—Direction finder reconnaissance and/or surveillance	(V)—Variable grouping
F—Fixed ground	G—Telegraph or Teletype	E—Ejection and/or release	
G—General ground use	I—Interphone and public address	G—Fire control, or searchlight directing	
K—Amphibious	J—Electromechanical or Inertial wire covered	H—Recording and/or reproducing (graphic meteorological and sound)	
M—Ground, mobile	K—Telemetering	K—Computing	
P—Portable	L—Countermeasures	M—Maintenance and/or test assemblies (including tools)	
S—Water	M—Meteorological	N—Navigational aids (including altimeters, beacons, compasses, racons, depth sounding, approach and landing)	
T—Ground, transportable	N—Sound in air	Q—Special, or combination of purposes	
U—General utility	P—Radar	R—Receiving, passive detecting	
V—Ground, vehicular	Q—Sonar and underwater sound	S—Detecting and/or range and bearing, search	
W—Water surface and under water combination	R—Radio	T—Transmitting	
Z—Piloted and pilotless airborne vehicle combination	S—Special types, magnetic, etc., or combinations of types	W—Automatic flight or remote control	
	T—Telephone (wire)	X—Identification and recognition	
	V—Visual and visible light	Y—Surveillance (search detect, and multiple target tracking) and control (both fire control and air control)	
	W—Armament (peculiar to armament, not otherwise covered)		
	X—Facsimile or television	X—Facsimile or television	
	Y—Data processing		

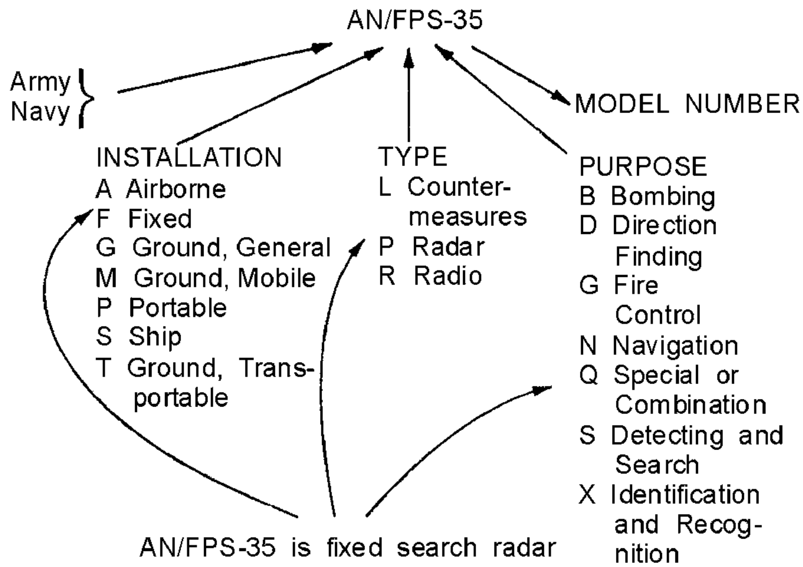

Figure 1-23.—Joint service classification system.

RADAR FUNCTIONS

No single radar system has yet been designed that can perform all of the many radar functions required by the military. Some of the newer systems combine several functions that formerly required individual radar systems, but no single system can fulfill all the requirements of modern warfare. As a result, modern warships, aircraft, and shore stations usually have several radar systems, each performing a different function.

One radar system, called SEARCH RADAR, is designed to continuously scan a volume of space to provide initial detection of all targets. Search radar is almost always used to detect and determine the position of new targets for later use by TRACK RADAR. Track radar provides continuous range, bearing, and elevation data on one or more targets. Most of the radar systems used by the military are in one of these two categories, though the individual radar systems vary in design and capability.

Some radar systems are designed for specific functions that do not precisely fit into either of the above categories. The radar speed gun is an example of radar designed specifically to measure the speed of a target. The military uses much more complex radar systems that are adapted to detect only fast-moving targets such as aircraft. Since aircraft usually move much faster than weather or surface targets, velocity-sensitive radar can eliminate unwanted clutter from the radar indicator. Radar systems that detect and process only moving targets are called MOVING-TARGET INDICATORS (mti) and are usually combined with conventional search radar.

Another form of radar widely used in military and civilian aircraft is the RADAR ALTIMETER. Just as some surface-based radars can determine the height of a target, airborne radar can determine the distance from an aircraft to the ground. Many aircraft use radar to determine height above the ground. Radar altimeters usually use frequency-modulated signals of the type discussed earlier in the chapter.

RADAR TYPES

The preceding paragraphs indicated that radar systems are divided into types based on the designed use. This section presents the general characteristics of several commonly used radar systems. Typical characteristics are discussed rather than the specific characteristics of any particular radar system.

SEARCH RADAR

Search radar, as previously mentioned, continuously scans a volume of space and provides initial detection of all targets within that space. Search radar systems are further divided into specific types, according to the type of object they are designed to detect. For example, surface-search, air-search, and height-finding radars are all types of search radar.

Surface-Search Radar

A surface-search radar system has two primary functions: (1) the detection and determination of accurate ranges and bearings of surface objects and low-flying aircraft and (2) the maintenance of a 360-degree search pattern for all objects within line-of-sight distance from the radar antenna.

The maximum range ability of surface-search radar is primarily limited by the radar horizon; therefore, higher frequencies are used to permit maximum reflection from small, reflecting areas, such as ship masthead structures and the periscopes of submarines. Narrow pulse widths are used to permit a high degree of range resolution at short ranges and to achieve greater range accuracy. High pulse-repetition rates are used to permit a maximum definition of detected objects. Medium peak power can be used to permit the detection of small objects at line-of-sight distances. Wide vertical-beam widths permit compensation for the pitch and roll of own ship and detection of low flying aircraft. Narrow horizontal-beam widths permit accurate bearing determination and good bearing resolution. For example, a common shipboard surface-search radar has the following design specifications:

- Transmitter frequency 5,450-5,825 MHz
- Pulse width .25 or 1.3 microseconds
- Pulse-repetition rate between 625 and 650 pulses per second
- Peak power between 190 and 285 kW
- Vertical beam width between 12 and 16 degrees
- Horizontal beam width 1.5 degrees

Surface-search radar is used to detect the presence of surface craft and low flying aircraft and to determine their presence. Shipboard surface-search radar provides this type of information as an input to the weapons system to assist in the engagement of hostile targets by fire-control radar. Shipboard surface-search radar is also used extensively as a navigational aid in coastal waters and in poor weather conditions. A typical surface-search radar antenna is shown in figure 1-24.

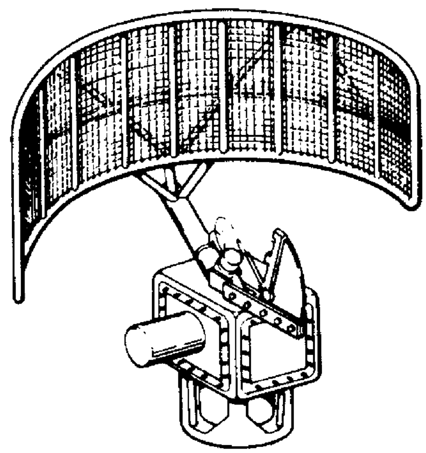

Figure 1-24.—Surface-search radar.

Q32. What type of radar provides continuous range, bearing, and elevation data on an object?

Q33. Radar altimeters use what type of transmission signal?

Q34. A surface-search radar normally scans how many degrees of azimuth?

Q35. What limits the maximum range of a surface-search radar?

Q36. What is the shape of the beam of a surface-search radar?

Air-Search Radar

Air-search radar systems initially detect and determine the position, course, and speed of air targets in a relatively large area. The maximum range of air-search radar can exceed 300 miles, and the bearing coverage is a complete 360-degree circle. Air-search radar systems are usually divided into two categories, based on the amount of position information supplied. As mentioned earlier in this chapter, radar sets that provide only range and bearing information are referred to as two-dimensional, or 2D, radars. Radar sets that supply range, bearing, and height are called three-dimensional, or 3D, radars. (3D radar will be covered in the next section.) The coverage pattern of a typical 2D radar system is illustrated in figure 1-25. A typical 2D air-search radar antenna is shown in figure 1-26.

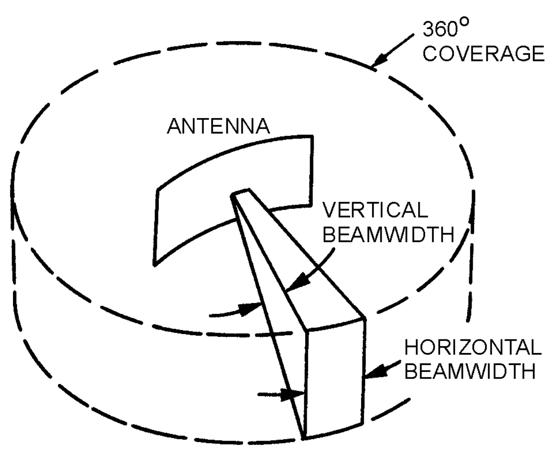

Figure 1-25.—2D radar coverage pattern.

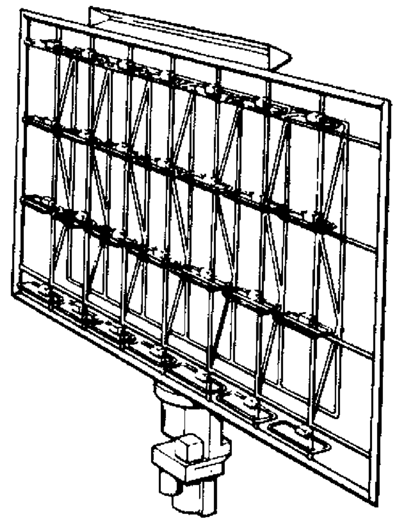

Figure 1-26.—2D air-search radar.

Relatively low transmitter frequencies are used in 2D search radars to permit long-range transmissions with minimum attenuation. Wide pulse widths and high peak power are used to aid in detecting small objects at great distances. Low pulse-repetition rates are selected to permit greater maximum range. A wide vertical-beam width is used to ensure detection of objects from the surface to relatively high altitudes and to compensate for pitch and roll of own ship. The output characteristics of specific air-search radars are classified; therefore, they will not be discussed.

Air-search radar systems are used as early-warning devices because they can detect approaching enemy aircraft or missiles at great distances. In hostile situations, early detection of the enemy is vital to a successful defense against attack. Antiaircraft defenses in the form of shipboard guns, missiles, or fighter planes must be brought to a high degree of readiness in time to repel an attack. Range and bearing information, provided by air-search radars, used to initially position a fire-control tracking radar on a target. Another function of the air-search radar system is guiding combat air patrol (CAP) aircraft to a position suitable to intercept an enemy aircraft. In the case of aircraft control, the guidance information is obtained by the radar operator and passed to the aircraft by either voice radio or a computer link to the aircraft.

Height-Finding Search Radar

The primary function of a height-finding radar (sometimes referred to as a three-coordinate or 3D radar) is that of computing accurate ranges, bearings, and altitudes of aircraft targets detected by air-search radars. Height-finding radar is also used by the ship's air controllers to direct CAP aircraft during interception of air targets. Modern 3D radar is often used as the primary air-search radar (figure 1-27). This is because of its high accuracy and because the maximum ranges are only slightly less than those available from 2D radar.

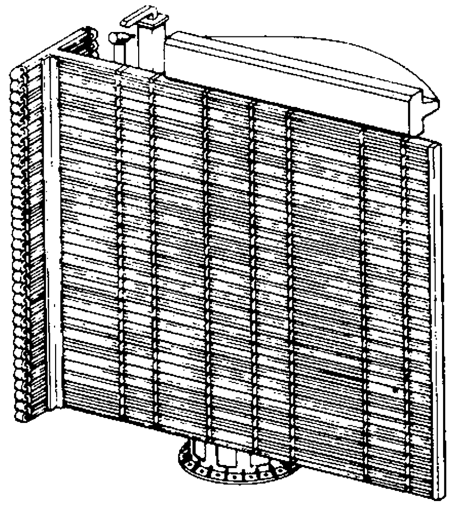

Figure 1-27.—3D air-search radar.

The range capability of 3D search radar is limited to some extent by an operating frequency that is higher than that of 2D radar. This disadvantage is partially offset by higher output power and a beam width that is narrower in both the vertical and horizontal planes.

The 3D radar system transmits several narrow beams to obtain altitude coverage and, for this reason, compensation for roll and pitch must be provided for shipboard installations to ensure accurate height information.

Applications of height-finding radars include the following:

- Obtaining range, bearing, and altitude data on enemy aircraft and missiles to assist in the control of CAP aircraft
- Detecting low-flying aircraft
- Determining range to distant land masses
- Tracking aircraft over land
- Detecting certain weather phenomena
- Tracking weather balloons
- Providing precise range, bearing, and height information for fast, accurate initial positioning of fire-control tracking radars

Q37. Air-search radar is divided into what two basic categories?

Q38. What position data are supplied by 2D search radar?

Q39. Why do 2D air-search radars use relatively low carrier frequencies and low pulse-repetition rates?

Q40. Why is the range capability of 3D radar usually less than the range of 2D radar?

TRACKING RADAR

Radar that provides continuous positional data on a target is called tracking radar. Most tracking radar systems used by the military are also fire-control radar; the two names are often used interchangeably.

Fire-control tracking radar systems usually produce a very narrow, circular beam.

Fire-control radar must be directed to the general location of the desired target because of the narrow-beam pattern. This is called the DESIGNATION phase of equipment operation. Once in the general vicinity of the target, the radar system switches to the ACQUISITION phase of operation. During acquisition, the radar system searches a small volume of space in a prearranged pattern until the target is located. When the target is located, the radar system enters the TRACK phase of operation. Using one of several possible scanning techniques, the radar system automatically follows all target motions. The radar system is said to be *locked on* to the target during the track phase. The three sequential phases of operation are often referred to as MODES and are common to the target-processing sequence of most fire-control radars.

Typical fire-control radar characteristics include a very high prf, a very narrow pulse width, and a very narrow beam width. These characteristics, while providing extreme accuracy, limit the range and make initial target detection difficult. A typical fire-control radar antenna is shown in figure 1-28. In this example the antenna used to produce a narrow beam is covered by a protective radome.

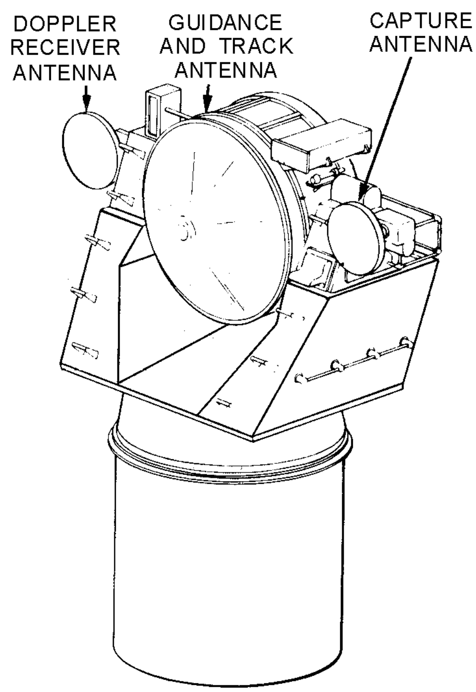

Figure 1-28.—Fire-control radar.

MISSILE-GUIDANCE RADAR

A radar system that provides information used to guide a missile to a hostile target is called GUIDANCE RADAR. Missiles use radar to intercept targets in three basic ways: (1) Beam-rider missiles follow a beam of radar energy that is kept continuously pointed at the desired target; (2) homing missiles detect and home in on radar energy reflected from the target; the reflected energy is provided by a radar transmitter either in the missile or at the launch point and is detected by a receiver in the missile; (3) passive homing missiles home in on energy that is radiated by the target. Because target position must be known at all times, a guidance radar is generally part of, or associated with, a fire-control tracking radar. In some instances, three radar beams are required to provide complete guidance for a missile. The beam-riding missile, for example, must be launched into the beam and then must ride the beam to the target. Initially, a wide beam is radiated by a capture radar to gain (capture) control of the missile. After the missile enters the capture beam, a narrow beam is radiated by a guidance radar to guide the missile to the target. During both capture and guidance operations, a tracking radar continues to track the target. Figure 1-29 illustrates the relationships of the three different radar beams.

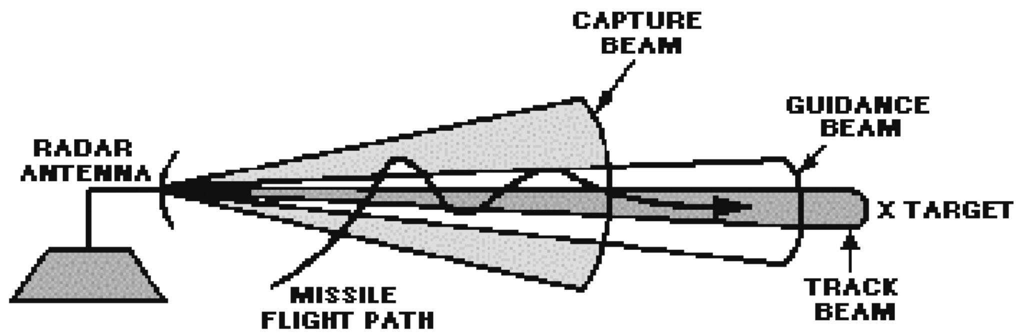

Figure 1-29.—Beam relationship of capture, guidance, and track beams.

Q41. Fire-control tracking radar most often radiates what type of beam?

Q42. Tracking radar searches a small volume of space during which phase of operation?

Q43. What width is the pulse radiated by fire-control tracking radar?

Q44. Which beam of missile-guidance radar is very wide?

CARRIER-CONTROLLED APPROACH (CCA) AND GROUND-CONTROLLED APPROACH (GCA) RADAR

CARRIER-CONTROLLED APPROACH and GROUND-CONTROLLED APPROACH radar systems are essentially shipboard and land-based versions of the same type of radar. Shipboard CCA radar systems are usually much more sophisticated systems than GCA systems. This is because of the movements of the ship and the more complicated landing problems. Both systems, however, guide aircraft to safe landing under conditions approaching zero visibility. By means of radar, aircraft are detected and observed during the final approach and landing sequence. Guidance information is supplied to the pilot in the form of verbal radio instructions, or to the automatic pilot (autopilot) in the form of pulsed control signals.

AIRBORNE RADAR

Airborne radar is designed especially to meet the strict space and weight limitations that are necessary for all airborne equipment. Even so, airborne radar sets develop the same peak power as shipboard and shore-based sets.

As with shipboard radar, airborne radar sets come in many models and types to serve many different purposes. Some of the sets are mounted in blisters (or domes) that form part of the fuselage; others are mounted in the nose of the aircraft.

In fighter aircraft, the primary mission of a radar is to aid in the search, interception, and destruction of enemy aircraft. This requires that the radar system have a tracking feature. Airborne radar also has many other purposes. The following are some of the general classifications of airborne radar: search, intercept and missile control, bombing, navigation, and airborne early warning.

SUMMARY

The following paragraphs summarize the important points of this chapter.

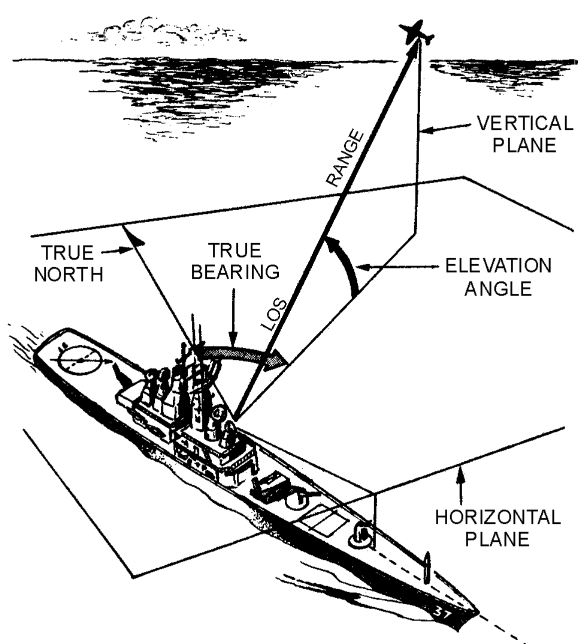
RADAR is an electronic system that uses reflected electromagnetic energy to detect the presence and position of objects invisible to the eye.

TARGET POSITION is defined in reference to true north, the horizontal plane, and the vertical plane.

TRUE BEARING is the angle between true north and the line of sight to the target, measured in a clockwise direction in the horizontal plane.

ELEVATION ANGLE is the angle between the horizontal plane and the line of sight, measured in the vertical plane.

RANGE is the distance from the radar site to the target measured along the line of sight. The concepts are illustrated in the figure.



RANGE to any target can be calculated by measuring the time required for a pulse to travel to a target and return to the radar receiver and by dividing the elapsed time by 12.36 microseconds.

$$\text{target range} = \frac{\text{elapsed time}}{\text{12.36 microseconds per nautical mile}}$$

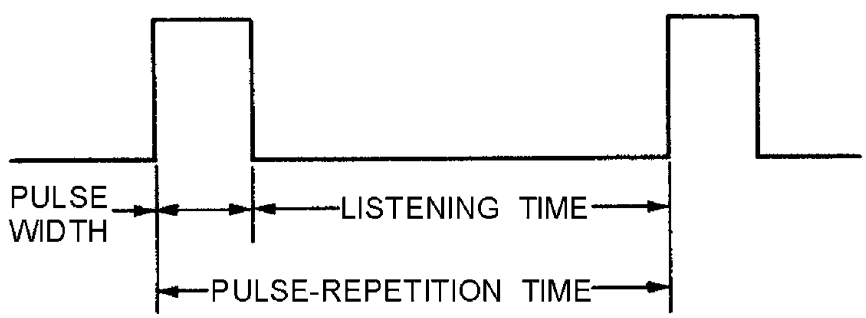
The **MINIMUM RANGE** of a radar system can be calculated from the formula:

$$\text{minimum range} = (\text{pulse width} + \text{recovery time}) \times 164 \text{ yards/microsecond}$$

The **MAXIMUM RANGE** of a pulse radar system depends on the CARRIER FREQUENCY, PEAK POWER, PULSE-REPETITION FREQUENCY, and RECEIVER SENSITIVITY.

PULSE-REPETITION TIME is the time between the beginning of one pulse and the beginning of the next pulse and is the reciprocal of prf.

$$\text{prt} = \frac{1}{\text{prf}}$$



AMBIGUOUS RETURNS are echoes from targets that exceed the prt of the radar system and result in false range readings. The maximum (unambiguous) range for a radar system can be determined by the formula:

$$R_{max} = \frac{\text{162, 000 mile/second}}{2} \times \text{prt}$$

The **PEAK POWER** of a radar system is the total energy contained in a pulse. Peak power is obtained by multiplying the maximum power level of a pulse by the pulse width.

Since most instruments are designed to measure AVERAGE POWER over a period of time, prt must be included in transmitter power measurements. The formula for average power is:

$$P_{avg} = P_{pk} \times \frac{pw}{prt}$$

or

$$P_{avg} = P_{pk} \times pw \times prf$$

The product of pw and prf is called the DUTY CYCLE of a radar system and is the ratio of transmitter time on to time off.

The formula for the peak power (using average power) of a radar system is:

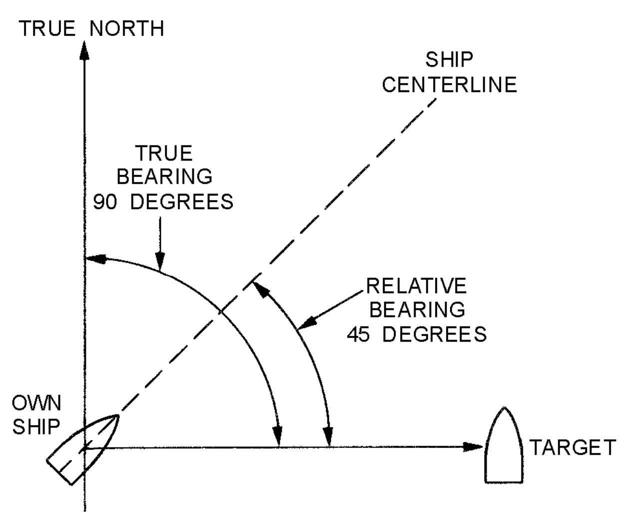
$$P_{pk} = \frac{P_{avg}}{\text{duty cycle}}$$

Antenna height and ROTATION SPEED affect radar range. Since high-frequency energy does not normally bend to follow the curvature of the earth, most radar systems cannot detect targets below the RADAR HORIZON. The distance to the horizon for a radar system can be determined by the formula:

$$\text{radar horizon distance} = 1.25\sqrt{\text{antenna height in feet}}$$
$$\text{(in nautical miles)}$$

The slower an antenna rotates, the larger the HITS PER SCAN value. The likelihood that a target will produce a usable echo is also increased.

The bearing to a target may be referenced to true north or to your own ship. Bearing referenced to true north is TRUE BEARING and bearing referenced to your ship is RELATIVE BEARING, as shown in the illustration. The bearing angle is obtained by moving the antenna to the point of maximum signal return.



Radar systems that detect only range and bearing are called TWO-DIMENSIONAL (2D) radars. Radars that detect height as well as range and bearing are called THREE-DIMENSIONAL (3D) RADARS.

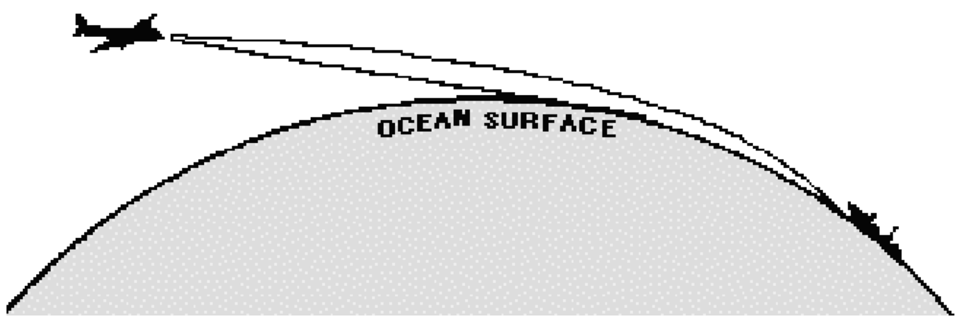
The target RESOLUTION of a radar system is its ability to distinguish between targets that are very close together.

RANGE RESOLUTION is the ability to distinguish between two or more targets on the same bearing and is primarily dependent on the pulse width of the radar system. The formula for range resolution is:

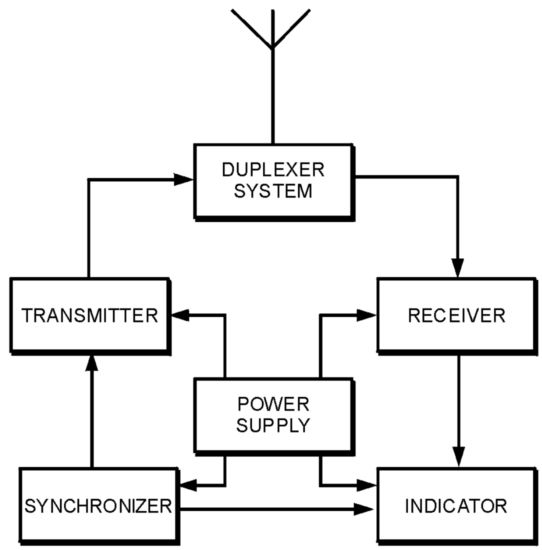
$$\text{resolution} = \text{pw} \times 164 \text{ yards per microsecond}$$

BEARING RESOLUTION is the ability of a radar to separate targets at the same range but different bearings. The degree of bearing resolution is dependent on beam width and range. The accuracy of radar is largely dependent on resolution.

ATMOSPHERIC CONDITIONS affect the speed and direction of travel of electromagnetic wavefronts traveling through the air. Under normal conditions, the wavefronts increase uniformly in speed as altitude increases which causes the travel path to curve downward. The downward curve extends the radar horizon as shown in the illustration. The density of the atmosphere, the presence of water vapor, and temperature changes also directly affect the travel of electromagnetic wavefronts.



The major components in a typical PULSE RADAR SYSTEM are shown in the illustration. The SYNCHRONIZER supplies the timing signals to coordinate the operation of the entire system. The TRANSMITTER generates electromagnetic energy in short, powerful pulses. The DUPLEXER allows the same antenna to be used to both transmit and receive. The RECEIVER detects and amplifies the return signals. The INDICATOR produces a visual indication of the range and bearing of the echo.



SCANNING is the systematic movement of a radar beam while searching for or tracking a target.

STATIONARY-LOBE SCANNING is the simplest type of scanning and is usually used in 2D search radar. Monopulse scanning, used in fire-control radars, employs four signal quantities to accurately track moving targets. The two basic methods of scanning are MECHANICAL and ELECTRONIC.

Radar systems are often divided into operational categories based on energy transmission methods—continuous wave (cw), frequency modulation (fm), and pulse modulation (pm).

The **CONTINUOUS WAVE (cw)** method transmits a constant frequency and detects moving targets by detecting the change in frequency caused by electromagnetic energy reflecting from a moving target. This change in frequency is called the DOPPLER SHIFT or DOPPLER EFFECT.

In the **FREQUENCY MODULATION (fm)** method, a signal that constantly changes in frequency around a fixed reference is used to detect stationary objects.

The **PULSE-MODULATION (pm) METHOD** uses short pulses of energy and relatively long listening times to accurately determine target range. Since this method does not depend on signal frequency or target motion, it has an advantage over cw and fm methods. It is the most common type of radar.

Radar systems are also classified by function. SEARCH RADAR continuously scans a volume of space and provides initial detection of all targets. TRACK RADAR provides continuous range, bearing, and elevation data on one or more specific targets. Most radar systems are variations of these two types.

ANSWERS TO QUESTIONS Q1. AND Q44.

A1. Horizontal plane.

A2. Range.

A3. Approximately the speed of light (162,000 nautical miles per second).

A4. 12.36 microseconds.

A5. Pulse width.

A6. Frequency.

A7.

$$\frac{1}{\mathrm{prt}} = \mathrm{prf}$$

A8. Average power.

A9. Duty cycle.

A10. Relative bearing.

A11. Three-dimensional.

A12. Frequency or phase.

A13. Target resolution.

A14. Beam width and range.

A15. Speed increases.

A16. Temperature inversion.

A17. Synchronizer.

A18. High-voltage pulse from the modulator.

A19. Duplexer.

A20. Single lobe.

A21. The reflected signals decrease in strength.

A22. Mechanical and electronic.

A23. Nutation.

A24. Frequency.

A25. Velocity.

A26. Fast-moving targets.

A27. Range.

A28. Travel time.

A29. Stationary.

A30. Pulse modulation.

A31. Pulse-Doppler.

A32. Track radar.

A33. Frequency modulated (fm).

A34. 360 degrees.

A35. Radar horizon.

A36. Wide vertically, narrow horizontally.

A37. 2D and 3D.

A38. Range and bearing.

A39. Increased maximum range.

A40. Higher operating frequency.

A41. A narrow circular beam.

A42. Acquisition.

A43. Very narrow.

A44. Capture beam.

CHAPTER 2

RADAR SUBSYSTEMS

LEARNING OBJECTIVES

Upon completion of this chapter, the student will be able to:

1. Describe, in general terms, the function of a radar synchronizer.
2. State the basic requirements and types of master synchronizers.
3. Describe the purpose, requirements, and operation of a radar modulator.
4. Describe the basic operating sequence of a keyed-oscillator transmitter.
5. Describe the basic operating sequence of a power-amplifier transmitter.
6. State the purpose of a duplexer.
7. State the operational principles of tr and atr tubes.
8. Describe the basic operating sequence of series and parallel connected duplexers.
9. List the basic design requirements of an effective radar receiver.
10. List the major sections of a typical radar receiver.
11. Using a block diagram, describe the operational characteristics of a typical radar receiver.

INTRODUCTION TO RADAR SUBSYSTEMS

Any radar system has several major subsystems that perform standard functions. A typical radar system consists of a SYNCHRONIZER (also called the TIMER or TRIGGER GENERATOR), a TRANSMITTER, a DUPLEXER, a RECEIVER, and an INDICATOR. These major subsystems were briefly described in chapter 1. This chapter will describe the operation of the synchronizer, transmitter, duplexer, and receiver of a typical pulse radar system and briefly analyze the circuits used. Chapter 3 will describe typical indicator and antenna subsystems. Because radar systems vary widely in specific design, only a general description of representative circuits is presented in this chapter.

SYNCHRONIZERS

The synchronizer is often referred to as the "heart" of the radar system because it controls and provides timing for the operation of the entire system. Other names for the synchronizer are the TIMER and the KEYER. We will use the term synchronizer in our discussion. In some complex systems the synchronizer is part of a system computer that performs many functions other than system timing.

SYNCHRONIZER FUNCTION

The specific function of the synchronizer is to produce TRIGGER PULSES that start the transmitter, indicator sweep circuits, and ranging circuits.

Timing or control is the function of the majority of circuits in radar. Circuits in a radar set accomplish control and timing functions by producing a variety of voltage waveforms, such as square waves, sawtooth waves, trapezoidal waves, rectangular waves, brief rectangular pulses, and sharp peaks. Although all of these circuits can be broadly classified as timing circuits, the specific function of any individual circuit could also be wave shaping or wave generation. The operation of many of these circuits and associated terms were described in detail in NEETS, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*.

Q1. What is the purpose of the synchronizer in a radar system?

Q2. What is the purpose of the majority of circuits in a radar system?

SYNCHRONIZER OPERATION

Radar systems may be classified as either SELF-SYNCHRONIZED or EXTERNALLY SYNCHRONIZED systems. In a self-synchronized system, the timing trigger pulses are generated in the transmitter. In an externally synchronized system, the timing trigger pulses are generated by a MASTER OSCILLATOR, which is usually external to the transmitter.

The master oscillator in an externally synchronized system may be a BLOCKING OSCILLATOR, a SINE-WAVE OSCILLATOR, or an ASTABLE (FREE-RUNNING) MULTI-VIBRATOR. When a blocking oscillator is used as a master oscillator, the timing trigger pulses are usually obtained directly from the oscillator. When a sine-wave oscillator or an astable multivibrator is used as a master oscillator, pulse-shaping circuits are required to form the necessary timing trigger pulses. In an externally synchronized radar system, the pulse repetition rate (prr) of the timing trigger pulses from the master oscillator determines the prr of the transmitter.

In a self-synchronized radar system, the prr of the timing trigger pulses is determined by the prr of the modulator or transmitter.

Associated with every radar system is an indicator, such as a cathode-ray tube, and associated circuitry. The indicator can present range, bearing, and elevation data in visual form so that a detected object may be located. Trigger pulses from the synchronizer are frequently used to produce gate (or enabling) pulses. When applied to the indicator, gate pulses perform the following functions:

1. Initiate and time the duration of the indicator sweep voltage

2. Intensify the cathode-ray tube electron beam during the sweep period so that the echo pulses may be displayed

3. Gate a range marker generator so that range marker signals may be superimposed on the indicator presentation

Figure 2-1 shows the time relationships of the various waveforms in a typical radar set. The timing trigger pulses are applied to both the transmitter and the indicator. When a trigger pulse is applied to the transmitter, a short burst of transmitter pulses (rf energy) is generated.

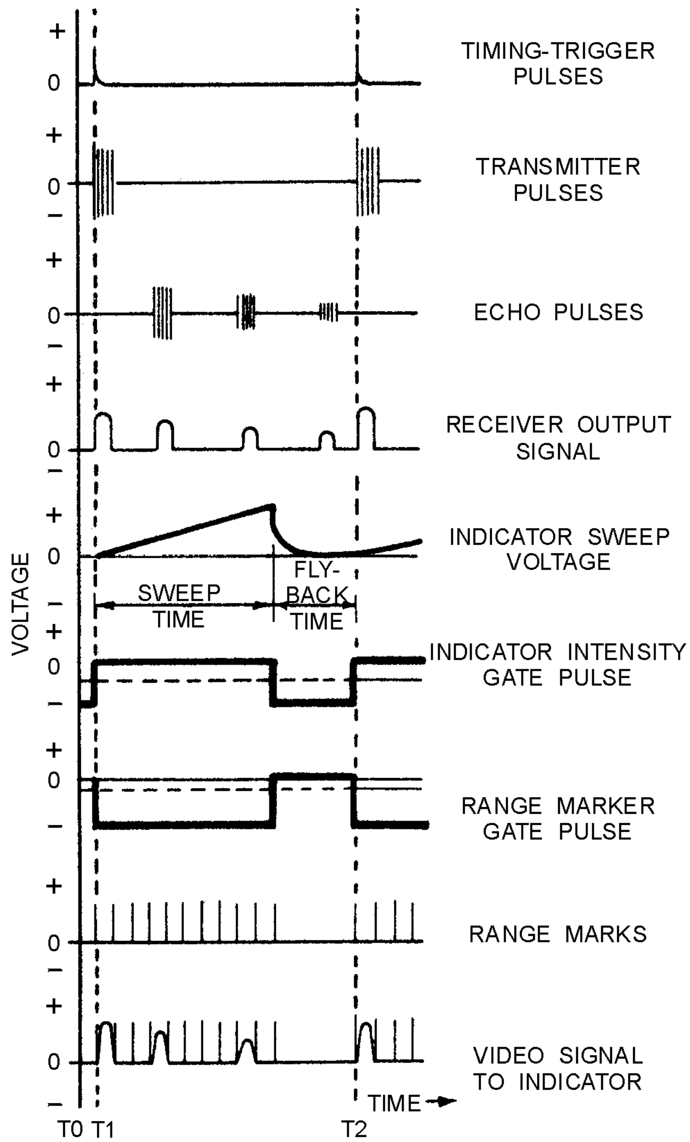


Figure 2-1.—Time relationship of waveforms.

This energy is conducted along a transmission line to the radar antenna. It is radiated by the antenna into space. When this transmitter energy strikes one or more reflecting objects in its path, some of the transmitted energy is reflected back to the antenna as echo pulses. Echo pulses from three reflecting targets at different ranges are illustrated in figure 2-1. These echoes are converted to the corresponding receiver output signals as shown in the figure. The larger initial and final pulses in the receiver output signal are caused by the energy that leaks through the duplexer when a pulse is being transmitted.

The indicator sweep voltage shown in figure 2-1 is initiated at the same time the transmitter is triggered. In other applications, it may be more desirable to delay the timing trigger pulse that is to be fed to the indicator sweep circuit. Delaying the trigger pulse will initiate the indicator sweep *after* a pulse is transmitted.

Note in figure 2-1 that the positive portion of the indicator intensity gate pulse (applied to the cathode-ray tube control grid) occurs only during the indicator sweep time. As a result, the visible cathode-ray tube trace occurs only during sweep time and is eliminated during the flyback (retrace) time. The negative portion of the range-marker gate pulse also occurs during the indicator sweep time. This negative gate pulse is applied to a range-marker generator, which produces a series of range marks.

The range marks are equally spaced and are produced only for the duration of the range-marker gate pulse. When the range marks are combined (mixed) with the receiver output signal, the resulting video signal applied to the indicator may appear as shown at the bottom of figure 2-1.

Q3. A self-synchronized radar system obtains timing trigger pulses from what source?

Q4. What type of multivibrator can be used as a radar master oscillator?

Q5. In an externally synchronized radar, what determines the prr of the transmitter?

Q6. In figure 2-1, what causes the initial and final pulses on the receiver output signal?

BASIC SYNCHRONIZER CIRCUITS

The basic synchronizer circuit should meet the following three basic requirements:

1. It must be *free running* (astable). Because the synchronizer is the heart of the radar, it must establish the zero time reference and the prf (prr).

2. It should be *stable in frequency*. For accurate ranging, the prr and its reciprocal, pulse-repetition time (prt), must not change between pulses.

3. The *frequency must be variable* to enable the radar to operate at different ranges.

Three basic synchronizer circuits can meet the above mentioned requirements. They are the SINE-WAVE OSCILLATOR, the SINGLE-SWING BLOCKING OSCILLATOR, and the MASTER-TRIGGER (ASTABLE) MULTIVIBRATOR.

Figure 2-2 shows the block diagrams and waveforms of these three synchronizers as they are used in externally synchronized radar systems. In each case, equally spaced timing trigger pulses are produced. The prr of each series of timing trigger pulses is determined by the operating frequency of the associated master oscillator.

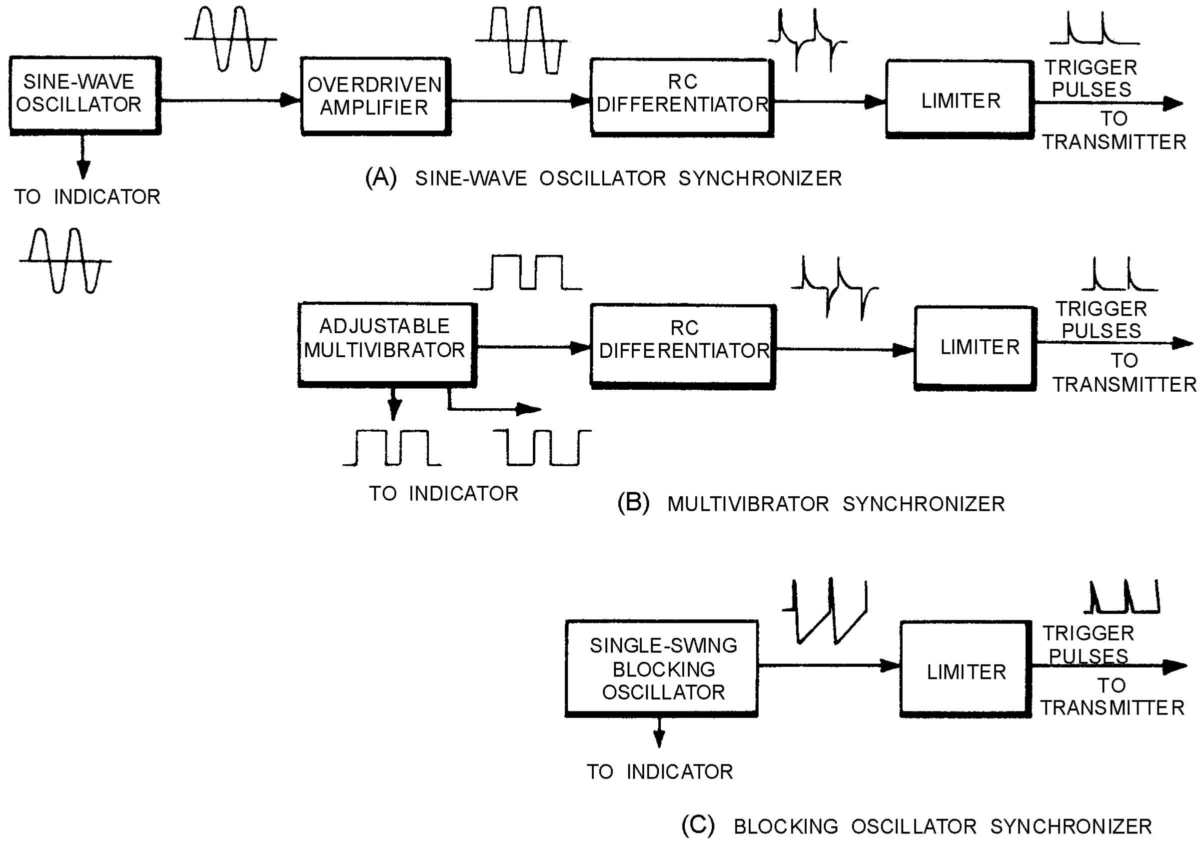

Figure 2-2.—Timers used in externally synchronized radar systems.

Sine-Wave Oscillator Synchronizer

In the sine-wave oscillator synchronizer (figure 2-2, view A), a sine-wave oscillator is used for the basic timing device (master oscillator). The oscillator output is applied to both an overdriven amplifier and the radar indicator. The sine waves applied to the overdriven amplifier are shaped into square waves. These square waves are then converted into positive and negative timing trigger pulses by means of a short-time-constant RC differentiator.

By means of a limiter, either the positive or negative trigger pulses from the RC differentiator are removed. This leaves trigger pulses of only one polarity. For example, the limiter in view A of figure 2-2 is a negative-lobe limiter; that is, the limiter removes the negative trigger pulses and passes only positive trigger pulses to the radar transmitter.

A disadvantage of a sine-wave oscillator synchronizer is the large number of pulse-shaping circuits required to produce the necessary timing trigger pulses.

Master Trigger (Astable) Multivibrator Synchronizer

In a master trigger (astable) multivibrator synchronizer (view B, figure 2-2), the master oscillator generally is an astable multivibrator. The multivibrator is either ASYMMETRICAL or SYMMETRICAL. If the multivibrator is asymmetrical, it generates rectangular waves. If the multivibrator is symmetrical, it generates square waves. In either case, the timing trigger pulses are equally spaced after a limiter removes undesired positive or negative lobes.

There are two transistors in an astable multivibrator. The two output voltages are equal in amplitude, but are 180 degrees out of phase. The output of the astable multivibrator consists of positive and negative rectangular waves. Positive rectangular waves are applied to an RC differentiator and converted into positive and negative trigger pulses. As in the sine-wave synchronizer, the negative trigger pulses are removed by means of a negative-lobe limiter, and the positive pulses are applied to the transmitter.

Both positive and negative rectangular waves from the astable multivibrator are applied to the indicator. One set of waves is used to intensify the cathode-ray tube electron beam for the duration of the sweep. The other set of waves is used to gate (turn on) the range marker generator.

Single-Swing Blocking Oscillator Synchronizer

In the single-swing, blocking-oscillator synchronizer, shown in view C of figure 2-2, a free-running, single-swing blocking oscillator is generally used as the master oscillator. The advantage of the single-swing blocking oscillator is that it generates sharp trigger pulses without additional shaping circuitry. Timing trigger pulses of only one polarity are obtained by means of a limiter.

Gating pulses for the indicator circuits are produced by applying the output of the blocking oscillator to a one-shot multivibrator or another variable time delay circuit (not shown). Crystal-controlled oscillators may be used when very stable frequency operation is required.

Q7. What basic circuits meet the requirements of an externally synchronized master oscillator?

Q8. Name a disadvantage of sine-wave oscillator synchronizers.

Q9. Which of the basic timing circuits produces sharp trigger pulses directly?

TRANSMITTERS

The TRANSMITTER produces the short duration high-power rf pulses of energy that are radiated into space by the antenna. Two main types of transmitters are now in common use. The first is the KEYED-OSCILLATOR type. In this transmitter one stage or tube, usually a magnetron, produces the rf pulse. The oscillator tube is keyed by a high-power dc pulse of energy generated by a separate unit called the MODULATOR (discussed in the following section). The second type of transmitter consists of a POWER-AMPLIFIER CHAIN. This transmitter system begins with an rf pulse of very low power. This low-level pulse is then amplified by a series (chain) of power amplifiers to the high level of power desired in a transmitter pulse. In most power-amplifier transmitters, each of the power-amplifier stages is pulse modulated in a manner similar to the oscillator in the keyed-oscillator type. Because the modulator is common to both types of transmitter systems, the operation of a typical modulator will be discussed first.

RADAR MODULATOR

The modulator controls the radar pulse width by means of a rectangular dc pulse (modulator pulse) of the required duration and amplitude. The peak power of the transmitted rf pulse depends on the amplitude of the modulator pulse.

Figure 2-3 shows the waveforms of the trigger pulse applied by the synchronizer to the modulator, the modulator pulse applied to the radar transmitter, and the transmitted rf pulse.

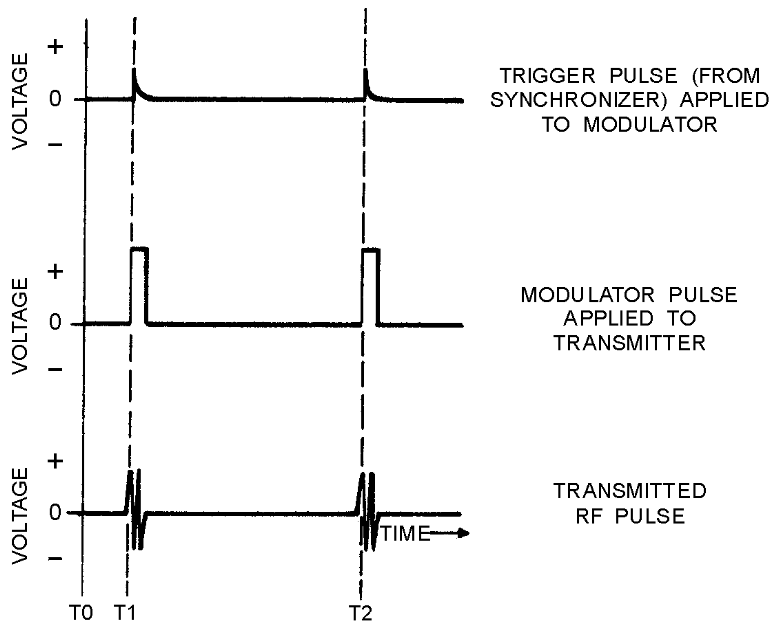

Figure 2-3.—Transmitter waveforms.

As you can see in the figure, the modulator pulse is applied to the transmitter the instant the modulator receives the trigger pulse from the synchronizer (T1, T2). The modulator pulse is flat on top and has very steep leading and trailing edges. These pulse characteristics are necessary for the proper operation of the transmitter and for the accurate determination of target range. The range timing circuits must be triggered the instant the leading edge of the transmitted rf pulse leaves the transmitter. In this way, the trigger pulse that controls the operation of the modulator also synchronizes the cathode-ray tube sweep circuits and range measuring circuits.

MAGNETRON OSCILLATORS are capable of generating rf pulses with very high peak power at frequencies ranging from 600 to 30,000 megahertz. However, if its cathode voltage changes, the magnetron oscillator shifts in frequency. To avoid such a frequency change, you must ensure that the amplitude of the modulator (dc) pulse remains constant for the duration of the transmitted rf pulse. That is, the modulator pulse must have a flat top. The range of cathode voltages over which a magnetron oscillates in the desired frequency spectrum is relatively small.

When a low voltage is applied to a magnetron, the magnetron produces a noise voltage output instead of oscillations. If this noise enters the receiver, it can completely mask the returning echoes. If a modulator pulse builds up and decays slowly, noise is produced at both the beginning and end of the pulse. Therefore, for efficient radar operation, a magnetron requires a modulator pulse that has a flat top and steep leading and trailing edges. An effective modulator pulse must perform in the following manner:

- Rise from zero to its maximum value almost instantaneously
- Remain at its maximum value for the duration of the transmitted rf pulse
- Fall from its maximum value to zero almost instantaneously

In radars that require accurate range measurement, the transmitted rf pulse must have a steep leading edge. The leading edge of the echo is used for range measurement. If the leading edge of the echo is not steep and clearly defined, accurate range measurement is not possible. The leading and trailing edges of echoes have the same shape as the leading and trailing edges of the transmitted rf pulse.

A transmitted rf pulse with a steep trailing edge is essential for the detection of objects at short ranges. If the magnetron output voltage drops gradually from its maximum value to zero, it contributes very little to the usable energy of the transmitted rf pulse. Furthermore, part of the magnetron output voltage enters the receiver and obscures nearby object echoes.

Types of Modulators

The two types of modulators are the LINE-PULSING MODULATOR and the HARD-TUBE MODULATOR. (A hard tube is a high-vacuum electron tube.) The line-pulsing modulator stores energy and forms pulses in the same circuit element. This element is usually the pulse-forming network. The hard-tube modulator forms the pulse in the driver; the pulse is then amplified and applied to the modulator. The hard tube modulator has been replaced by the line-pulsed modulator in most cases. This is because the hard-tube modulator has lower efficiency, its circuits are more complex, a higher power supply voltage is required, and it is more sensitive to voltage changes.

The line-pulsing modulator is easier to maintain because of its less complex circuitry. Also, for a given amount of power output, it is lighter and more compact. Because it is the principally used modulator in modern radar, it is the only type that will be discussed.

Figure 2-4 shows the basic sections of a radar modulator. They are as follows:

- The *power supply*.
- The *storage element* (a circuit element or network used to store energy).
- The *charging impedance* (used to control the charge time of the storage element and to prevent short-circuiting of the power supply during the modulator pulse).
- The *modulator switch* (used to discharge the energy stored by the storage element through the transmitter oscillator during the modulator pulse).

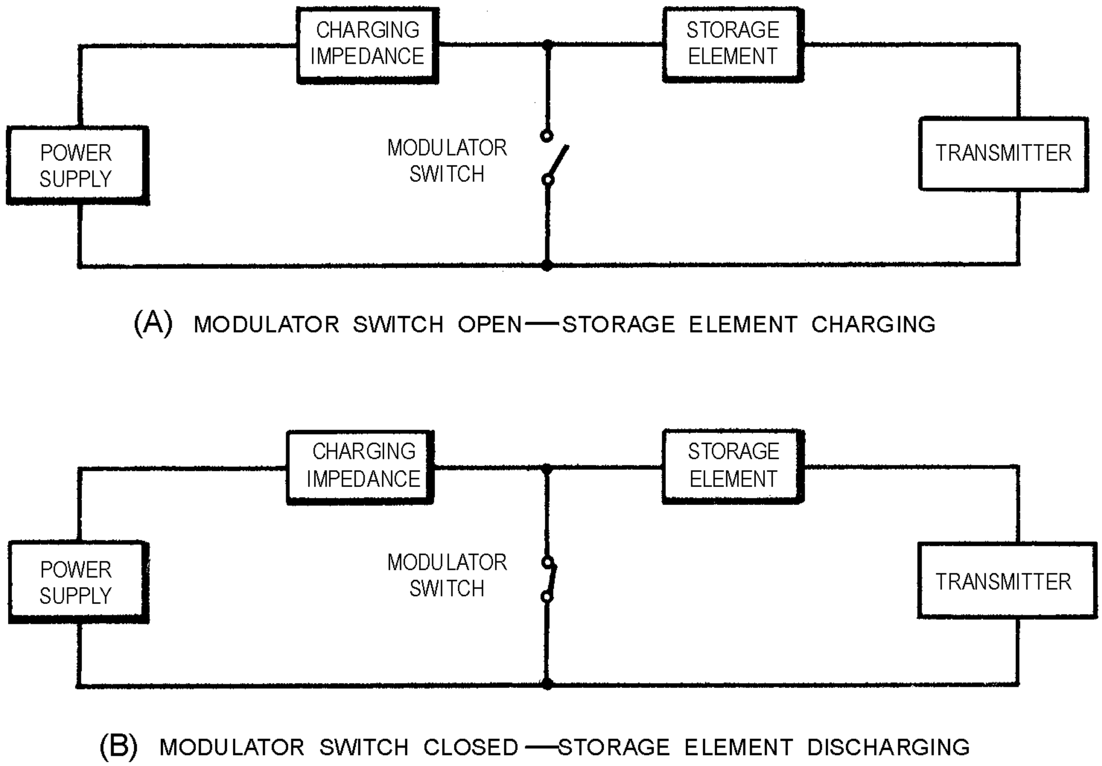

Figure 2-4.—Basic line-pulsing modulator block diagram.

View A of figure 2-4 shows the modulator switch open and the storage element charging. With the modulator switch open, the transmitter produces no power output, but the storage element stores a large amount of energy. View B shows the modulator switch closed and the storage element discharging through the transmitter. The energy stored by the storage element is released in the form of a high-power, dc modulator pulse. The transmitter converts the dc modulator pulse to an rf pulse, which is radiated into space by the radar antenna. Thus, the modulator switch is closed for the duration of a transmitted rf pulse, but open between pulses.

Many different kinds of components are used in radar modulators. The power supply generally produces a high-voltage output, either alternating or direct current. The charging impedance may be a resistor or an inductor. The storage element is generally a capacitor, an artificial transmission line, or a pulse-forming network. The modulator switch is usually a thyratron.

Modulator Storage Element

Capacitor storage elements are used only in modulators that have a dc power supply and an electron-tube modulator switch.

The capacitor storage element is charged to a high voltage by the dc power supply. It releases only a small part of its stored energy to the transmitter. The electron-tube modulator switch controls the charging and discharging of the capacitor storage element.

The artificial transmission line storage element, shown in view A of figure 2-5, consists of identical capacitors (C) and inductors (L) arranged to simulate sections of a transmission line. The artificial transmission line serves two purposes: (1) to store energy when the modulator switch is open (between transmitted rf pulses) and (2) to discharge and form a rectangular dc pulse (modulator pulse) of the required duration when the modulator switch is closed.

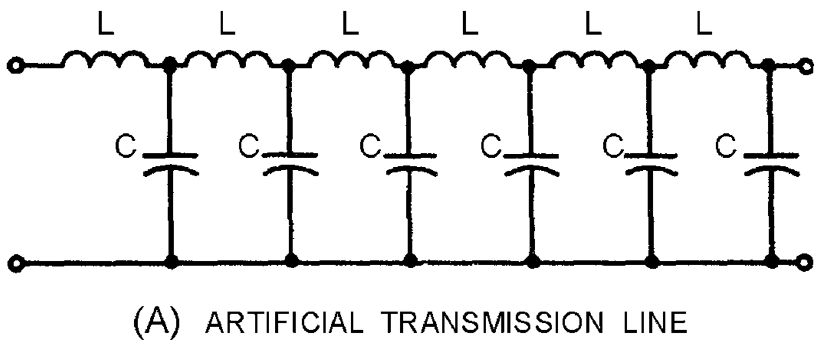

Figure 2-5A.—Modulator storage elements.

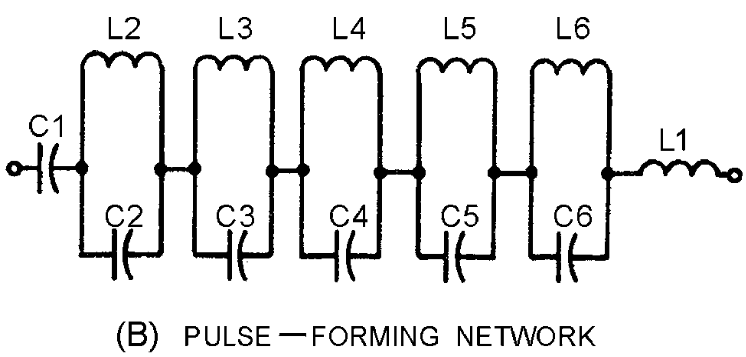

Figure 2-5B.—Modulator storage elements.

The duration of the modulator pulse depends on the values of inductance and capacitance in each LC section of the artificial transmission line in view A and the number of LC sections used. Other arrangements of capacitors and inductors (such as the pulse-forming network shown in view B) are very similar in operation to artificial transmission lines.

ARTIFICIAL TRANSMISSION LINES and PULSE-FORMING NETWORKS (pfn) are used more often than the capacitor-type storage elements.

ARTIFICIAL TRANSMISSION LINE.—Figure 2-6 shows a radar modulator that uses an artificial transmission line as its storage element. A modulator switch controls the pulse-repetition rate. When the modulator switch is open (between transmitted rf pulses), the transmission line charges.

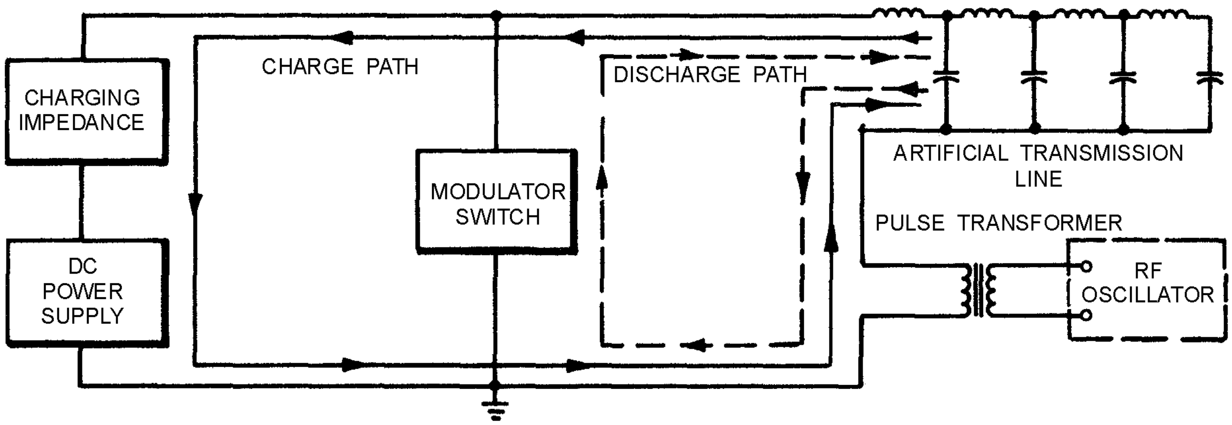

Figure 2-6.—Modulator with an artificial transmission line for the storage element.

The charge path includes the primary of the pulse transformer, the dc power supply, and the charging impedance. When the modulator switch is closed, the transmission line discharges through the series circuit. This circuit consists of the modulator switch and the primary of the pulse transformer.

The artificial transmission line is effectively an open circuit at its output end. Therefore, when the voltage wave reaches the output end of the line, it is reflected. As the reflected wave propagates from the output end back toward the input end of the line, it completely discharges each section of the line. When the reflected wave reaches the input end of the line, the line is completely discharged, and the modulator pulse ceases abruptly. If the oscillator and pulse transformer circuit impedance is properly matched to the line impedance, the voltage pulse that appears across the transformer primary equals one-half the voltage to which the line was initially charged.

The width of the pulse generated by an artificial transmission line depends on the time required for a voltage wave to travel from the input end to the output end of the line and back. Therefore, we can say the pulse width depends on the velocity of propagation along the line (determined by the inductances and capacitances of each section of the line) and the number of line sections (the length of the line).

PULSE-FORMING NETWORKS.—A pulse-forming network is similar to an artificial transmission line in that it stores energy between pulses and produces a nearly rectangular pulse. The pulse-forming network in view B of figure 2-5 consists of inductors and capacitors so arranged that they approximate the behavior of an artificial transmission line.

Each capacitor in the artificial transmission line, shown in view A, must carry the high voltage required for the modulator pulse. Because each capacitor must be insulated for this high voltage, an artificial transmission line consisting of many sections would be bulky and cumbersome.

The pulse-forming network, shown in view B of figure 2-5, can carry high voltage but does not require bulky insulation on all of its capacitors. Only series capacitor C1 must have high-voltage insulation. Because the other capacitors are in parallel with the corresponding inductors, the modulator-pulse voltage divides nearly equally among them. Thus, except for C1, the elements of the pulse-forming network are relatively small.

Pulse-forming networks are often insulated by immersing each circuit element in oil. The network is usually enclosed in a metal box on which the pulse width, characteristic impedance, and safe operating voltage of the network are marked. If one element in such a network fails, the entire network must be replaced.

Q10. What are the two basic types of transmitters?

Q11. What controls transmitter pulse width?

Q12. In addition to a flat top, what characteristics must a modulator pulse have?

Q13. What type of modulator is most commonly used in modern radar systems?

Q14. What three types of storage elements most often are used in modulators?

Q15. What characteristic is determined by the time required for a voltage wave to travel from the input end of an artificial transmission line to the output end and back again?

Modulator Switching Devices

The voltage stored in a storage-element capacitor, artificial transmission line, or pulse-forming network must be discharged through a MODULATOR SWITCHING DEVICE. The modulator switching device conducts for the duration of the modulator pulse and is an open circuit between pulses. Thus, the modulator switch must perform the following four functions:

1. Close very quickly and then reach full conduction in a small fraction of a microsecond
2. Conduct large currents (tens or hundreds of amperes) and withstand large voltages (thousands of volts)
3. Cease conducting (become an open circuit) with the same speed that it starts to conduct
4. Consume only a very small fraction of the power that passes through it

These switching and conducting requirements are met best by the THYRATRON tube. The thyratron tube is normally held below cutoff by a negative grid voltage and conducts when a positive trigger pulse is applied to its grid. Once fired, the thyratron tube continues to conduct as long as the storage element (artificial transmission line or pulse-forming network) is discharging.

During discharge of the storage element, the gas in the thyratron tube is highly ionized. While the storage element discharges, the plate-to-cathode resistance of the thyratron is practically zero. When the storage element is completely discharged, current ceases to flow through the thyratron and the gases become deionized; the negative grid bias regains control, and the thyratron is cut off (the modulator switch opens).

Most radar modulators use a high-voltage, dc power supply. Typical dc power supplies for radar modulators use a half-wave rectifier, a full-wave rectifier, or a bridge rectifier.

The modulator charging impedance, shown in figure 2-7, prevents the dc power supply from becoming short-circuited when the modulator switch closes. When the modulator switch is open, the charging impedance also controls the rate at which the storage element charges. When the charging impedance is small, the storage element charges rapidly.

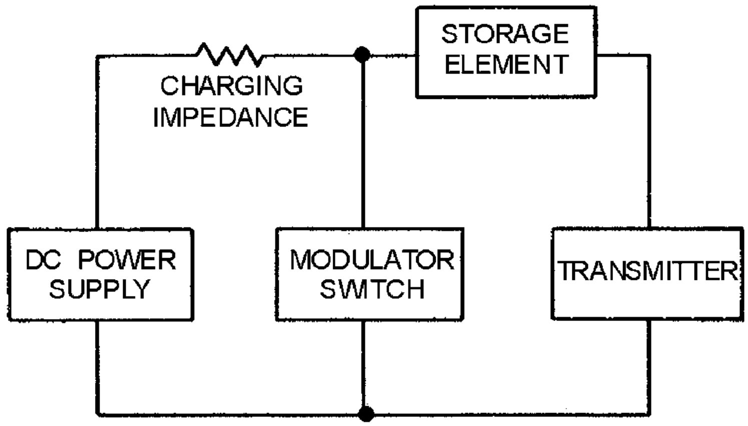

Figure 2-7.—Modulator charging impedance.

Many different kinds of charging impedance and charging circuits are used in radar modulators. The type of charging impedance and charging circuit used depends on the following five elements:

1. The type of power supply (ac or dc)
2. The type of storage element
3. The amount of modulator pulse voltage required
4. The pulse-repetition rate
5. The frequency of the available ac supply voltage

Q16. What type of tube best meets the requirements of a modulator switching element?

Q17. What modulator element controls the rate at which the storage element charges?

KEYED-OSCILLATOR TRANSMITTER

The KEYED-OSCILLATOR TRANSMITTER most often uses a MAGNETRON as the power oscillator. The following discussion is a description of a magnetron used as a keyed-oscillator radar transmitter.

Figure 2-8 shows the typical transmitter system that uses a magnetron oscillator, waveguide transmission line, and microwave antenna. The magnetron at the bottom of the figure is connected to the waveguide by a coaxial connector. High-power magnetrons, however, are usually coupled directly to the waveguide. A cutaway view of a typical waveguide-coupled magnetron is shown in figure 2-9.

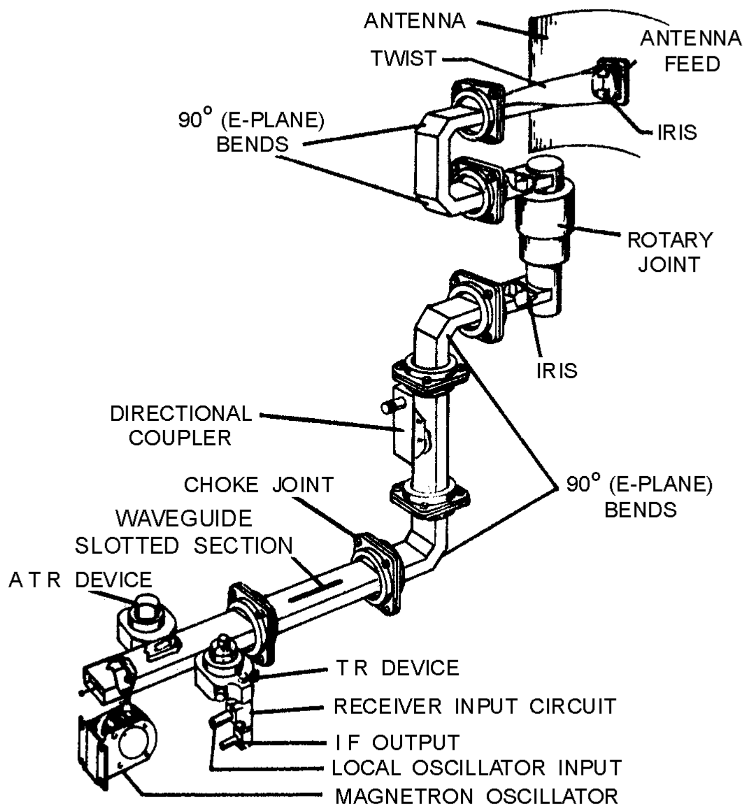

Figure 2-8.—Keyed oscillator transmitter physical layout.

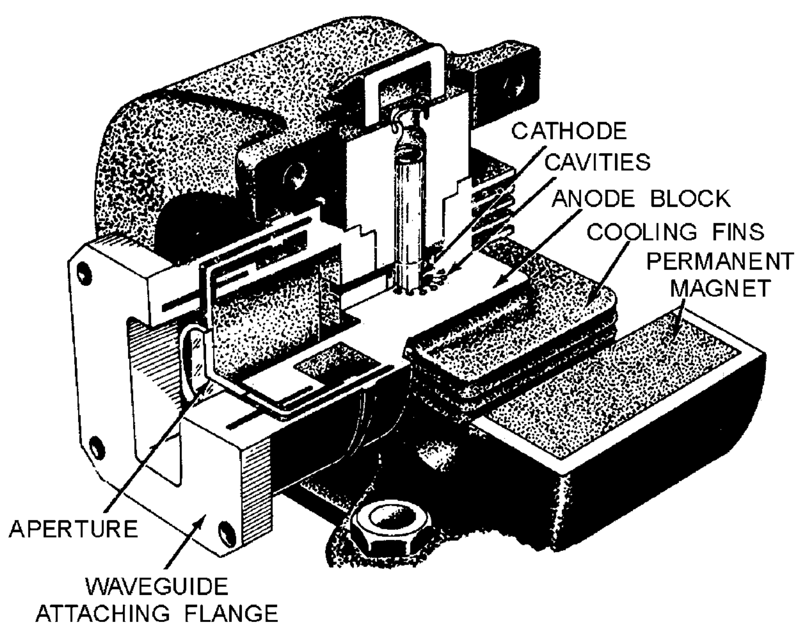

Figure 2-9.—Typical magnetron.

The magnetron is an electron tube in which a magnetic (H) field between the cathode and plate is perpendicular to an electric (E) field. Tuned circuits, in the form of cylindrical cavities in the plate, produce rf electric fields. Electrons interact with these fields in the space between the cathode and plate to produce an ac power output. Magnetrons function as self-excited microwave oscillators. These multicavity devices may be used in radar transmitters as either pulsed or cw oscillators at frequencies ranging from approximately 600 to 30,000 megahertz. (If you wish to review magnetron operation in more detail, refer to NEETS, Module 11, *Microwave Principles*.)

Let's examine the following characteristics of a magnetron used as a pulse radar transmitter oscillator stage:

- Stability
- Pulse characteristics
- The magnet
- Output coupling

Stability

In speaking of a magnetron oscillator, STABILITY usually refers to the stability of the mode of operation of the magnetron. The two main types of mode instability are MODE SKIPPING and MODE SHIFTING.

Mode skipping (or misfiring) is a condition in which the magnetron fires randomly in an undesired, interfering mode during some pulse times, but not in others. Pulse characteristics and tube noises are factors in mode skipping.

Mode shifting is a condition in which the magnetron changes from one mode to another during pulse time. This is highly undesirable and does not occur if the modulator pulse is of the proper shape, unless the cathode of the magnetron is in very poor condition.

Pulse Characteristics

PULSE CHARACTERISTICS are the make up of the high-voltage modulator pulse that is applied to the magnetron. The pulse should have a steep leading edge, a flat top, and a steep trailing edge. If the leading edge is not steep, the magnetron may begin to oscillate before the pulse reaches its maximum level. Since these low-power oscillations will occur in a different mode, the mode of the magnetron will be shifted as the pulse reaches maximum power. This mode shifting will result in an undesirable magnetron output. For the same reason (to prevent mode shifting), the top of the modulator pulse should be as flat as possible. Variations in the applied operating power will cause variations in the mode of operation. The trailing edge of the pulse should also be steep for the same reason--to prevent mode shifting.

Magnet

The purpose of the MAGNET is to produce a fairly uniform magnetic field of the desired value over the interaction space between the cathode and plate of the magnetron. The strength of the magnet is critical for proper operation. If the magnetic field strength is too high, the magnetron will not oscillate. If the magnetic field strength is too low, the plate current will be excessive and power output will be low. Frequency of operation will also be affected.

Since the strength of the magnet is critical, you should be careful when handling the magnet. Striking the magnet, especially with a ferromagnetic object, will misalign the molecular structure of the magnet and decrease the field strength.

Output Coupling

The OUTPUT COUPLING transfers the rf energy from the magnetron to the output transmission line (coaxial line or waveguide). A number of considerations impose restrictions upon the output circuit. The wavelength (frequency) and the power level of the magnetron output energy determine whether the transmission line to the antenna will be waveguide or coaxial line.

The coaxial output circuit consists of a length of coaxial line in which the center conductor is shaped into a loop and inserted into one of the magnetron cavities for magnetic coupling. The load side of the coupling line may feed either an external coaxial line or a waveguide. If the external line is coaxial, the connection may be direct or by means of choke joints. If the external line is a waveguide, the output circuit must include a satisfactory junction from the coaxial line to the waveguide. One type of junction used quite often is the PROBE COUPLER. The probe coupler acts as an antenna radiating into the waveguide.

The waveguide output may be fed directly by an opening (slot) into one of the magnetron cavities, as shown in figure 2-9. This opening must be covered by an iris window to maintain the vacuum seal.

The peak power ratings of magnetrons range from a few thousand watts (kilowatts) to several million watts (megawatts). The average power ratings are much lower, however, and vary from a few watts to several kilowatts. Additionally, many of the magnetrons used in modern radar systems are tunable in frequency. Typically, a tunable magnetron can vary the output frequency ±5 percent about the center of its frequency band. Thus the carrier frequency of radar can be changed to obtain the best operation or avoid electronic jamming on a particular frequency.

Modulator signals of many thousands of volts are applied to the magnetron cathode during operation. These high voltage levels require large glass posts to insulate the cathode and filaments from the anode block. In some high-power magnetrons, the cathode is completely enclosed in a container filled with insulating oil.

WARNING

> **All radar transmitters contain lethal voltages. Extreme care and strict observance of all posted safety precautions are essential when working on a radar transmitter.**

Q18. What is the frequency range of magnetron oscillators?

Q19. What two forms of instability are common in magnetrons?

Q20. What is the effect on magnetron operation if the magnetic field strength is too high?

Q21. What is the typical frequency range about the center frequency of a tunable magnetron?

POWER-AMPLIFIER TRANSMITTER

POWER-AMPLIFIER TRANSMITTERS are used in many recently developed radar sets. This type of transmitter was developed because of the need for more stable operation of the moving target indicator (mti). In a magnetron transmitting system, the high-power magnetron oscillator has a tendency to drift in frequency because of temperature variations, changes in the modulating pulse, and various other effects.

Frequency drift is compensated for, in part, by the use of automatic frequency control (afc) circuits designed to control the frequency of the local oscillator in the receiver system. This, however, does not completely eliminate the undesirable effects of frequency drift on mti operation.

The power-amplifier transmitter system does the same thing as the keyed-oscillator transmitter but with fewer stability problems. It generates, shapes, and amplifies pulses of rf energy for transmission.

Figure 2-10 is a block diagram of a typical power-amplifier transmitter system. In this transmitter system a multicavity klystron tube amplifies lower-powered rf pulses that have been generated and shaped in other stages. CROSSED-FIELD AMPLIFIERS (AMPLITRONS) are used in radar systems with a wide band of transmitted frequencies because they are stable over a wider frequency range. A crossed-field amplifier transmitter is discussed later in this section.

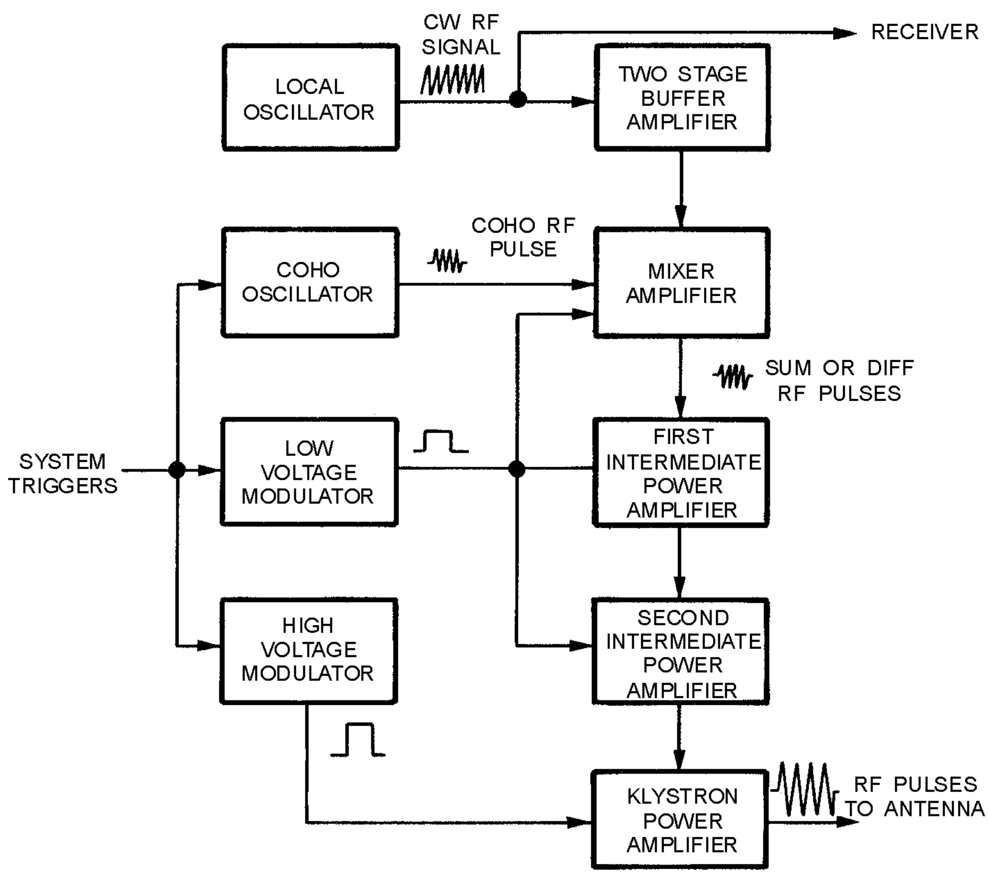

Figure 2-10.—Power amplifier transmitter block diagram.

In figure 2-10, the power-amplifier chain input signals are generated by heterodyning (mixing) two frequencies. That is, two different frequencies are fed to a mixer stage (mixer amplifier) and the resultant, either the sum or difference frequency, may be selected as the output. (The operation of mixer circuits is explained in more detail in the section on receivers.) The low-power pulse is then amplified by intermediate power amplifier stages and applied to the klystron power-amplifier. The klystron power-amplifier concentrates the rf output energy into a very narrow frequency spectrum. This concentration makes the system more sensitive to smaller targets. In addition the detection range of all targets is increased.

To examine the operation of the transmitter, we will trace the signal through the entire circuit. The local oscillator shown at the left of figure 2-10 is a very stable rf oscillator that produces two cw rf outputs. As shown, the cw output is sent to the receiver system; the cw output is also one of the two rf signals fed to the mixer amplifier by way of the two BUFFER AMPLIFIER STAGES. The buffer amplifiers raise the power level of the signal and also isolate the local oscillator.

The COHERENT OSCILLATOR (COHO) is triggered by the system trigger and produces as its output an rf pulse. This rf pulse is fed directly to the mixer amplifier.

The mixer-amplifier stage receives three signals: the coherent rf pulse, the local oscillator cw rf signal, and a dc modulating pulse from the low-voltage modulator. The coherent and local oscillator signals are mixed to produce sum and difference frequency signals. Either of these may be selected as the output. The modulator pulse serves the same purpose as in the keyed-oscillator transmitter, because it determines the pulse width and power level. The mixer stage functions only during the modulator pulse time. Thus the mixer amplifier produces an output of rf pulses in which the frequency may be either the sum or difference of the coherent and local oscillator signals.

The mixer-amplifier feeds the pulses of rf energy to an intermediate power amplifier. This amplifier stage is similar to the buffer-amplifier stage except that it is a pulsed amplifier. That is, the pulsed amplifier has operating power only during the time the modulator pulse from the low-voltage modulator is applied to the stage. The amplified output signal is fed to a second intermediate power amplifier that operates in the same manner as the first.

From the second intermediate power amplifier, the signal is fed to the KLYSTRON POWER AMPLIFIER. This stage is a multicavity power klystron. The input rf signal is used as the exciter signal for the first cavity. High-voltage modulating pulses from the high-voltage modulator are also applied to the klystron power amplifier. These high-voltage modulating pulses are stepped up across a pulse transformer before being applied to the klystron. All cavities of the klystron are tunable and are tuned for maximum output at the desired frequency.

Provisions are made in this type of transmitter to adjust the starting time of the modulating pulses applied to the coherent oscillator, mixer amplifier, intermediate power amplifiers, and klystron power-amplifier. By this means the various modulator pulses are made to occur at the same time.

This transmitter produces output rf pulses of constant power and minimum frequency modulation and ensures good performance.

Q22. What is the primary advantage of power-amplifier transmitters over keyed-oscillator transmitters?

Q23. In the power amplifier shown in figure 2-10, what two signals are mixed to produce the output signal?

Q24. What type of klystron is used as the final stage of a power-amplifier transmitter?

Figure 2-11 is a block diagram of a power-amplifier transmitter that uses a FREQUENCY SYNTHESIZER to produce the transmitted frequency rather than the heterodyning mixer. The frequency synthesizer allows the transmitter to radiate a large number of discrete frequencies over a relatively wide band. Such a system is commonly used with frequency-scan search radars that must transmit many different frequencies to achieve elevation coverage and to compensate for the roll and pitch of a ship.

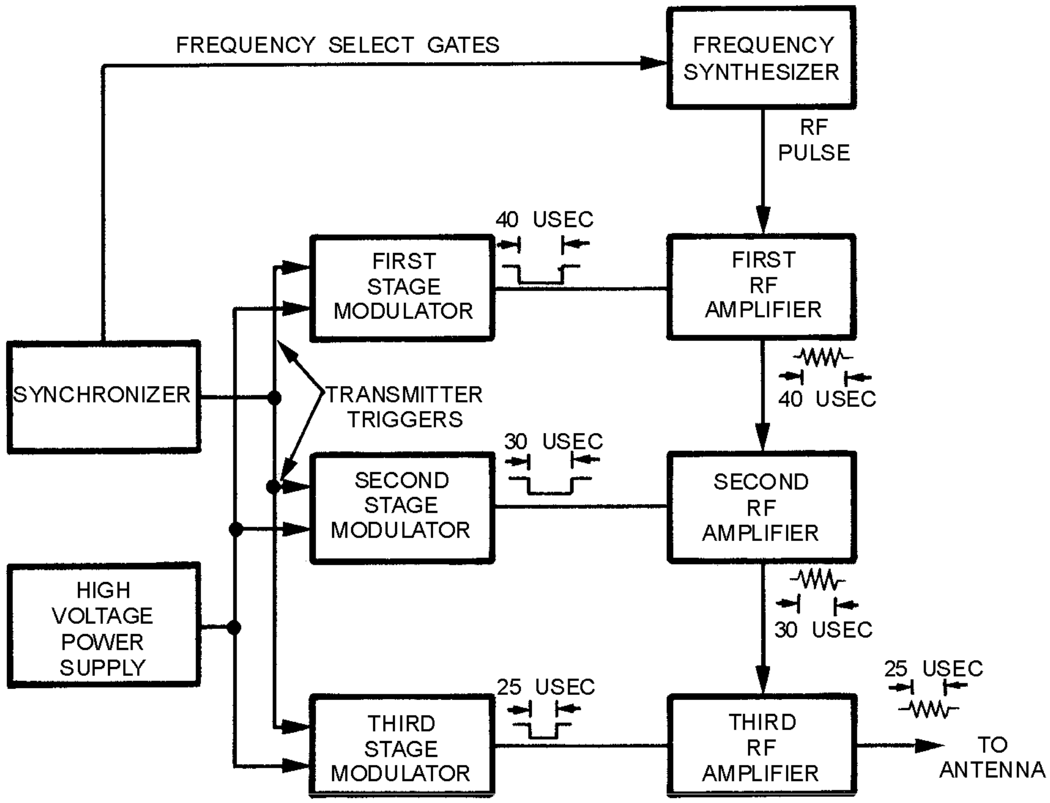

Figure 2-11.—Power amplifier transmitter using crossed-field amplifiers.

A typical frequency synthesizer consists of a bank of oscillators producing different fixed frequencies. The outputs of a relatively few fixed oscillators can be mixed in various combinations to produce a wide range of frequencies. In mti systems the selected oscillator frequencies are mixed with a coherent oscillator frequency to provide a stable reference for the mti circuits. The frequency synthesizer also produces the local oscillator signals for the receiver system. Because the transmitted pulse changes frequency on each transmission, the local oscillator signal to the receiver must also change and be included in the transmitted frequency. A system of this type is frequency-programmed by select gates from the synchronizer.

The detailed operation of frequency synthesizers is beyond the scope of this manual but may be found in the technical manuals for most frequency scan radar systems.

The first rf amplifier receives the pulses of the selected frequency from the synthesizer and a modulator pulse (from the first stage modulator) at the same time. The rf pulse is usually slightly wider than the modulator pulse which prevents the amplifier tube from pulsing when no rf energy is present. Most pulsed rf amplifiers will oscillate at an undesired frequency if pulsed without an rf input. The output of the first rf amplifier is an amplified rf pulse that is the same width as the first stage modulator pulse. The second stage modulator is designed to produce a pulse slightly narrower than the first stage modulator pulse; this also prevents the amplifier from pulsing when no rf is present. Therefore, the second stage amplifier receives a modulator pulse a short time after the first stage rf arrives at the input. As shown in figure 2-11, the same procedure is repeated in the third and final stage.

The amplifiers in this type of power-amplifier transmitter must be broad-band microwave amplifiers that amplify the input signals without frequency distortion. Typically, the first stage and the second stage are traveling-wave tubes (twt) and the final stage is a crossed-field amplifier. Recent technological advances in the field of solid-state microwave amplifiers have produced solid-state amplifiers with enough output power to be used as the first stage in some systems. Transmitters with more than three stages usually use crossed-field amplifiers in the third and any additional stages. Both traveling-wave tubes and crossed-field amplifiers have a very flat amplification response over a relatively wide frequency range.

Crossed-field amplifiers have another advantage when used as the final stages of a transmitter; that is, the design of the crossed-field amplifier allows rf energy to pass through the tube virtually unaffected when the tube is not pulsed. When no pulse is present, the tube acts as a section of waveguide. Therefore, if less than maximum output power is desired, the final and preceding cross-field amplifier stages can be shut off as needed. This feature also allows a transmitter to operate at reduced power, even when the final crossed-field amplifier is defective.

Q25. What transmitter component allows the radiation of a large number of discrete frequencies over a wide band?

Q26. What is the result of pulsing a pulsed rf amplifier when no rf is present?

DUPLEXERS

Whenever a single antenna is used for both transmitting and receiving, as in a radar system, problems arise. Switching the antenna between the transmit and receive modes presents one problem; ensuring that maximum use is made of the available energy is another. The simplest solution is to use a switch to transfer the antenna connection from the receiver to the transmitter during the transmitted pulse and back to the receiver during the return (echo) pulse. No practical mechanical switches are available that can open and close in a few microseconds. Therefore, ELECTRONIC SWITCHES must be used. Switching systems of this type are called DUPLEXERS.

BASIC DUPLEXER OPERATION

In selecting a switch for this task, you must remember that protection of the receiver input circuit is as important as are output power considerations. At frequencies where amplifiers may be used, amplifier tubes can be chosen to withstand large input powers without damage. However, the input circuit of the receiver is easily damaged by large applied signals and must be carefully protected.

An effective radar duplexing system must meet the following four requirements:

1. During the period of transmission, the switch must connect the antenna to the transmitter and disconnect it from the receiver.

2. The receiver must be thoroughly isolated from the transmitter during the transmission of the high-power pulse to avoid damage to sensitive receiver components.

3. After transmission, the switch must rapidly disconnect the transmitter and connect the receiver to the antenna. For targets close to the radar to be seen, the action of the switch must be extremely rapid.

4. The switch should absorb an absolute minimum of power both during transmission and reception.

Therefore, a radar duplexer is the microwave equivalent of a fast, low-loss, single-pole, double-throw switch. The devices developed for this purpose are similar to spark gaps in which high-current microwave discharges furnish low-impedance paths. A duplexer usually contains two switching tubes (spark gaps) connected in a microwave circuit with three terminal transmission lines, one each for the transmitter, receiver, and antenna. As shown in views A and B of figure 2-12, these circuits may be connected in parallel or in series. Both systems will be discussed in detail in this section. One tube is called the TRANSMIT-RECEIVER TUBE, or TR TUBE; the other is called the ANTITRANSMIT-RECEIVE TUBE, or ATR TUBE. The tr tube has the primary function of disconnecting the receiver, and the atr tube of disconnecting the transmitter.

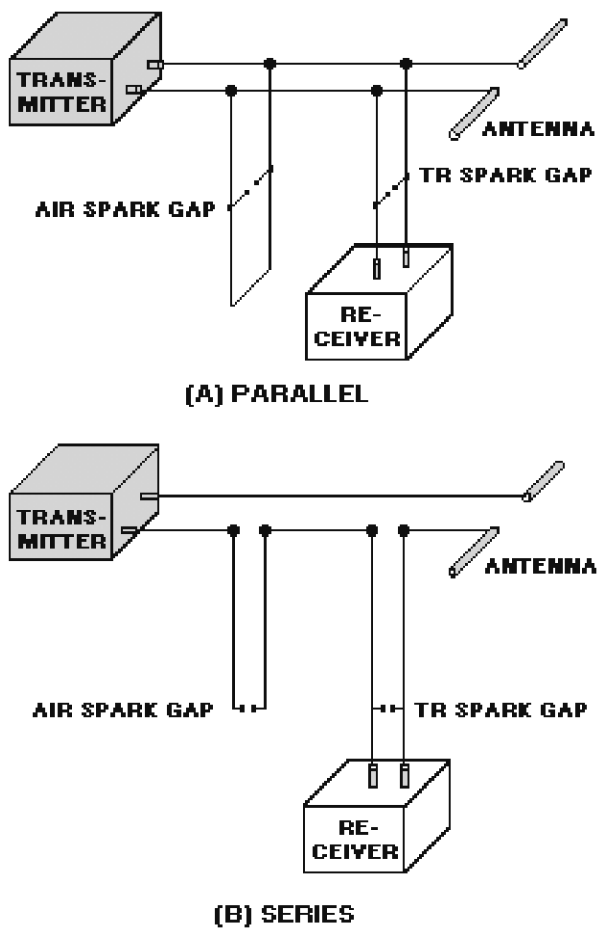

Figure 2-12.—Duplexer systems.

The overall action of the tr and atr circuits depends upon the impedance characteristics of the quarter-wavelength section of transmission line. A quarter-wavelength, or an odd multiple of the quarter-wavelength, transmission line presents opposite impedance values at the ends; one end of the line appears as a short and the other end appears as an open.

TR Tube

The type of spark gap used as a tr tube may vary. It may be one that is simply formed by two electrodes placed across the transmission line; or it may be one enclosed in an evacuated glass envelope with special features to improve operation. The requirements of the spark gap are (1) high impedance prior to the arc and (2) very low impedance during arc time. At the end of the transmitted pulse the arc should be extinguished as rapidly as possible. Extinguishing the arc stops any loss caused by the arc and permits signals from nearby targets to reach the receiver.

The simple gap formed in air has a resistance during conduction of from 30 to 50 ohms. This is usually too high for use with any but an open-wire transmission line. The time required for the air surrounding the gap to completely deionize after the pulse voltage has been removed is about 10 microseconds. During this time the gap acts as an increasing resistance across the transmission line to which it is connected. However, in a tr system using an air gap, the echo signals reaching the receiver beyond the gap will be permitted to increase to half their proper magnitude 3 microseconds after the pulse voltage has been removed. This interval is known as RECOVERY TIME.

Tr tubes are usually conventional spark gaps enclosed in partially evacuated, sealed glass envelopes, as shown in figure 2-13. The arc is formed as electrons are conducted through the ionized gas or vapor. You may lower the magnitude of voltage necessary to break down a gap by reducing the pressure of the gas that surrounds the electrodes. Optimum pressure achieves the most efficient tr operation. You can reduce the recovery time, or DEIONIZATION TIME, of the gap by introducing water vapor into the tr tube. A tr tube containing water vapor at a pressure of 1 millimeter of mercury will recover in 0.5 microseconds. It is important for a tr tube to have a short recovery time to reduce the range at which targets near the radar can be detected. If, for example, echo signals reflected from nearby objects return to the radar before the tr tube has recovered, those signals will be unable to enter the receiver.

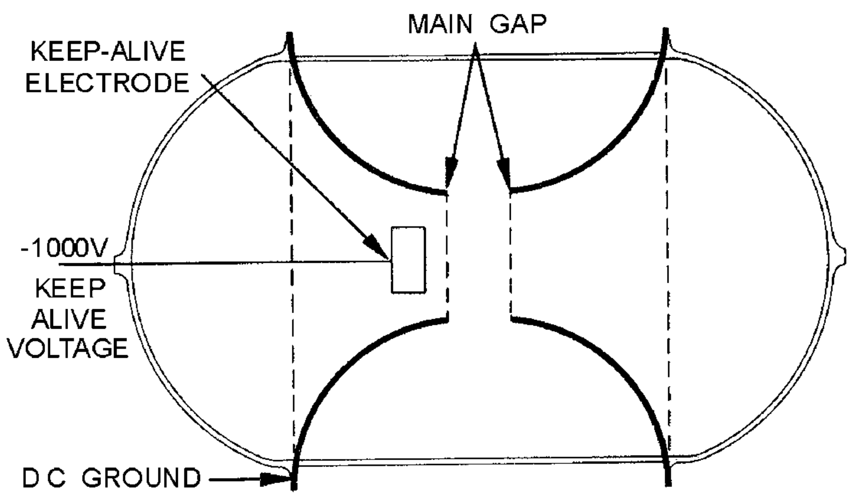

Figure 2-13.—Tr tube with keep-alive electrode.

Tr tubes used at microwave frequencies are built to fit into, and become a part of, a resonant cavity. You may increase the speed with which the gap breaks down after the transmitter fires by placing a voltage across the gap electrodes. This potential is known as KEEP-ALIVE VOLTAGE and ranges from 100 volts to 1,000 volts. A glow discharge is maintained between the electrodes. (The term GLOW DISCHARGE refers to the discharge of electricity through a gas-filled electron tube. This is distinguished by a cathode glow and voltage drop much higher than the gas-ionization voltage in the cathode vicinity.) This action provides for rapid ionization when the transmitter pulse arrives.

Failure of the tr tube is primarily caused by two factors. The first and most common cause of failure is the gradual buildup of metal particles that have been dislodged from the electrodes. Such metal bits become spattered on the inside of the glass envelope. These particles act as small, conducting areas and tend to lower the Q of the resonant cavity and dissipate power. If the tube continues in use for too long a period in this condition, the particles will form a detuning wall within the cavity and eventually prevent the tube from functioning. A second cause of failure is the absorption of gas within the enclosure by the metal electrodes. This results in a gradual reduction of pressure within the tube to a point where gap breakdown becomes very difficult. The final result is that extremely strong signals (from the transmitter) are coupled to the receiver. Because both types of failures develop gradually, the tr tube periodically must be checked carefully to determine performance level.

Q27. What type of switches are used as duplexers?

Q28. What tube in a duplexer has the primary function of disconnecting the receiver?

Q29. How may the tr tube ionization speed be increased?

ATR Tube

The atr tube is usually a simpler device than a tr tube. An atr tube might use a pure inert gas, such as argon, because recovery time generally is not a vital factor. Furthermore, a priming agent, such as keep-alive voltage, is not needed. The absence of either a chemically active gas or a keep-alive voltage results in atr tubes having longer useful lives than tr tubes.

WARNING

Tr and atr tubes may contain radioactive material. Handle with care to avoid breakage and possible contamination.

There are two basic tr-atr duplexer configurations. They are the parallel-connected and the series-connected duplexer systems. The following paragraphs describe the operation of both systems.

Parallel Connected Duplexer Operation

First, let's consider a PARALLEL-CONNECTED DUPLEXER system, as shown in figure 2-14. The tr spark gap shown in figure 2-14 is located in the receiver coupling line one-quarter wavelength from the T-junction. A half-wavelength, closed-end section of transmission line, called a STUB, is shunted across the main transmission line. An atr spark gap is located in this line one-quarter wavelength from the main transmission line and one-quarter wavelength from the closed end of the stub. As shown in the figure, antenna impedance, line impedance, and transmitter output impedance, when transmitting, are all equal. The action of the circuit during transmission is shown in figure 2-15.

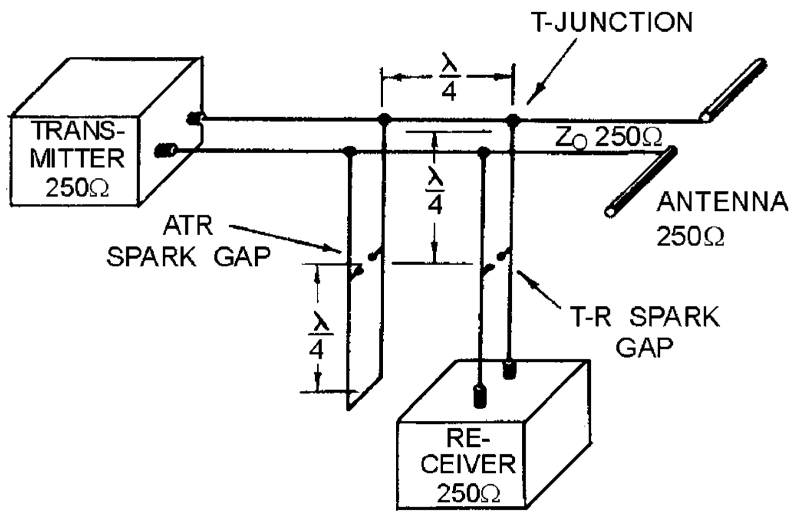

Figure 2-14.—Parallel-connected duplexer showing distance and impedance.

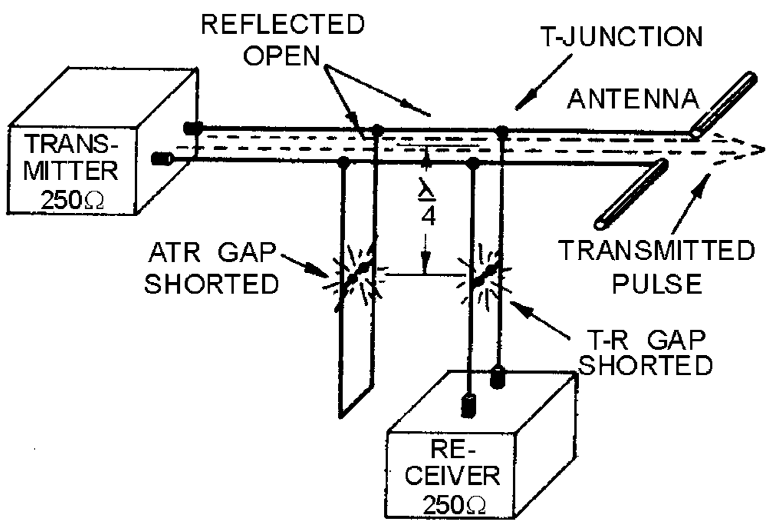

Figure 2-15.—Parallel-connected duplexer during transmission.

During the transmitting pulse, an arc appears across both spark gaps and causes the tr and atr circuits to act as shorted (closed-end) quarter-wave stubs. The circuits then reflect an open circuit to the tr and atr circuit connections to the main transmission line. None of the transmitted energy can pass through these reflected opens into the atr stub or into the receiver. Therefore, all of the transmitted energy is directed to the antenna.

During reception, as shown in figure 2-16, the amplitude of the received echo is not sufficient to cause an arc across either spark gap. Under this condition, the atr circuit now acts as a half-wave transmission line terminated in a short-circuit. This is reflected as an open circuit at the receiver T-junction, three-quarter wavelengths away. The received echo sees an open circuit in the direction of the transmitter. However, the receiver input impedance is matched to the transmission line impedance so that the entire received signal will go to the receiver with a minimum amount of loss.

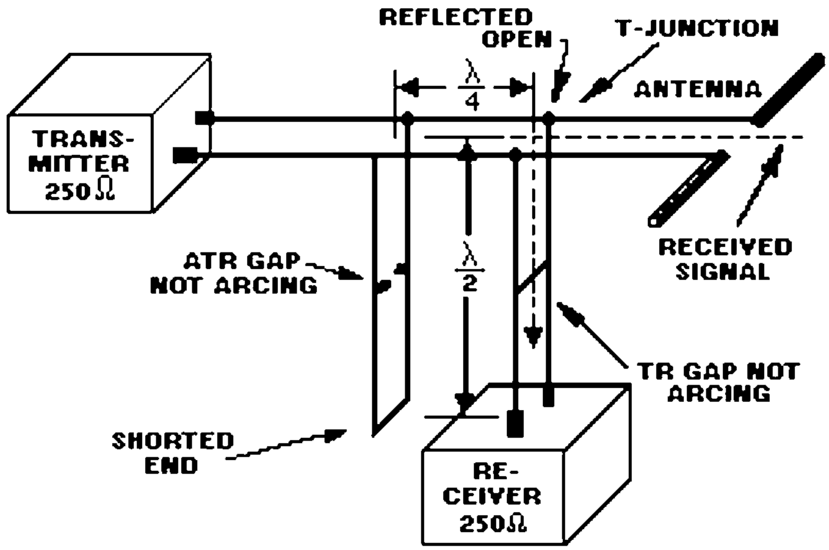

Figure 2-16.—Parallel-connected duplexer during reception.

Series-Connected Duplexer Operation

In the SERIES-CONNECTED DUPLEXER SYSTEM, shown in figure 2-17, the tr spark gap is located one-half wavelength from the receiver T-junction. The atr spark gap is located one-half wavelength from the transmission line and three-quarters wavelength from the receiver T-junction. During transmission, the tr and atr gaps fire in the series-connected duplexer system, as shown in figure 2-18. This causes a short-circuit to be reflected at the series connection to the main transmission line one-half wavelength away. The transmitted pulse "sees" a low impedance path in the direction of the antenna and does not go into the atr stub or the receiver.

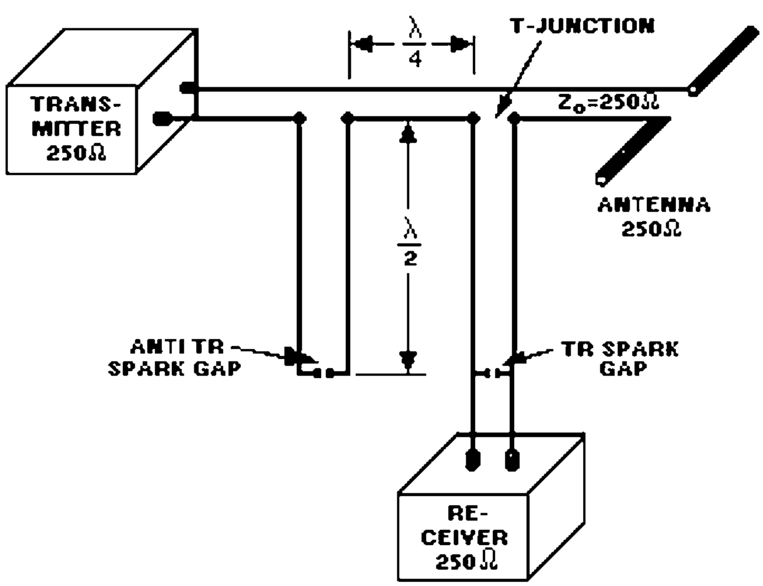

Figure 2-17.—Series-connected duplexer showing distance and impedance.

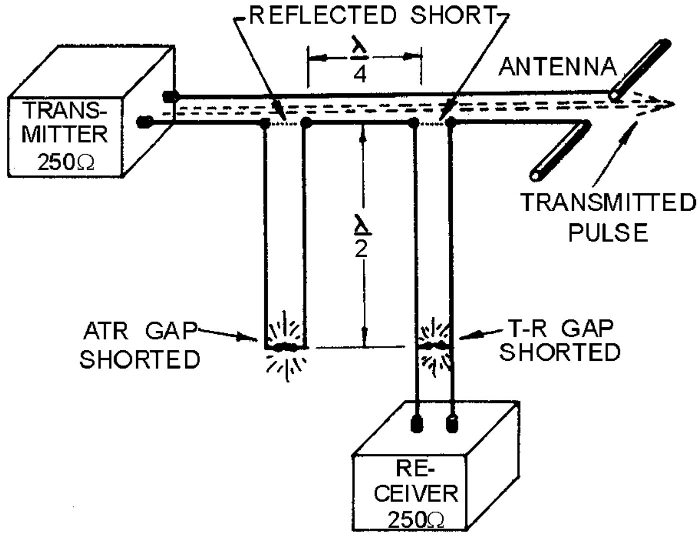

Figure 2-18.—Series-connected duplexer during transmission.

During reception, neither spark gap is fired, as shown in figure 2-19. The atr acts as a half-wave stub terminated in an open. This open is reflected as a short-circuit at the T-junction three-quarters of a wavelength away. Consequently, the received signal sees a low impedance path to the receiver, and none of the received signal is lost in the transmitting circuit.

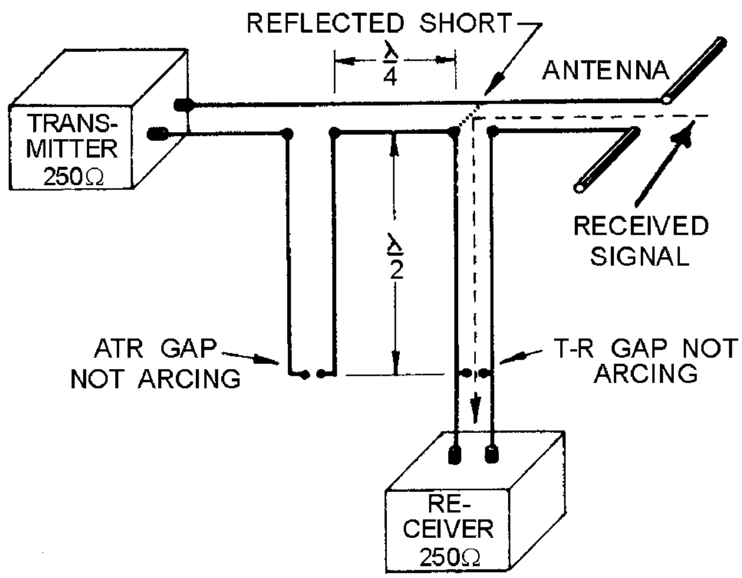

Figure 2-19.—Series-connected duplexer during reception.

DUPLEXER TYPES

Duplexers are constructed in many forms, such as RESONANT-CAVITY COAXIAL SYSTEMS, WAVEGUIDE SYSTEMS, and HYBRID RINGS. Since waveguide and hybrid-ring duplexers are most common in radar systems, those will be discussed in this section.

Waveguide Duplexer

WAVEGUIDE DUPLEXERS usually consist of tr tubes and atr tubes housed in a resonant cavity and attached to a waveguide system in some manner. Resonant-cavity tr tubes may be applied to waveguides, either directly or indirectly, to obtain switching action. The indirect method uses a coaxial line system, and then couples the coaxial line into the waveguide that feeds the antenna. If large losses are incurred by the use of a coaxial line, the resonant cavity can be coupled directly to the waveguide. Figure 2-20 shows a direct method of cavity tr switching in a waveguide system. The waveguide terminates in the antenna at one end and in a shorting plate at the other. The magnetron uses a voltage probe to excite the waveguide. The transmitted pulse travels up the guide and moves into the tr box through a slot. The cavity builds up a strong electric field across the gap, breaks it down, and detunes the cavity. This action effectively seals the opening and passes the pulse energy to the antenna.

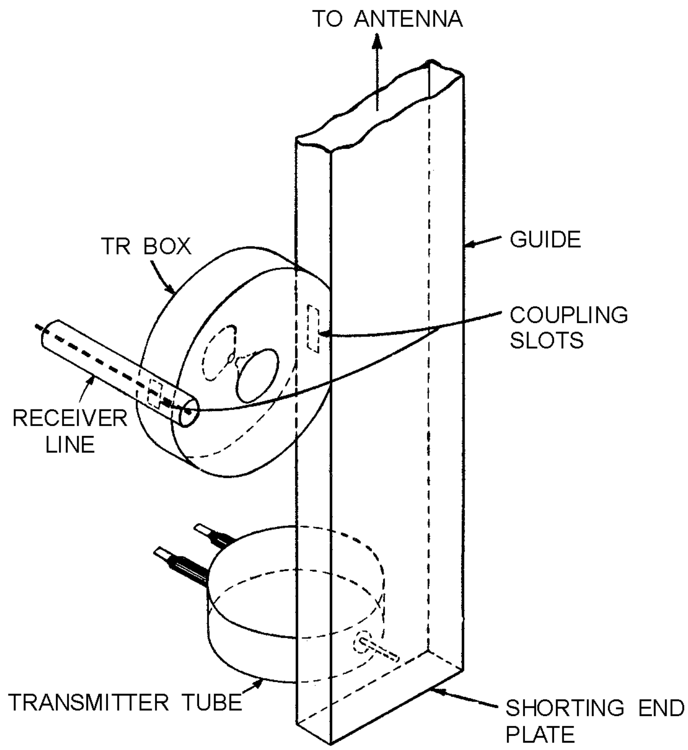

Figure 2-20.—Waveguide duplexer with cavity tr tube.

The signals received during the resting time travel down the guide to the magnetron and the shorting end plate where they are reflected. The slot coupling the waveguide to the cavity is located at a point where the standing-wave magnetic field produced by reflections in the waveguide is maximum. The maximum magnetic field, therefore, energizes the cavity. The echo signals are not strong enough to cause an arc, and the cavity field is undisturbed by the gap. Therefore, the cavity field couples rf energy into the receiver coaxial line and provides maximum energy transfer.

The cavity tr switch can also be applied to branch lines of the waveguide, as shown in figure 2-21. The magnetron is coupled to the guide by a voltage probe to produce proper excitation.

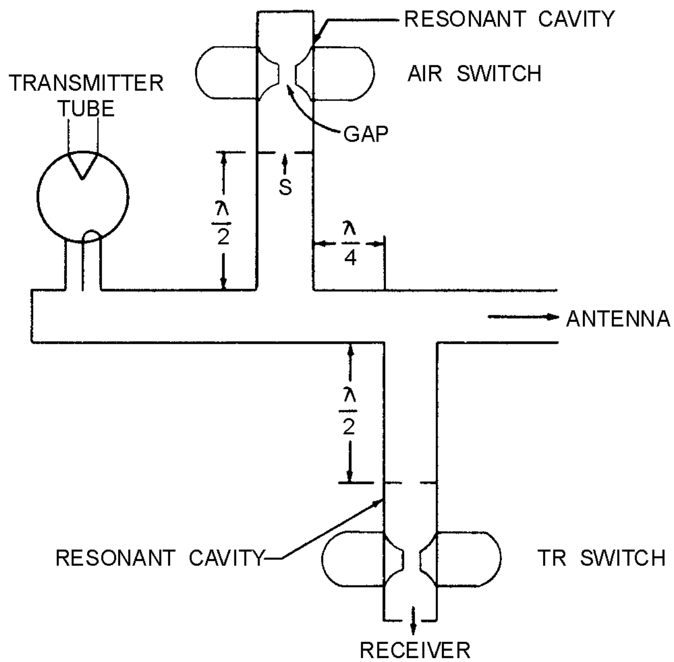

Figure 2-21.—Branched waveguide duplexer.

Maximum use of the received signals is ensured by an atr tube. The transmitted pulse travels from the magnetron to the atr branch where part of the energy is diverted into the gap. A slot (S) is placed across the waveguide one-half wavelength from the main guide, and passes the rf energy through it and into the cavity. The cavity builds up the electric field that breaks down the gap, detunes the cavity, and, as a result, effectively closes the slot. One-half wavelength away, this action effectively closes the entrance to the atr branch and limits the amount of energy entering the atr branch to a small value.

Most of the energy is, therefore, directed down the guide to the antenna. Upon reaching the receiver branch, the same effect is produced by the tr tube in the receiver line. Because the energy entering both openings is effectively limited by the gaps, maximum energy is transferred between the magnetron and the antenna.

During the resting time, the atr spark gap is not broken down by the received signals. The received signal sets up standing waves within the cavity that cause it to resonate. At resonance, the low impedance of the atr cavity is reflected as a high impedance at the entrance to the transmitter waveguide (three-quarter wavelength away). This ensures that the maximum received signal will enter the receiver branch.

Hybrid Ring Duplexer

The HYBRID RING is used as a duplexer in high-power radar systems. It is very effective in isolating the receiver during transmission. A simplified version of the hybrid-ring duplexer is shown in views A and B of figure 2-22. The operation of the duplexer, in terms of the E field distribution during transmission and reception, is illustrated in views C and D. The H lines, though present, have been omitted to simplify the explanation.

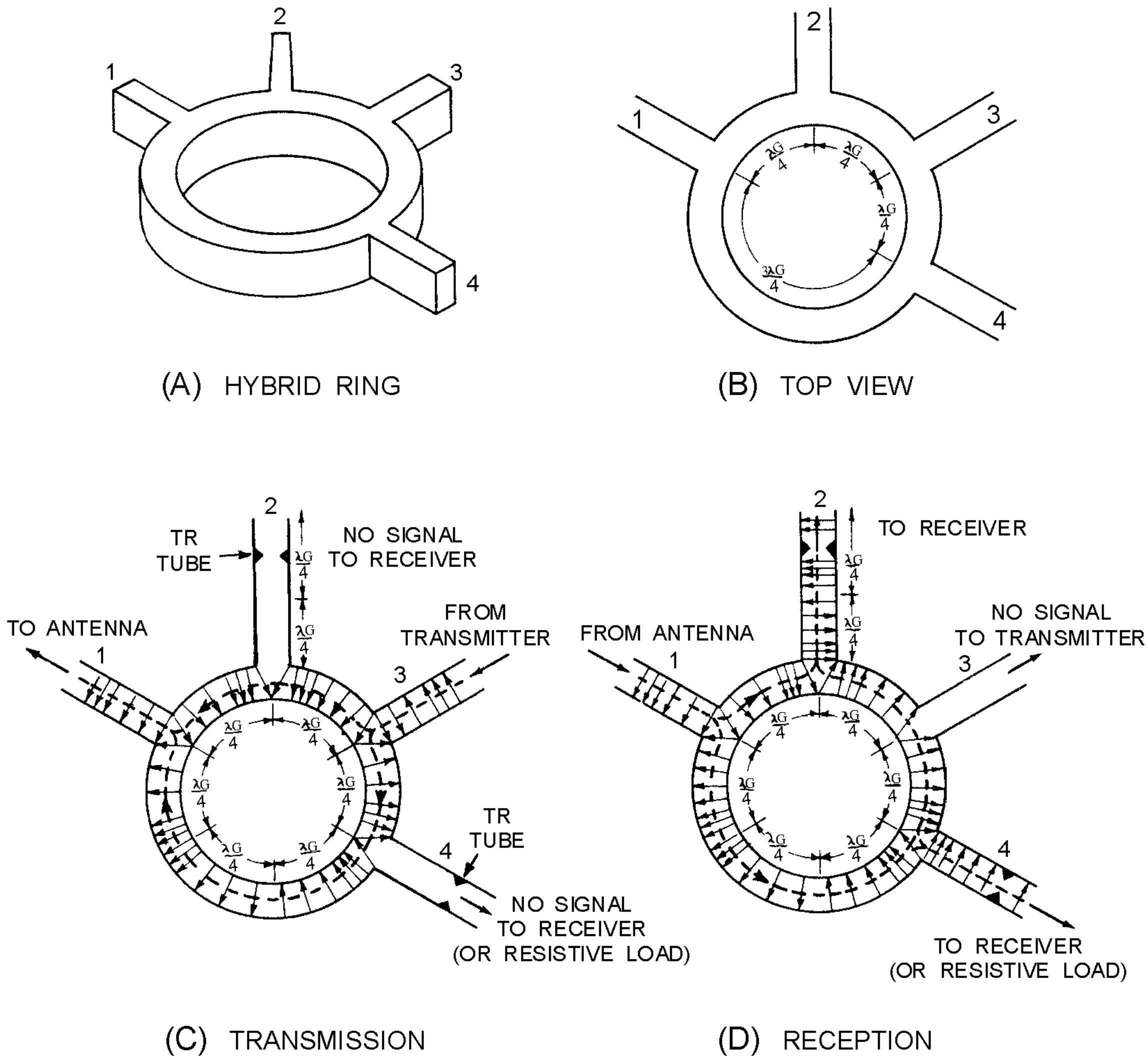

Figure 2-22.—Hybrid-ring duplexer.

During transmission the E field from the transmitter enters arm 3 and divides into two fields 180 degrees out of phase. One field moves clockwise around the ring and the other moves counterclockwise. The two fields must be 180 degrees out of phase at the entrance of an arm to propagate any energy down the arm. The field moving clockwise from arm 3 ionizes the tr tube in arm 4, and the energy is blocked from the receiver. The tr tube reflects a high impedance equivalent to an open circuit. This high impedance prevents any energy from entering the receiver - even though the two fields are out of phase at the entrance to arm 4. The field moving counterclockwise from arm 3 ionizes the tr tube in arm 2, which reflects a short circuit back to the ring junction. No energy is sent to the receiver, however, because the fields arriving at arm 2 are in phase. The clockwise and counterclockwise fields arrive at arm 1 out of phase by 180 degrees. They are then propagated through the arm to the antenna.

During reception, the relatively weak field from the antenna enters arm 1 and divides at the junction into two out-of-phase components. Neither field is sufficient to fire the tr tubes in arms 2 and 4; since the fields arrive at these arms out of phase, energy is propagated to the receiver. The energy arriving at arm 3 is in phase and will not be coupled to the transmitter. Since the operation of the arms of a hybrid ring is the same as the operation of E-type waveguide T-junctions, you may find it helpful to review NEETS, Module 11, *Microwave Principles*.

Q30. The actions of the tr and atr circuits depend on the impedance characteristics of what length of transmission line?

Q31. During which of the transmit or receive cycles are both the tr and atr tubes of a parallel-connected duplexer ionized (arcing)?

Q32. In a series-connected duplexer, what tube (tr or atr), if any, fires during the receive cycle?

Q33. To propagate energy down an arm of a hybrid ring duplexer, the two fields at the junction of the arm and the ring must have what phase relationship?

RECEIVERS

The energy that a distant object reflects back to the antenna in a radar system is a very small fraction of the original transmitted energy. The echoes return as pulses of rf energy of the same nature as those sent out by the transmitter. However, the power of a return pulse is measured in fractions of microwatts instead of in kilowatts, and the voltage arriving at the antenna is in the range of microvolts instead of kilovolts. The radar receiver collects those pulses and provides a visual display of object information.

Information about the position of the object is present visually when the reception of an echo causes the movement or appearance of a spot of light on a cathode-ray tube (crt). The crt requires a signal on the order of at least several volts for proper operation and will not respond to the high frequencies within a return pulse. Therefore, a receiver amplifier and detector must be used that are capable of producing a visible indication on the cathode-ray tube under the following conditions: (1) when the input signal to the amplifier is in the form of pulses of extremely high-frequency, (2) the amplitude of the pulses is in the microvolt range, and (3) the pulses last for only a few microseconds.

The radar receiver evolved directly from the simple radio receiver. The radar receiver operates on exactly the same principles as the radio receiver. However, the overall requirements and limitations of a radar receiver differ somewhat from those of a radio receiver because of the higher frequencies involved and the greater sensitivity desired.

In studying the radar receiver, we will first examine the overall requirements of a radar receiver. Second, we will examine a typical radar receiver that satisfies these requirements. Finally, we will discuss the individual components of the receiver.

RADAR RECEIVER REQUIREMENTS

The following characteristics determine the design requirements of an effective radar receiver:

- Noise
- Gain
- Tuning
- Distortion
- Blocking

Noise

The word NOISE is a carryover from sound-communications equipment terminology. Noise voltages in sound equipment produce actual noise in the loudspeaker output. In radar, noise voltages result in erratic, random deflection or intensity of the indicator sweep that can mask small return signals.

Were it not for noise, the maximum range at which an object would be detectable by radar could be extended almost infinitely. Objects at great range return exceedingly small echoes. However, without noise, almost any signal could be amplified to a usable level if enough stages were added to the receiver. Because of noise, the signal detection limit or sensitivity level of a receiver is reached when the signal level falls below the noise level to such an extent as to be obscured. A simple increase of amplification is of no help because both signal and noise are amplified at the same rate.

In the radar portion of the rf spectrum, external sources of noise interference are usually negligible; consequently, the sensitivity that can be achieved in a radar receiver is usually determined by the noise produced in the receiver. Not only must noise be kept down, but everything possible must be done to minimize attenuation of the video signal (echo) before it is amplified.

Gain

The GAIN of a radar receiver must be very high. This is because the strength of the signal at the antenna is at a level of microvolts and the required output to the indicator is several volts. The gain of a radar receiver is roughly in the range of 10^6 to 10^8. FEEDBACK, or REGENERATION, is one of the most serious difficulties in the design of an amplifier with such high gain. Special precautions must be taken to avoid feedback. Such precautions include careful shielding, decoupling (isolation) between voltage supplies for the different tubes, and amplification at different frequencies in separate groups of stages.

Tuning

The radar receiver requires a limited tuning range to compensate for transmitter and local oscillator frequency changes because of variations in temperature and loading. Microwave radar receivers usually use automatic frequency control (afc) for this purpose.

Distortion

If distortion occurs in the receiver, the time interval between the transmitted pulse and the received pulse changes, thereby affecting range accuracy.

Blocking

BLOCKING refers to a condition of the receiver in which the voltage pulse at the receiver input is too large. As a result, for a short time after the pulse, the receiver is insensitive or blocked to signals below a certain level. This condition results from one or more of the amplifier stages in the receiver being overdriven. After a strong pulse, the receiver may be biased to a point at which it will not amplify small signals. Recovery after blocking may be only a fraction of a microsecond, or it may take several hundred microseconds, depending upon the point in the receiver at which blocking occurs. To detect a weak echo immediately following a strong one, the receiver must have a short BLOCKING RECOVERY TIME. The blocking itself must be minimized as much as possible. If a portion of the transmitted pulse leaks into the receiver input, then the receiver may be blocked and not show small, nearby objects. In most receivers, blocking is minimized from this cause by a duplexer. The duplexer protects the receiver by isolating it during the transmitted pulse.

RECEIVER BLOCK DIAGRAM

The SUPERHETERODYNE receiver is almost always used in microwave radar systems. A typical superheterodyne radar receiver is shown in figure 2-23. A receiver of this type meets all the requirements listed above. Signals from the antenna enter the receiver via the duplexer. A low-noise rf amplifier is usually the first stage of modern radar receivers. Some receivers, however, send the antenna signal directly to the mixer, as shown by the dashed path. The low-noise amplifiers used in modern systems are usually solid-state devices, such as tunnel-diode, parametric, or microwave transistor amplifiers.

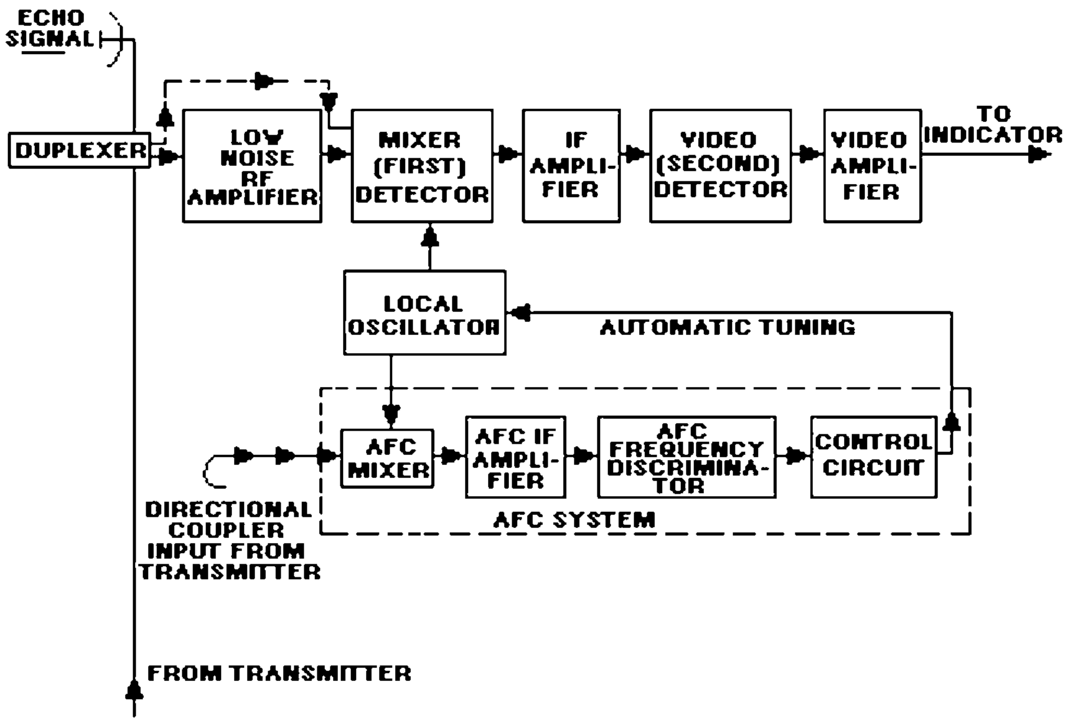

Figure 2-23.—Typical superheterodyne radar receiver.

The MIXER stage is often called the FIRST DETECTOR. The function of this stage is to convert the received rf energy to a lower, intermediate frequency (IF) that is easier to amplify and manipulate electronically. The intermediate frequency is usually 30 or 60 megahertz. It is obtained by heterodyning the received signal with a local-oscillator signal in the mixer stage. The mixer stage converts the received signal to the lower IF signal without distorting the data on the received signal.

After conversion to the intermediate frequency, the signal is amplified in several IF AMPLIFIER stages. Most of the gain of the receiver is developed in the IF amplifier stages. The overall bandwidth of the receiver is often determined by the bandwidth of the IF stages.

The output of the IF amplifiers is applied to the SECOND DETECTOR. It is then rectified and passed through one or more stages of amplification in the video amplifier(s). The output stage of the receiver is normally an emitter follower. The low-impedance output of the emitter follower matches the impedance of the cable. The video pulses are coupled through the cable to the indicator for video display on the crt.

As in all superheterodyne receivers, controlling the frequency of the local oscillator keeps the receiver tuned. Since this tuning is critical, some form of automatic frequency control (afc) is essential to avoid constant manual tuning. Automatic frequency control circuits mix an attenuated portion of the transmitted signal with the local oscillator signal to form an IF signal. This signal is applied to a frequency-sensitive discriminator that produces an output voltage proportional in amplitude and polarity to any change in IF frequency. If the IF signal is at the discriminator center frequency, no discriminator output occurs. The center frequency of the discriminator is essentially a reference frequency for the IF signal. The output of the DISCRIMINATOR provides a control voltage to maintain the local oscillator at the correct frequency.

Different receiving systems may vary in the type of coupling between stages, the type of mixer, the detector, the local oscillator, and the number of stages of amplification at the different frequencies. However, the receiver is always designed to have as little noise as possible. It is also designed to have sufficient gain so that noise, rather than lack of gain, limits the smallest visible signal.

RECEIVER COMPONENTS

This section will analyze in more detail the operation of the receiver circuits mentioned above. The circuits discussed are usually found in some form in all radar superheterodyne receivers.

Low-Noise Amplifier

LOW-NOISE AMPLIFIERS, sometimes called PREAMPS, are found in most modern radar receivers. As previously mentioned, these amplifiers are usually solid-state microwave amplifiers. The most common types are tunnel diode and parametric amplifiers. These amplifiers are discussed in detail in NEETS, Module 11, *Microwave Principles*. Some older systems may still use a traveling-wave tube (twt) as a low-noise first stage amplifier. However, the solid-state amplifiers produce lower noise levels and more gain.

Local Oscillator

Most radar receivers use a 30 or 60 megahertz intermediate frequency. The IF is produced by mixing a local oscillator signal with the incoming signal. The local oscillator is, therefore, essential to efficient operation and must be both tunable and very stable. For example, if the local oscillator frequency is 3,000 megahertz, a frequency change of 0.1 percent will produce a frequency shift of 3 megahertz. This is equal to the bandwidth of most receivers and would greatly decrease receiver gain.

The power output requirement for most local oscillators is small (20 to 50 milliwatts) because most receivers use crystal mixers that require very little power.

The local oscillator output frequency must be tunable over a range of several megahertz in the 4,000-megahertz region. The local oscillator must compensate for any changes in the transmitted frequency and maintain a constant 30 or 60 megahertz difference between the oscillator and the transmitter frequency. A local oscillator that can be tuned by varying the applied voltage is most desirable.

The REFLEX KLYSTRON is often used as a local oscillator because it meets all the requirements mentioned above. The reflex klystron is a very stable microwave oscillator that can be tuned by changing the repeller voltage.

Most radar systems use an automatic frequency control (afc) circuit to control the output of the local oscillator. A block diagram of a typical afc circuit is included in figure 2-23. Note that the afc circuits form a closed loop. This circuit is, in fact, often called the afc loop.

A sample of the transmitter energy is fed through the afc mixer and an IF amplifier to a discriminator. The output of the discriminator is a dc error voltage that indicates the degree of mistuning between the transmitter and the local oscillator. In this particular example let's assume that the IF is 30 megahertz. If the output of the mixer is correct, the discriminator will have no output. If the mixer output is above 30 megahertz, the output of the discriminator will be positive dc pulses; if the mixer output is below 30 megahertz, the discriminator output will be negative dc pulses. In either case, this output is fed through an amplifier to the control circuit. The control circuit adjusts the operating frequency of the local oscillator so that no mistuning exists and the IF is 30 megahertz. In this example the local oscillator is a reflex klystron and the control circuit provides he repeller plate voltage for the klystron; thus, the klystron directly controls the local oscillator frequency. In this manner the local oscillator is maintained exactly 30 megahertz below the transmitter frequency.

Q34. What is the greatest limiting factor in a receiver's detectable range?

Q35. What type of receiver is most often used in radar systems?

Q36. What IF frequencies are normally used in radar receivers?

Q37. Which component of the receiver produces the signal that is mixed with the received signal to produce the IF signal?

Mixer

Many older radar receivers do not use a low-noise amplifier as the receiver front end; they simply send the echo signal directly to a crystal mixer stage. A crystal is used rather than an electron-tube diode because, at microwave frequencies, the tube would generate excessive noise. Electron tubes are also limited by the effects of transit time at microwave frequencies. The crystal most commonly used is the point-contact crystal diode; however, recent developments in the field of solid-state microwave devices may soon replace the point-contact diode with devices that produce even less noise. The Schottky-barrier diode is an example of a relatively recent development that produces less noise than the point-contact crystal.

The simplest type of radar mixer is the SINGLE ENDED or UNBALANCED CRYSTAL MIXER, shown in figure 2-24. The mixer illustrated uses a tuned section of coaxial transmission line one-half wavelength long. This section matches the crystal to the signal echo and the local oscillator inputs. Local oscillator injection is accomplished by means of a probe. In the coaxial assembly, the signal is injected by means of a slot. This slot would normally be inserted in the duplexer waveguide assembly and be properly oriented to provide coupling of the returned signal. In this application, the unwanted signals at the output of the mixer (carrier frequency, the local oscillator frequency, and sum of these two signals) are effectively eliminated by a resonant circuit tuned to the intermediate, or difference frequency. One advantage of the unbalanced crystal mixer is its simplicity. It has one major disadvantage; its inability to cancel local oscillator noise. Difficulty in detecting weak signals will exist if noise is allowed to pass through the mixer along with the signal.

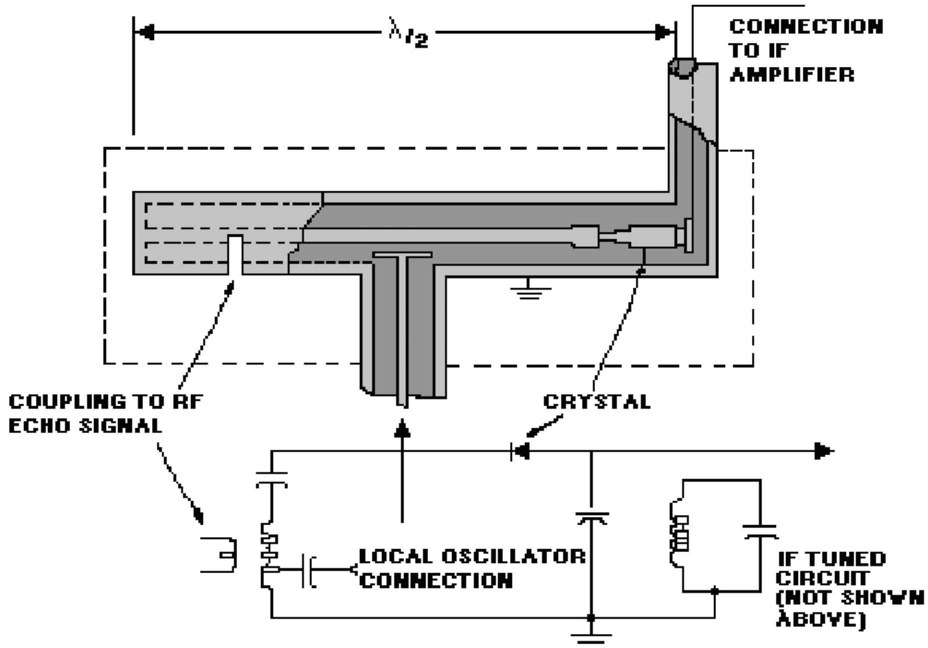

Figure 2-24.—Single-ended crystal mixer.

One type of mixer which cancels local oscillator noise is the BALANCED, OR HYBRID, MIXER (sometimes called the MAGIC T). Figure 2-25 shows this type of mixer. In hybrid mixers, crystals are inserted directly into the waveguide. The crystals are located one-quarter wavelength from their respective short-circuited waveguide ends (a point of maximum voltage along a tuned line). The crystals are also connected to a balanced transformer, the secondary of which is tuned to the desired IF. The local oscillator signal is introduced into the waveguide local oscillator arm and distributes itself as shown in view A of figure 2-26. Observe that the local oscillator signal is in phase across the crystals. In view B the echo signal is introduced into the echo signal arm of the waveguide and is out of phase across the crystals. The resulting fields are shown in view C.

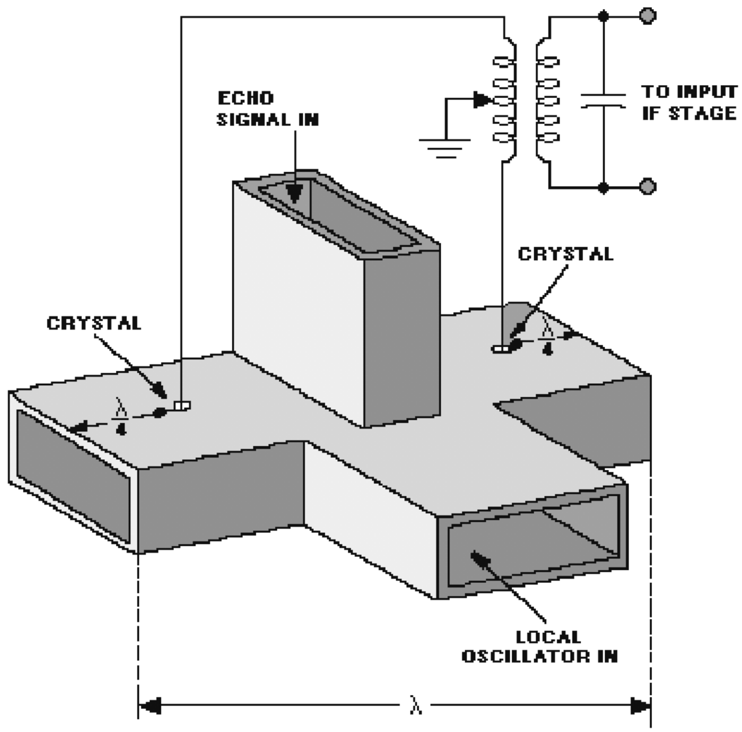

Figure 2-25.—Balanced (hybrid) crystal mixer.

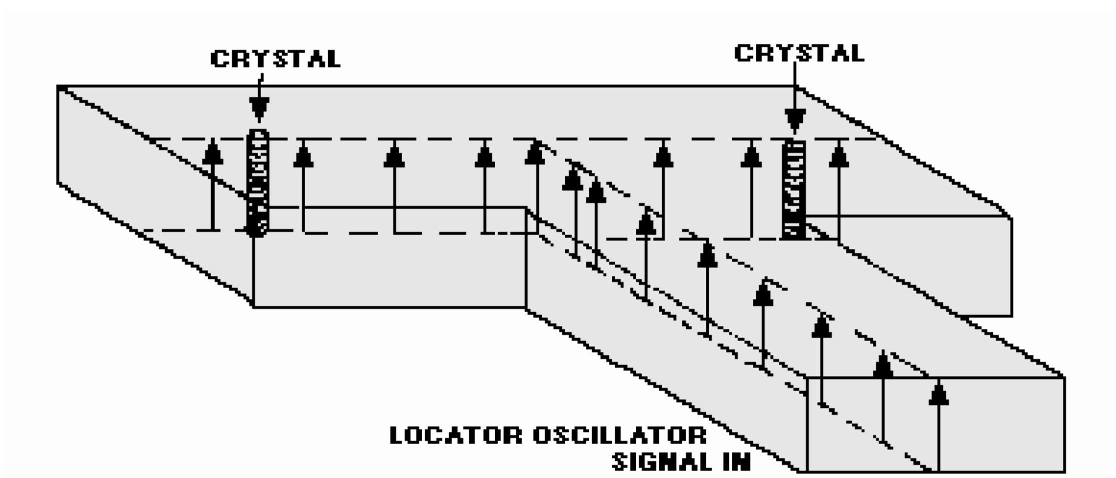

Figure 2-26A.—Balanced mixer fields. WAVEGUIDE AND LOCAL OSCILLATOR ARM.

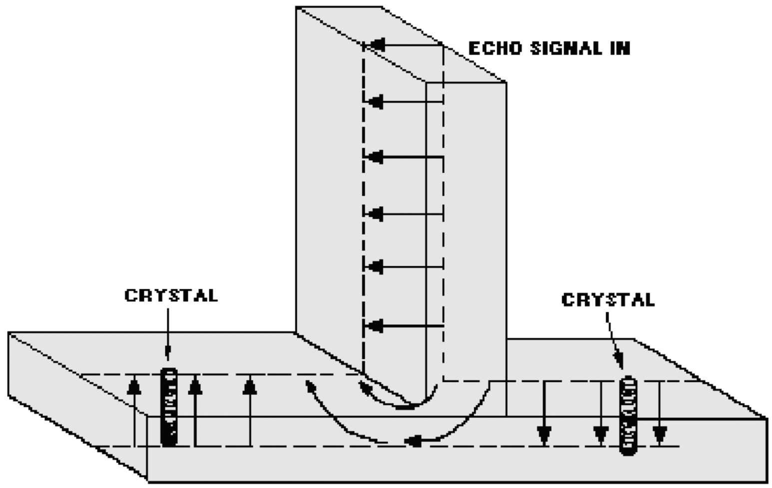

Figure 2-26B.—Balanced mixer fields. WAVEGUIDE AND ECHO SIGNAL ARM.

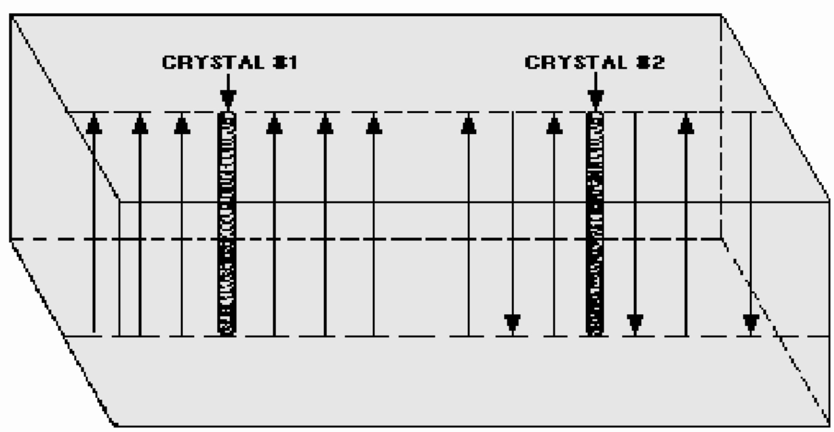

Figure 2-26C.—Balanced mixer fields. WAVEGUIDE.

A difference in phase exists between echo signals applied across the two crystals. The signal applied to the crystals from the local oscillator is in phase. Therefore, at some point both signals applied to crystal #1 will be in phase, and the signals applied to crystal #2 will be out of phase. This means that an IF signal of one polarity will be produced across crystal #1 and an IF signal of the opposite polarity will be produced across crystal #2. When these two signals are applied to the balanced output transformer (figure 2-25), they will add. Outputs of the same polarity will cancel across the balanced transformer.

This action eliminates the noise of the local oscillator. Noise components introduced from the local oscillator are in phase across the crystals and are, therefore, cancelled in the balanced transformer. The rf characteristics of the crystals must be nearly equal, or the noise of the local oscillator will not completely cancel. Note that only the noise produced by the local oscillator is canceled. Noise arriving with the echo signal is not affected.

IF Amplifier Stage

The IF AMPLIFIER SECTION of a radar receiver determines the gain, signal-to-noise ratio, and effective bandwidth of the receiver. The typical IF amplifier (commonly called an IF strip) usually contains from three to ten amplifier stages. The IF amplifier has the capability to vary both the bandpass and the gain of a receiver. Normally, the bandpass is as narrow as possible without affecting the actual signal energy. When a selection of pulse widths is available, such as short and long pulses, the bandpass must be able to match the bandwidth of the two different signals. Gain must be variable to provide a constant voltage output for input signals of different amplitudes. Figure 2-27 is a block diagram of an IF amplifier that meets these requirements.

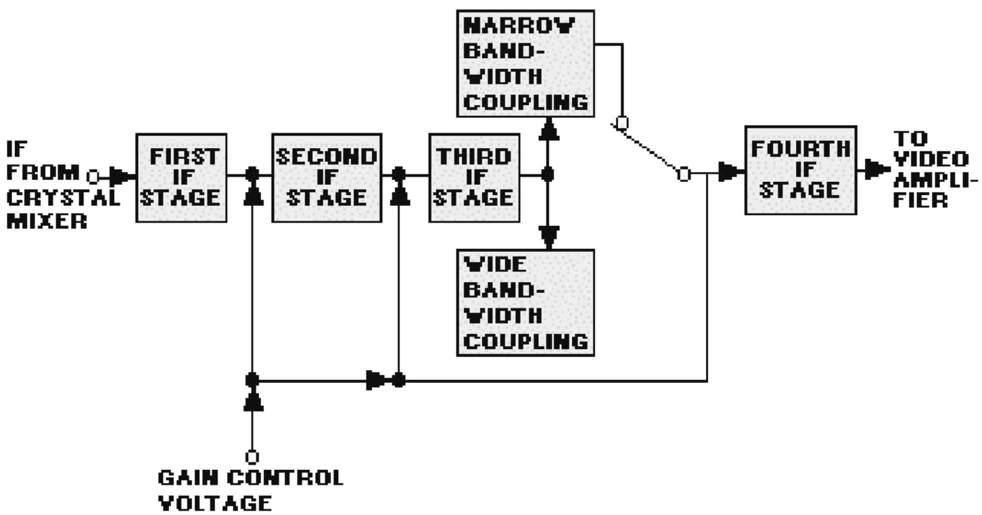

Figure 2-27.—IF amplifier block diagram.

The most critical stage of the IF section is the input (first stage). The quality of this stage determines the noise figure of the receiver and the performance of the entire receiving system with respect to detection of small objects at long ranges. Gain and bandwidth are not the only considerations in the design of the first IF stage. A consideration perhaps of more importance is noise generation. Noise generation in this stage must be low. Noise generated in the input IF stage will be amplified by succeeding stages and may exceed the echo signal in strength.

Detectors

The detector in a microwave receiver serves to convert the IF pulses into video pulses. After amplification, these are applied to the indicator. The simplest form of detector, and the one most commonly used in microwave receivers, is the DIODE DETECTOR.

A diode detector circuit is shown in view A of figure 2-28. The secondary of T1 and C1 form a tuned circuit that is resonant at the intermediate frequency. Should an echo pulse of sufficient amplitude be received, the voltage (e_i) developed across the tuned circuit is an IF pulse. Its shape is indicated by the dashed line in view B. Positive excursions of e_i cause no current to flow through the diode. However, negative excursions result in a flow of diode current and a subsequent negative voltage (e_o) to be developed across R1 and C2. Between peak negative voltage excursions of the e_i wave, capacitor C2 discharges through R1. Thus, the e_o waveform is a negative video pulse with sloping edges and superimposed IF ripple, as indicated by the solid line in view B. A negative polarity of the output pulse is ordinarily preferred, but a positive pulse may be obtained by reversing the connections of the diode. In view A, inductance L1, in combination with wiring capacitance and C2, forms a low-pass filter. This filter attenuates the IF components in the e_o waveform but results in a minimum loss of video high-frequency components.

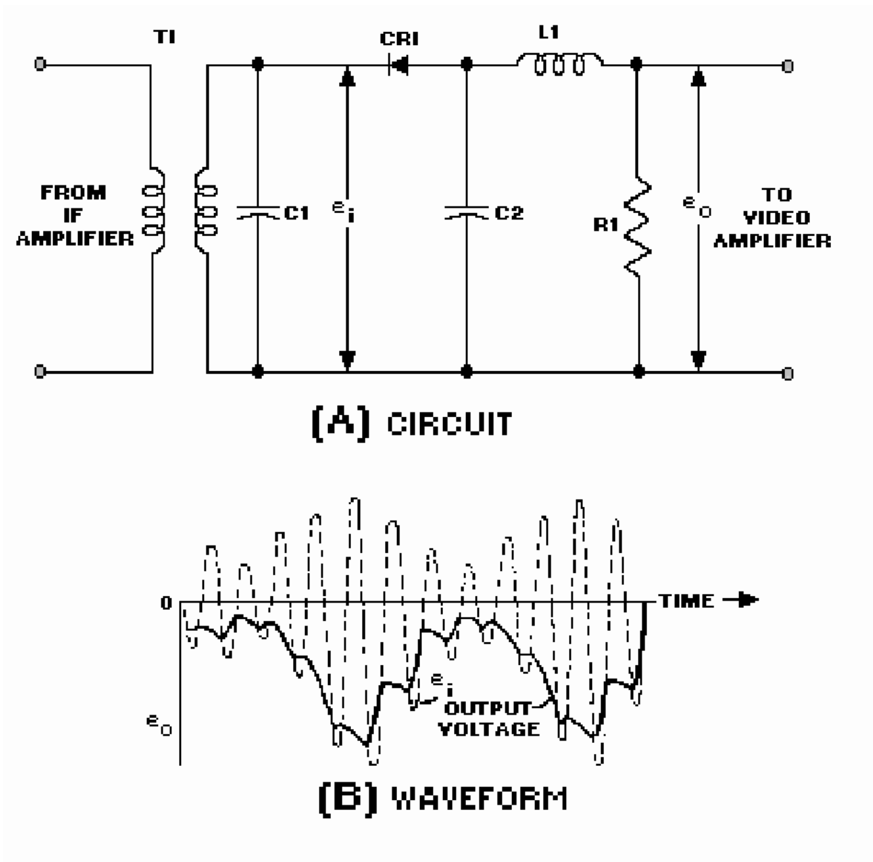

Figure 2-28.—Diode detector.

Video Amplifiers

The video amplifier receives pulses from the detector and amplifies these pulses for application to the indicating device. A video amplifier is fundamentally an RC coupled amplifier that uses high-gain transistors or pentodes. However, a video amplifier must be capable of a relatively wide frequency response. Stray and interelectrode capacitances reduce the high-frequency response of an amplifier, and the reactance of the coupling capacitor diminishes the low-frequency response. These problems are overcome by the use of FREQUENCY COMPENSATION NETWORKS in the video amplifier. The types of frequency compensation networks that may be used in a video amplifier stage are discussed in detail in NEETS, Module 8, *Introduction to Amplifiers*.

Q38. What receiver circuit actually produces the IF frequency?

Q39. The IF amplifiers are connected in what amplifier configuration?

Q40. Which receiver component converts the IF pulses to video pulses?

RECEIVER SPECIAL CIRCUITS

The performance efficiency of radar receivers is often greatly decreased by interference from one or more of several possible sources. Weather and sea return are the most common of these interference sources, especially for radar systems that operate above 3,000 megahertz. Unfavorable weather conditions can completely mask all radar returns and render the system useless. Electromagnetic interference from external sources, such as the deliberate interference by an enemy, called jamming or electronic counter measures (ECM), can also render a radar system useless. Many special circuits have been designed to help the radar receiver counteract the effects of external interference. These circuits are called VIDEO ENHANCEMENT FEATURES, ANTIJAMMING CIRCUITS, or ELECTRONIC COUNTER-COUNTERMEASURES (ECCM) CIRCUITS. This section will discuss, in general terms, some of the more common video enhancement features associated with radar receivers.

Automatic Gain Control (AGC)

Most radar receivers use some means to control the overall gain. This usually involves the gain of one or more IF amplifier stages. Manual gain control by the operator is the simplest method. Usually, some more complex form of automatic gain control (agc) or instantaneous automatic gain control (iagc) is used during normal operation. Gain control is necessary to adjust the receiver sensitivity for the best reception of signals of widely varying amplitudes. Agc and iagc circuits are designed with, a shut-off feature so that receiver gain may be adjusted manually. In this way, manual gain control can be used to adjust for best reception of a particular signal.

The simplest type of agc adjusts the IF amplifier bias (and gain) according to the average level of the received signal. Agc is not used as frequently as other types of gain control because of the widely varying amplitudes of radar return signals.

With agc, gain is controlled by the largest received signals. When several radar signals are being received simultaneously, the weakest signal may be of greatest interest. Iagc is used more frequently because it adjusts receiver gain for each signal.

The iagc circuit is essentially a wide-band, dc amplifier. It instantaneously controls the gain of the IF amplifier as the radar return signal changes in amplitude. The effect of iagc is to allow full amplification of weak signals and to decrease the amplification of strong signals. The range of iagc is limited, however, by the number of IF stages in which gain is controlled. When only one IF stage is controlled, the range of iagc is limited to approximately 20 dB. When more than one IF stage is controlled, iagc range can be increased to approximately 40 dB.

Sensitivity Time Control (STC)

In radar receivers, the wide variation in return signal amplitudes make adjustment of the gain difficult. The adjustment of receiver gain for best visibility of nearby target return signals is not the best adjustment for distant target return signals. Circuits used to adjust amplifier gain with time, during a single pulse-repetition period, are called stc circuits.

Sensitivity time-control circuits apply a bias voltage that varies with time to the IF amplifiers to control receiver gain. Figure 2-29 shows a typical stc waveform in relation to the transmitted pulse. When the transmitter fires, the stc circuit decreases the receiver gain to zero to prevent the amplification of any leakage energy from the transmitted pulse. At the end of the transmitted pulse, the stc voltage begins to rise, gradually increasing the receiver gain to maximum. The stc voltage effect on receiver gain is usually limited to approximately 50 miles. This is because close-in targets are most likely to saturate the receiver; beyond 50 miles, stc has no affect and the receiver operates normally.

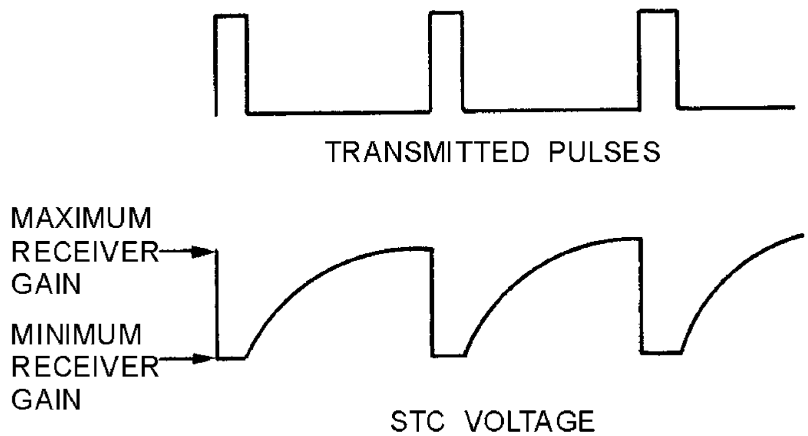

Figure 2-29.—Stc voltage waveform.

The combination of stc and iagc circuits results in better overall performance than with either type of gain control alone. Stc decreases the amplitude of nearby target return signals, while iagc decreases the amplitude of larger-than-average return signals. Thus, normal changes of signal amplitudes are adequately compensated for by the combination of iagc and stc.

Antijamming Circuits

Among the many circuits used to overcome the effects of jamming, two important ones are GATED AGC CIRCUITS and FAST-TIME-CONSTANT CIRCUITS. A gated agc circuit permits signals that occur only in a very short time interval to develop the agc. If large-amplitude pulses from a jamming transmitter arrive at the radar receiver at any time other than during the gating period, the agc does not respond to these jamming pulses.

Without gated agc, a large jamming signal would cause the automatic gain control to follow the interfering signal. This would decrease the target return signal amplitude to an unusable value. Gated agc produces an output signal for only short time periods; therefore, the agc output voltage must be averaged over several cycles to keep the automatic gain control from becoming unstable.

Gated agc does not respond to signals that arrive at times other than during the time of a target return signal. However, it cannot prevent interference that occurs during the gating period. Neither can gating the agc prevent the receiver from overloading because of jamming signal amplitudes far in excess of the target return signal. This is because the desired target is gated to set the receiver gain for a signal of that particular amplitude. As an aid in preventing radar receiver circuits from overloading during the reception of jamming signals, fast-time-constant coupling circuits are used. These circuits connect the video detector output to the video amplifier input circuit.

A fast-time-constant (ftc) circuit is a differentiator circuit located at the input of the first video amplifier. When a large block of video is applied to the ftc circuit, only the leading edge will pass. This is because of the short time constant of the differentiator. A small target will produce the same length of signal on the indicator as a large target because only the leading edge is displayed. The ftc circuit has no effect on receiver gain; and, although it does not eliminate jamming signals, ftc greatly reduces the effect of jamming.

Q41. Which of the two types of automatic gain control, agc or iagc, is most effective in radar use for the Navy?

Q42. Immediately after the transmitter fires, stc reduces the receiver gain to what level?

Q43. How does ftc affect receiver gain, if at all?

SPECIAL RECEIVERS

The basic receiver of a radar system often does not meet all the requirements of the radar system, nor does it always function very well in unfavorable environments. Several special receivers have been developed to enhance target detection in unfavorable environments or to meet the requirements of special transmission or scanning methods. A radar system with a moving target indicator (mti) system or a monopulse scanning system requires a special type of receiver. Other types of special receivers, such as the logarithmic receiver, have been developed to enhance reception during unfavorable conditions. These receivers will be discussed in general terms in this section.

Moving Target Indicator (mti) System

The MOVING TARGET INDICATOR (mti) system effectively cancels CLUTTER (caused by fixed unwanted echoes) and displays only moving target signals. Clutter is the appearance on a radar indicator of confusing, unwanted echoes which interfere with the clear display of desired echoes. Clutter is the result of echoes from land, water, weather, and so forth. The unwanted echoes can consist of GROUND CLUTTER (echoes from surrounding land masses), SEA CLUTTER (echoes from the irregular surface of the sea), or echoes from the clouds and rain. The problem is to find the desired echo in the midst of the clutter. To do this, the mti system must be able to distinguish between fixed and moving targets and then must eliminate only the fixed targets. This is accomplished by phase detection and pulse-to-pulse comparison.

Target echo signals from stationary objects have the same phase relationship from one receiving period to the next. Moving objects produce echo signals that have a different phase relationship from one receiving period to the next. This principle allows the mti system to discriminate between fixed and moving targets.

Signals received from each transmitted pulse are delayed for a period of time exactly equal to the pulse-repetition time. The delayed signals are then combined with the signals received from the next transmitted pulse. This is accomplished in such a manner that the amplitudes subtract from each other as shown in figure 2-30, views Aand B. Since the fixed targets have approximately the same amplitude on each successive pulse, they will be eliminated. The moving target signals, however, are of different amplitudes on each successive pulse and, therefore, do not cancel. The resulting signal is then amplified and presented on the indicators.

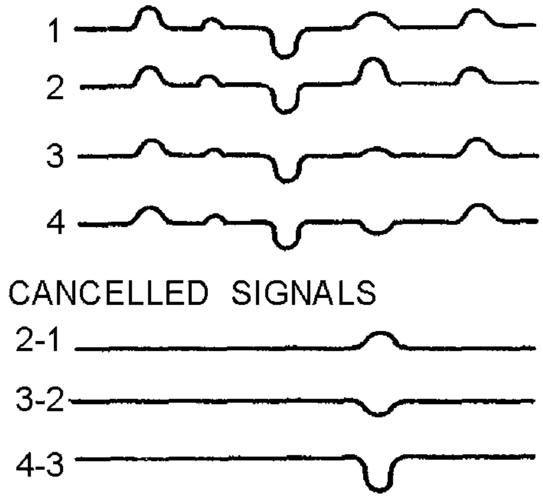

Figure 2-30A.—Fixed target cancellation.

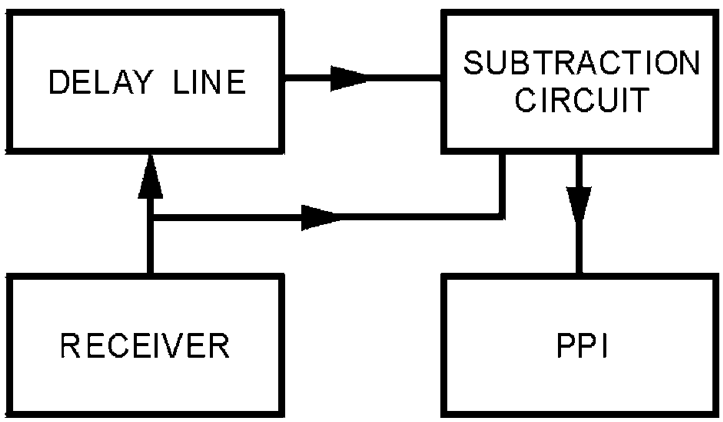

Figure 2-30B.—Fixed target cancellation.

In figure 2-31, 30-megahertz signals from the signal mixer are applied to the 30-megahertz amplifier. The signals are then amplified, limited, and fed to the phase detector. Another 30-megahertz signal, obtained from the coherent oscillator (coho) mixer, is applied as a lock pulse to the coho. The coho lock pulse is originated by the transmitted pulse. It is used to synchronize the coho to a fixed phase relationship with the transmitted frequency at each transmitted pulse. The 30-megahertz, cw reference signal output of the coho is applied, together with the 30-megahertz echo signal, to the phase detector.

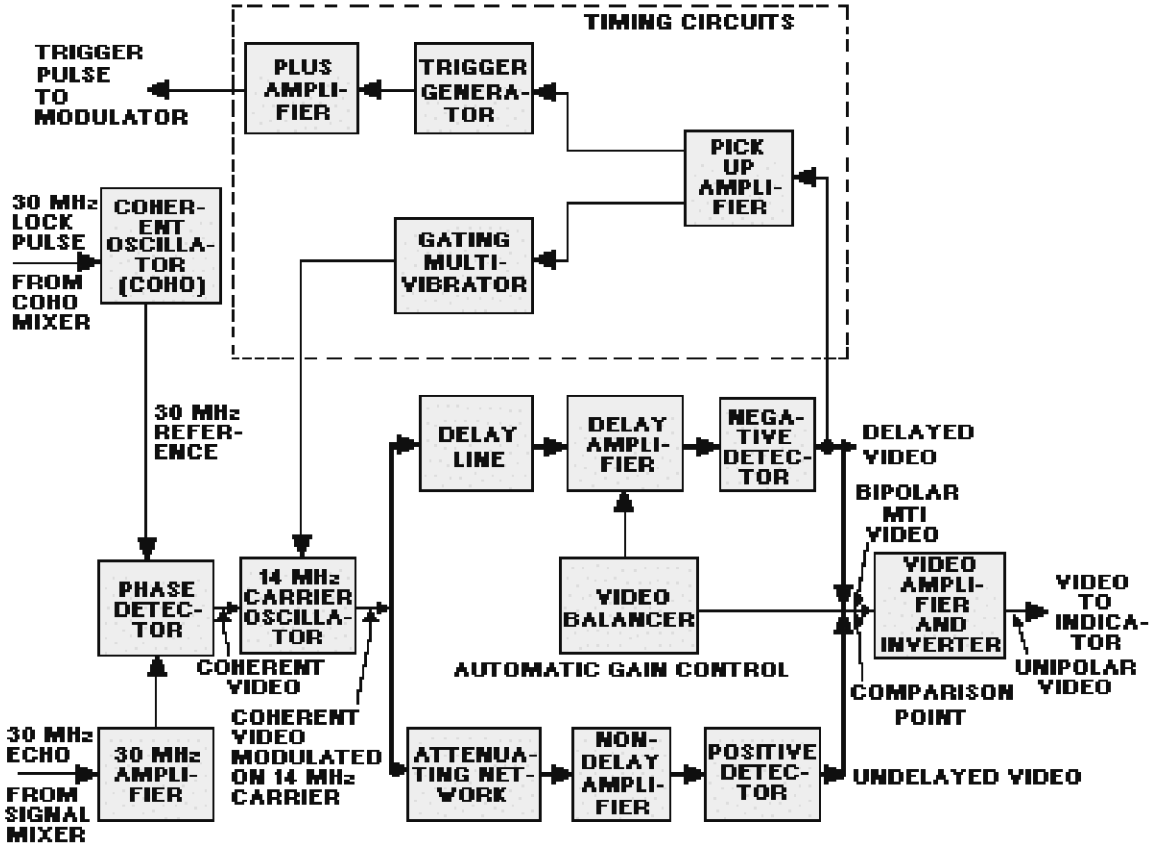

Figure 2-31.—Mti block diagram.

The phase detector produces a video signal. The amplitude of the video signal is determined by the phase difference between the coho reference signal and the IF echo signals. This phase difference is the same as that between the actual transmitted pulse and its echo. The resultant video signal may be either positive or negative. This video output, called coherent video, is applied to the 14-megahertz cw carrier oscillator.

The 14-megahertz cw carrier frequency is amplitude modulated by the phase-detected coherent video. The modulated signal is amplified and applied to two channels. One channel delays the 14-megahertz signal for a period equal to the time between transmitted pulses. The signal is then amplified and detected. The delay required (the period between transmitted pulses) is obtained by using a mercury delay line or a fused-quartz delay line, which operates ultrasonically at 14 megahertz.

The signal to the other channel is amplified and detected with no delay introduced. This channel includes an attenuating network that introduces the same amount of attenuation as does the delay line in the delayed video channel. The resulting nondelayed video signal is combined in opposite polarity with the delayed signal. The amplitude difference, if any, at the comparison point between the two video signals is amplified; because the signal is bipolar, it is made unipolar. The resultant video signal, which represents only moving targets, is sent to the indicator system for display.

An analysis of the mti system operation just described shows that signals from fixed targets produce in the phase detector recurring video signals of the same amplitude and polarity. (Fixed targets have an unchanging phase relationship to their respective transmitted pulses.) Thus, when one video pulse is combined with the preceding pulse of opposite polarity, the video signals cancel and are not passed on to the indicator system.

Signals from *moving targets*, however, will have a varying phase relationship with the transmitted pulse. As a result, the signals from successive receiving periods produce signals of different amplitudes in the phase detector. When such signals are combined, the difference in signal amplitude provides a video signal that is sent to the indicator system for display.

The timing circuits, shown in figure 2-31, are used to accurately control the transmitter pulse-repetition frequency to ensure that the pulse-repetition time remains constant from pulse to pulse. This is necessary, of course, for the pulses arriving at the comparison point to coincide in time and achieve cancellation of fixed targets.

As shown in figure 2-31, a feedback loop is used from the output of the delay channel, through the pickoff amplifier, to the trigger generator and gating multivibrator circuits. The leading edge of the square wave produced by the detected carrier wave in the delayed video channel is differentiated at the pickoff amplifier. It is used to activate the trigger generator and gating multivibrator. The trigger generator sends an amplified trigger pulse to the modulator, causing the radar set to transmit.

The gating multivibrator is also triggered by the negative spike from the differentiated square wave. This stage applies a 2,000-microsecond negative gate to the 14-megahertz oscillator. The oscillator operates for 2,400 microseconds and is then cut off. Because the delay line time is 2,500 microseconds, the 14-megahertz oscillations stop before the initial waves reach the end of the delay line. This wave train, when detected and differentiated, turns the gating multivibrator on, producing another 2,400-microsecond wave train. The 100 microseconds of the delay line is necessary to ensure that the mechanical waves within the line have time to damp out before the next pulse-repetition time. In this manner the pulse-repetition time of the radar set is controlled by the delay of the mercury, or quartz delay line. Because this delay line is also common to the video pulses going to the comparison point, the delayed and the undelayed video pulses will arrive at exactly the same time.

Q44. What type of target has a fixed phase relationship from one receiving period to the next?

Q45. What signal is used to synchronize the coherent oscillator to a fixed phase relationship with the transmitted pulse?

Q46. What is the phase relationship between the delayed and undelayed video?

Logarithmic Receiver

The LOGARITHMIC RECEIVER uses a linear logarithmic amplifier, commonly called a LIN-LOG AMPLIFIER, instead of a normal IF amplifier. The lin-log amplifier is a nonsaturating amplifier that does not ordinarily use any special gain-control circuits. The output voltage of the lin-log amplifier is a linear function of the input voltage for low-amplitude signals. It is a logarithmic function for high-amplitude signals. In other words, the range of linear amplification does not end at a definite saturation point, as is the case in normal IF amplifiers. The comparison of the response curves for normal IF and lin-log amplifiers is shown in figure 2-32. The curves show that a continued increase in the input to the lin-log amplifier causes a continued increase in the output, but at a reduced rate. Therefore, a large signal does not saturate the lin-log amplifier; rather, it merely reduces the amplification of a simultaneously applied small signal. A small echo signal can often be detected by the lin-log receiver when a normal receiver would be saturated.

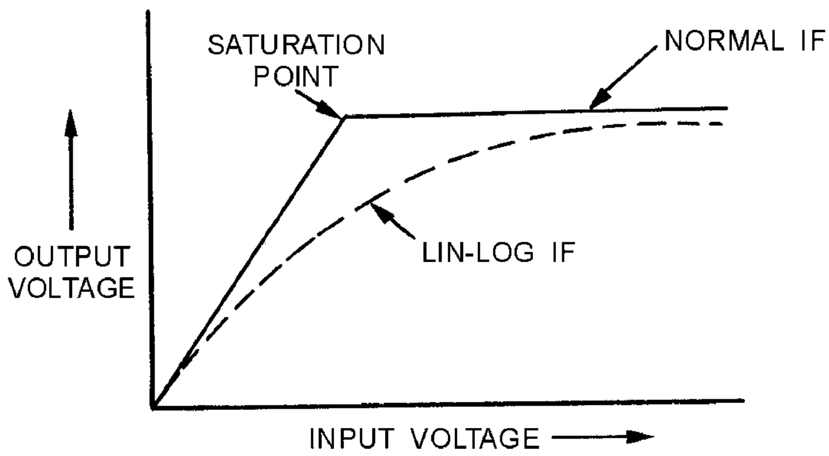

Figure 2-32.—Lin-Log amplifier versus normal IF amplifier.

A typical circuit for obtaining a lin-log response is shown in figure 2-33. If detectors 2 and 3 were not present, the output voltage would be limited by the saturation point of the final IF stage, as it is in a normal IF section. However, when the final stage of the lin-log is saturated, larger signals cause an increase in the output of the next to last stage. This increase is detected by detector 2 and summed with the output of detector 1. This sum produces an increase in the output even though the final stage is saturated. Detector 3 causes the output to continue to increase after the second stage saturates. The overall gain becomes less and less as each stage saturates, but some degree of amplification is still available. The proper choice of IF stage gains and saturation points produces an approximately logarithmic response curve.

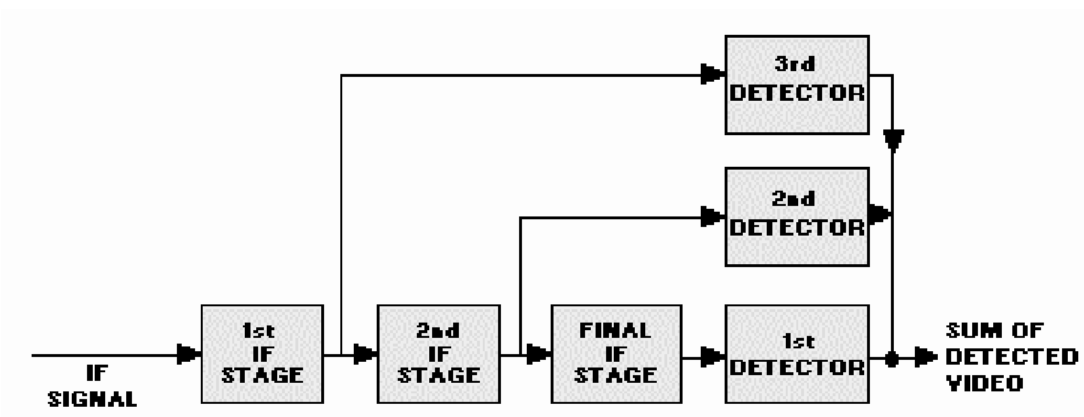

Figure 2-33.—Lin-Log receiver block diagram.

Figure 2-34, shows the response curves of the three IF stages in the lin-log amplifier shown in figure 2-33. The responses of the individual stages produce a segmented overall response curve for the receiver.

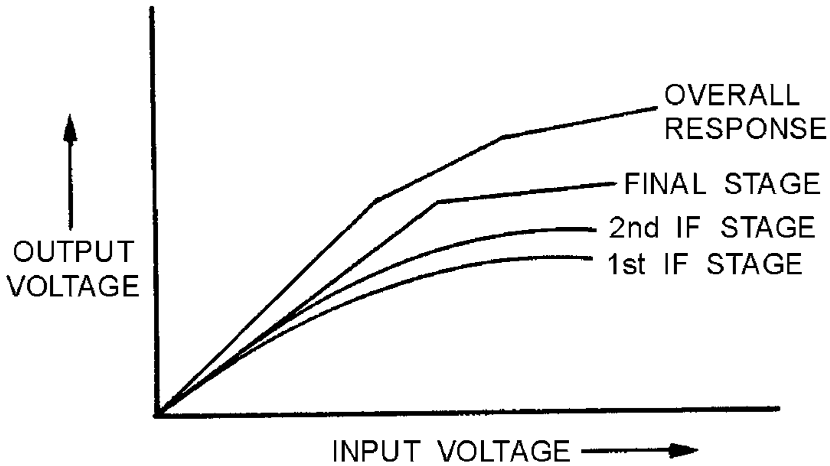

Figure 2-34.—Lin-Log amplifier stage response curves.

Monopulse Receiver

The most common of the automatic tracking radars is the MONOPULSE RADAR. The monopulse radar obtains the three target position coordinates of range, bearing, and elevation from a single pulse. The receiver for a monopulse radar must have three separate channels to process range, bearing, and elevation information. The block diagram of a simplified monopulse receiver is shown in figure 2-35.

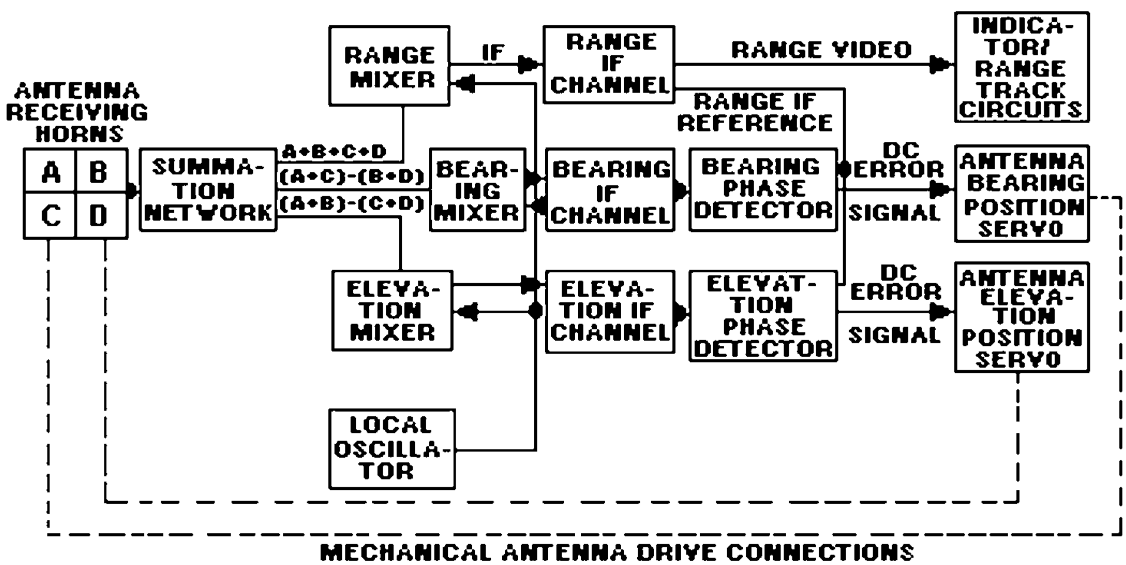

Figure 2-35.—Monopulse receiver block diagram.

As in a conventional receiver, each channel of the monopulse receiver converts the return echo to an IF frequency by mixing the returned signal with a common local oscillator signal. The sum of the energy from all four return signals is mixed with the local oscillator signal to produce range IF information. Bearing information is obtained by subtracting the energy from horns B and D from the energy from horns A and C:

$$(A + C) - (B + D)$$

and mixing the difference with the local oscillator signal. The result is a bearing IF signal. Elevation information is obtained in the same way, except the energy from horns C and D is subtracted from the energy from horns A and B:

$$(A + B) - (C + D)$$

If the target is on the elevation and bearing axis, the summations will both be zero; therefore, neither the bearing nor elevation channels will receive an input signal. If either of the bearing or elevation signals is off the axis, an input to the IF channel is produced. This input is subsequently converted to an IF signal in the appropriate channel.

The major difference between the monopulse receiver and the conventional receiver is the requirement for a dc error voltage output from the bearing and elevation channels. The range channel of a monopulse receiver is sent to a conventional ranging circuit for presentation are on an indicator or for use by a range-tracking circuit. However, since most monopulse radars are automatic tracking radars, the outputs of the bearing and elevation channels must be converted to dc error signals for use by automatic bearing and elevation tracking systems. The dc error voltages are applied to the antenna bearing and elevation positioning servos. These servos reposition the antenna until the errors are nulled.

The phase detectors compare the phase of the bearing and elevation IF with a reference IF from the range channels. This *comparison* produces the dc error pulses needed to drive the antenna servos. The signals from both the bearing and elevation channels are the result of a summation process. They can be either positive (in-phase) or negative (180-degrees out of phase) when compared to the reference IF signal. For example, if the output of horns A and C is smaller than the output of horns B and D, a negative or 180-degree-out-of-phase signal is produced by the bearing channel (A + C) - (B + D). If output A + C is greater than output B + D, a positive or in-phase signal is produced by the bearing channel. The phase of the bearing and elevation output signals determines the direction in which the antenna moves; the magnitude of the signal determines the amount of movement. Since two signals must be present at the phase detector to produce an output, an error signal occurs only when a return echo is not on the antenna beam axis.

This technique produces an error signal when the target moves off the radiated beam axis in either bearing or elevation. The error signal causes the antenna to move in the proper direction and for the proper duration to cancel the error signal. This method of automatic tracking is commonly used by weapons-control tracking radar systems.

Q47. When a large signal and a small signal are applied to a lin-log amplifier at the same time, what is the effect on the small signal?

Q48. What happens to the overall gain of a lin-log amplifier as each stage saturates?

Q49. A monopulse receiver has how many separate channels?

Q50. If a target is on the bearing axis of the radiated beam, what is the input to the bearing IF channel?

Q51. What characteristic of the bearing and elevation output signals determines the direction of antenna movement?

SUMMARY

The following paragraphs summarize the important points of this chapter.

The **SYNCHRONIZER** is essential to any radar because it controls and times the operation of the entire system. Radar systems may be self-synchronized by triggers from the transmitter or externally synchronized from a master oscillator.

Most modern systems are synchronized by a **MASTER OSCILLATOR**, which may be a SINEWAVE OSCILLATOR, an ASTABLE MULTIVIBRATOR, or a BLOCKING OSCILLATOR.

Each of these oscillators fulfills the basic requirements of a synchronizer, which must be:

- free running
- stable in frequency
- frequency variable (in steps)

The **TRANSMITTER** produces the short-duration, high-power, rf pulses of energy that are radiated into space by the antenna.

The **MODULATOR** controls the radar pulse, width and amplitude.

KEYED-OSCILLATOR TRANSMITTERS produce a high-power output pulse by keying a high-power oscillator, such as a MAGNETRON.

POWER-AMPLIFIER TRANSMITTERS amplify a low-level pulse to the desired power level using a series of microwave amplifiers such as TRAVELING-WAVE TUBES or KLYSTRONS.

The **DUPLEXER** is a device that allows the same antenna to both transmit and receive. Most duplexers use the impedance characteristics of transmission lines and waveguides in conjunction with TR and ATR tubes to route the energy to the correct place. One of the most important functions of the duplexer is isolation of the receiver during transmission.

The **RECEIVER** detects the very small target return echo and amplifies it to a usable level for display on the indicator.

A typical **SUPERHETERODYNE RECEIVER** consists of a low-noise amplifier, a mixer, a local oscillator, an IF amplifier, a detector, and a video amplifier.

Some special purpose receivers are the MOVING TARGET INDICATOR and MONOPULSE RECEIVERS.

ANSWERS TO QUESTIONS Q1. THROUGH Q51.

A1. Controls system operation and timing.

A2. Timing and control.

A3. Transmitter.

A4. Free-running.

A5. The master oscillator.

A6. Leakage from the duplexer.

A7. Sine-wave oscillator, single-swing blocking oscillator, and master-trigger (astable) multivibrator.

A8. It requires additional shaping circuits.

A9. Blocking oscillators.

A10. Keyed oscillator and power-amplifier chain.

A11. The modulator.

A12. Steep leading and trailing edges.

A13. Line-pulsed.

A14. Capacitor, artificial transmission line, or pulse-forming network.

A15. Pulse width.

A16. Thyratron.

A17. The charging impedance.

A18. 600-30,000 megahertz.

A19. Mode skipping and mode shifting.

A20. The magnetron will not oscillate.

A21. ±5 percent.

A22. Frequency stability.

A23. Local oscillator and coherent oscillator.

A24. Multicavity klystron.

A25. Frequency synthesizer.

A26. Oscillations at an undesired frequency.

A27. Electronic.

A28. Tr tube.

A29. Apply keep-alive voltage.

A30. Quarter-wavelength section.

A31. Transmit.

A32. Neither fires.

A33. 180 degrees out of phase.

A34. Noise.

A35. Superheterodyne.

A36. Thirty or sixty megahertz.

A37. Local oscillator.

A38. Mixer.

A39. Cascade.

A40. Detector.

A41. IAGC.

A42. Zero.

A43. FTC has no effect on receiver gain.

A44. Stationary.

A45. Coho lock pulse.

A46. Opposite.

A47. Amplification is reduced.

A48. Decreases.

A49. Three.

A50. Zero.

A51. Phase.

CHAPTER 3

RADAR INDICATORS AND ANTENNAS

LEARNING OBJECTIVES

Upon completion of this chapter, the student will be able to:

1. Describe the purpose of the A scope, the range-height indicator (rhi), and the plan position indicator (ppi).
2. State the relationship between range and sweep speed and length on a radar indicator.
3. Explain the purpose of timing triggers, video, and antenna position inputs to a radar indicator.
4. List the major units of a ppi and describe their functions.
5. Describe the basic operation of sweep deflection and sweep rotation in a ppi.
6. List and describe the operation of the three range measurement circuits.
7. Describe antenna directivity and power gain characteristics.
8. Describe the focusing action of a basic parabolic antenna.
9. Describe the basic radiation patterns of the most common parabolic reflectors.
10. Describe the basic characteristics of horn radiators.

INTRODUCTION

Radar systems require an antenna to both transmit and receive radar energy and an indicator system to display the video information generated. This chapter will briefly describe some commonly used indicators and antenna systems. Antenna systems are described in more detail in NEETS, Module 10, *Introduction to Wave Generation, Transmission Lines, and Antennas*, and Module 11, *Microwave Principles*.

RADAR INDICATORS

The information available from a radar receiver may contain as many as several million separate data bits per second. From these and other data, such as the orientation of the antenna, the indicator should present to the observer a continuous, easily understandable, graphic picture of the relative position of radar targets. It should provide size, shape, and insofar as possible, indications of the type of targets. A cathode-ray tube (crt) fulfills these requirements to an astonishing degree. The cathode-ray tube's principal shortcoming is that it cannot present a true three-dimensional picture.

The fundamental geometrical quantities involved in radar displays are the RANGE, AZIMUTH ANGLE (or BEARING), and ELEVATION ANGLE. These displays relate the position of a radar target to the origin at the antenna. Most radar displays include one or two of these quantities as coordinates of the crt face.

The actual range of a target from the radar, whether on the ground, in the water, or in the air is known as SLANT RANGE. The majority of displays use as one coordinate the value of slant range, its horizontal projection (GROUND RANGE), or its vertical projection (ALTITUDE). Since slant range is involved in every radar situation, it inevitably appears in at least one display on every set. Slant range is the coordinate that is duplicated most often when more than one type of display is used. This is partly because displays presenting range have the highest signal-to-noise discrimination and partly for geometrical reasons.

Range is displayed by means of a linear time-base sweep, starting from a given point or line at a definite time in each pulse cycle. Thus, distances along this range sweep actually measure slant range. The sweep speed determines the scale factor, which relates the distance on the tube to actual range. The sweep length is the total distance represented. Distances are expressed in miles (statute or nautical) or yards. The origin of the range sweep may be on or off the tube face.

The angle at which the antenna is pointing, either in azimuth or elevation, may provide two-dimensional information in the display; that is, range and azimuth, or range and elevation.

A radar indicator, sometimes called a radar repeater, acts as the master timing device in *analyzing* the return of the video in a radar system. It also provides that capability to various other locations physically remote from the radar system. Each indicator should have the ability to select the outputs from any desired radar system aboard the ship. This is usually accomplished by the use of a RADAR DISTRIBUTION SWITCHBOARD. The switchboard contains a switching arrangement that has inputs from each radar system aboard ship and provides outputs to each repeater. The radar desired is selected by means of a selector switch on the repeater. For the repeater to present correct target position data, the indicator must have the following three inputs from the selected radar:

1. *Trigger timing pulses*. These pulses ensure that the sweep on the repeater starts from its point of origin each time the radar transmits. As discussed earlier, the repeater displays all targets at their actual range from the ship based on the time lapse between the instant of transmission and the instant the target's echo is received.

2. *The returning echo*. The echo, in rf form, is detected (converted to a video signal) by the radar receiver and applied to the repeater.

3. *Antenna information*. The angular sweep position of a plan position indicator (ppi) repeater must be synchronized to the angular position of the radar antenna to display target bearing (azimuth) information.

The three most common types of displays, called scopes, are the A-scope, the RANGE-HEIGHT INDICATOR (RHI) SCOPE, and the PLAN POSITION INDICATOR (PPI) SCOPE. The primary function of these displays will be discussed in this section. However, detailed descriptions will be limited to the ppi scope, which is the most common display.

THE A SCOPE

The A-scope display, shown in figure 3-1, presents only the range to the target and the relative strength of the echo. Such a display is normally used in weapons control radar systems. The bearing and elevation angles are presented as dial or digital readouts that correspond to the actual physical position of the antenna.

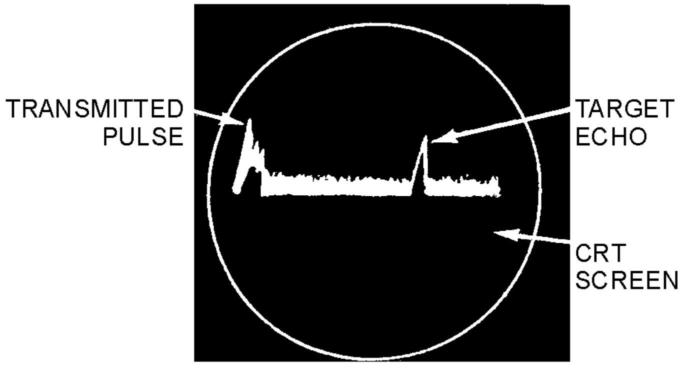

Figure 3-1.—A scope.

The A-scope normally uses an electrostatic-deflection crt. The sweep is produced by applying a sawtooth voltage to the horizontal deflection plates. The electrical length (time duration) of the sawtooth voltage determines the total amount of range displayed on the crt face.

The ranges of individual targets on an A-scope are usually determined by using a movable range gate or step that is superimposed on the sweep. Ranging circuits will be discussed in more detail later in this section.

RANGE-HEIGHT INDICATOR (RHI)

The range-height indicator (rhi) scope, shown in figure 3-2, is used with height-finding search radars to obtain altitude information. The rhi is a two-dimensional presentation indicating target range and altitude. The sweep originates in the lower left side of the scope. It moves across the scope, to the right, at an angle that is the same as the angle of transmission of the height-finding radar. The line of sight to the horizon is indicated by the bottom horizontal line. The area directly overhead is straight up the left side of the scope. Target echoes are displayed on the scope as vertical PIPS or BLIPS (spots of increased intensity that indicate a target location). The operator determines altitude by adjusting a movable height line to the point where it bisects the center of the blip. Target height is then read directly from an altitude dial or digital readout. Vertical range markers are also provided to estimate target range.

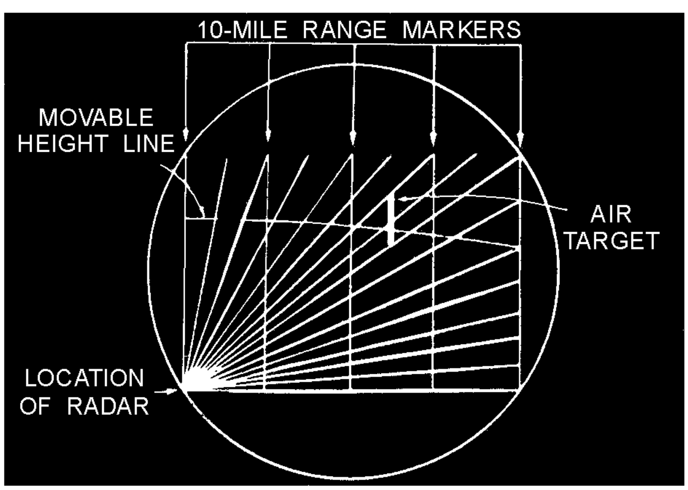

Figure 3-2.—RHI scope.

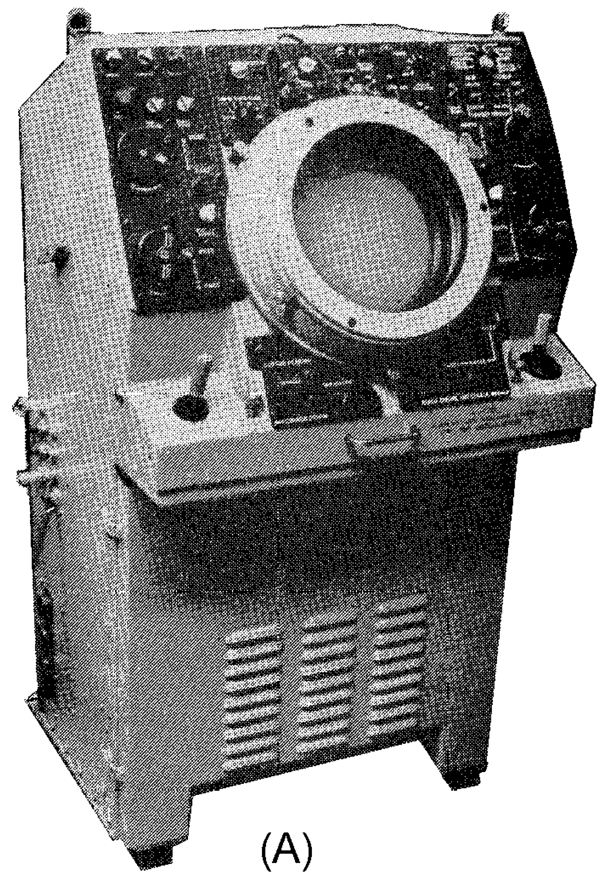
Q1. What are the three fundamental quantities involved in radar displays?

Q2. What are the required radar inputs for proper indicator operation?

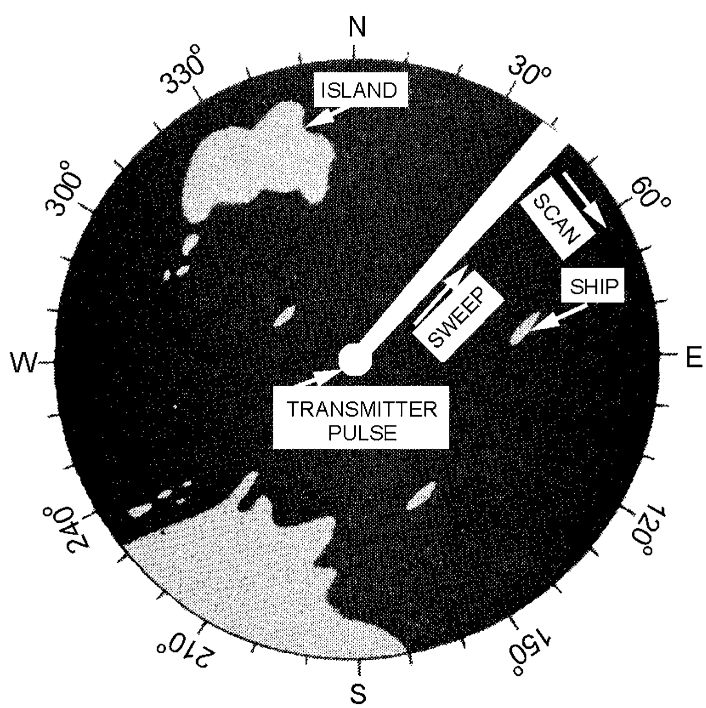
Q3. What coordinates are displayed on an rhi scope?

PLAN POSITION INDICATOR (PPI).

The ppi scope shown in figure 3-3, is by far the most used radar display. It is a polar coordinate display of the area surrounding the radar platform. Own ship is represented as the origin of the sweep, which is normally located in the center of the scope, but may be offset from the center on some sets. The ppi uses a radial sweep pivoting about the center of the presentation. This results in a map-like picture of the area covered by the radar beam. A long-persistence screen is used so that the display remains visible until the sweep passes again.



(A)



(B)

Figure 3-3.—PPI scope.

Bearing to the target is indicated by the target's angular position in relation to an imaginary line extending vertically from the sweep origin to the top of the scope. The top of the scope is either true north (when the indicator is operated in the true bearing mode) or ship's heading (when the indicator is operated in the relative bearing mode).

PPI Block Diagram

The basic block diagram, figure 3-4, illustrates the major units of a plan position indicator. Synchronization of events is particularly important in the presentation system. At the instant a radar transmitter fires (or at some predetermined time thereafter), circuits which control the presentation on the indicator must be activated. These events must be performed to a high degree of accuracy to ensure accurate range determination. The synchronization of these events is provided by the gate circuit.

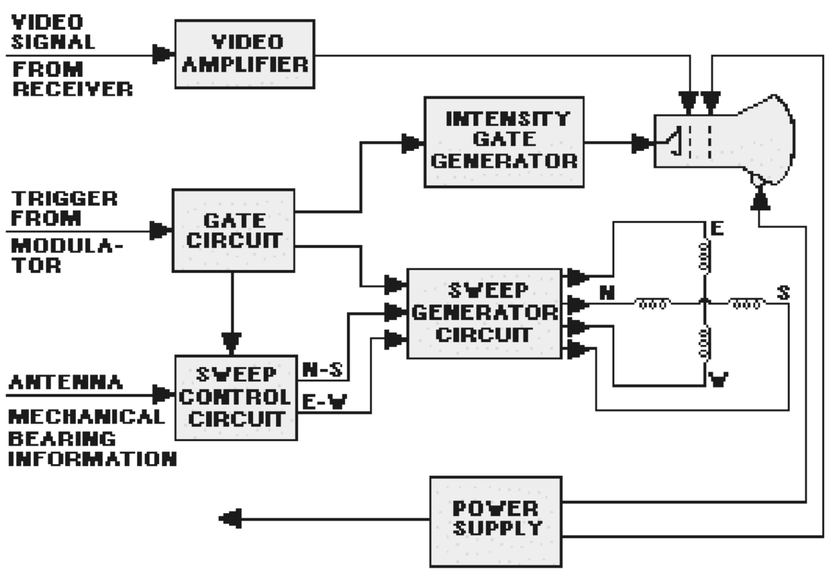


Figure 3-4.—Basic ppi block diagram.

GATE CIRCUIT.—The gate circuit develops pulses which synchronize the indicator with the transmitter. The gate circuit itself is synchronized by trigger pulses from the synchronizer. It then provides timing for the intensity gate generator, sweep generator circuit, and the sweep control circuit.

SWEEP CONTROL CIRCUIT.—The sweep control circuit converts mechanical bearing information from the antenna into voltages which control sweep circuit azimuth.

SWEEP GENERATOR CIRCUIT.—The sweep generator circuit produces currents which deflect an electron beam across the crt. Varying voltages from the sweep control circuit are applied to deflection coils. Gate voltages determine sweep rate, and therefore, the effective distance (range) covered by each sweep. Sweep potentials consist of separate north-south and east-west voltages; the amplitudes of these voltages determine sweep azimuth. The sweep generator is synchronized by an input from the gate circuit.

INTENSITY GATE GENERATOR.—The intensity gate generator provides a gate which unblanks the crt during sweep periods. The intensity of the trace appearing on the crt is determined by the dc level of this gate. This circuit is also synchronized by the gate circuit.

VIDEO AMPLIFIER.—The video amplifier circuit amplifies the video signal from the receiver and applies it to the crt intensity-modulating element (control grid).

POWER SUPPLY.—The power supply produces all voltages needed to operate the indicator. It also includes protective devices and metering circuits.

Although not shown in the basic block diagram, many indicators contain circuits which aid in range and bearing determination. These circuits are also synchronized by the gate circuit.

Sweep Deflection

In modern indicator systems, electromagnetic deflection of the crt electron beam is preferred to electrostatic deflection. Reasons for this choice are (1) increased control of the beam, (2) improved deflection sensitivity, (3) better beam position accuracy, and (4) simpler construction of the crt.

The primary difference between electromagnetic and electrostatic cathode-ray tubes lies in the method of controlling deflection and focusing of the electron beam. Both types employ electron guns and use electrostatic fields to accelerate and control the flow of electrons. The physical construction of a crt employing electromagnetic deflection is similar to an electrostatic type. The construction of a crt employing electromagnetic deflection is shown in figure 3-5.

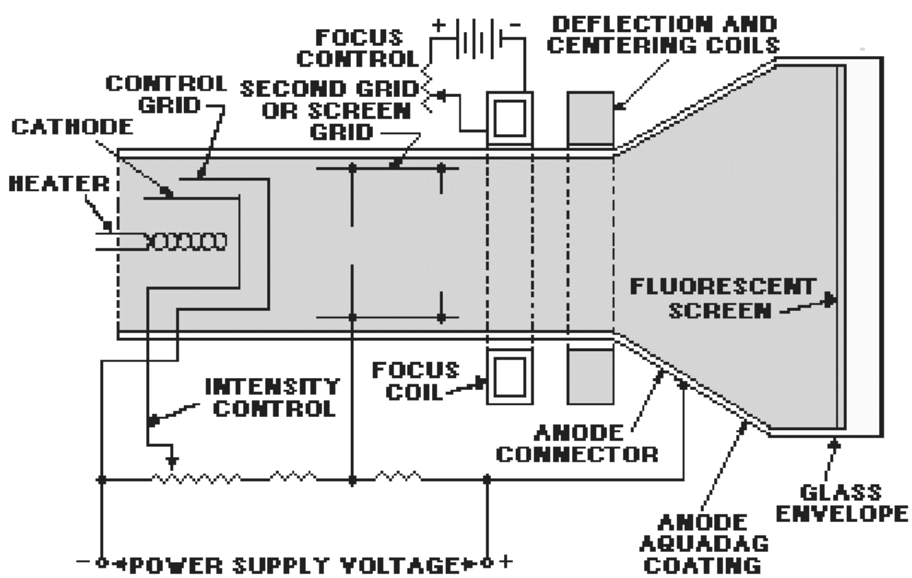

Figure 3-5.—Electromagnetic crt construction.

The electron gun in figure 3-5 is made up of a heater, cathode, control grid, second or screen grid, focus coil, and anode (composed of a special coating). Focusing the electron beam on the face of the screen is accomplished by the focus coil. A direct current through the windings sets up a strong magnetic field at the center of the coil. Electrons move precisely along the axis of the tube and pass through the focusing field with no deflection. This is because they move parallel to the magnetic field at all times.

Any electron which enters the focusing field at an angle to the axis of the tube has a force exerted on it that is perpendicular to its direction of motion. A second force on this electron is perpendicular to the magnetic lines and is, therefore, constantly changing in direction. These forces cause the electron to move in a helical or corkscrew path shown in figure 3-6. With the proper velocity of the electron and strength of the magnetic field, the electron will be caused to move at an angle which allows it to converge with other electrons at some point on the crt screen. Focusing is accomplished by adjusting the current flow through the focusing coils.

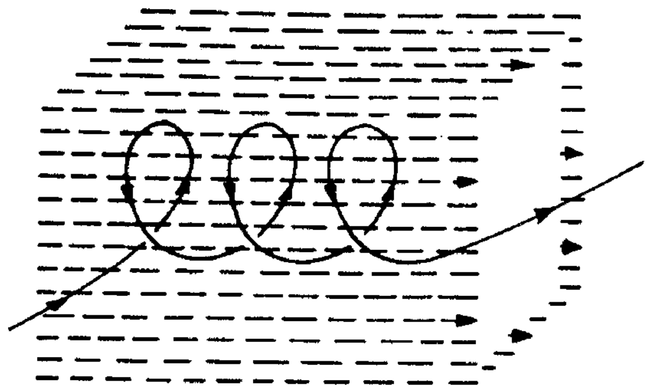

Figure 3-6.—Helical motion of electron through a uniform magnetic field.

The focused electron beam is deflected by a magnetic field that is generated by current flow through a set of deflection coils, as shown in figure 3-5. These coils are mounted around the outside surface of the neck of the crt. Normally, four deflection coils (**N**, **S**, **E**, and **W**) are used, as shown in figure 3-4. Two coils in series are positioned in a manner that causes the magnetic field produced to be in a vertical plane. The other two coils, also connected in series, are positioned so that their magnetic field is in a horizontal plane. The coils (**N-S**) which produce a horizontal field are called the VERTICAL DEFLECTION COILS and the coils (**E-W**) which produce a vertical field are called the HORIZONTAL DEFLECTION COILS. This may be more clearly understood if you recall that an electron beam will be deflected at right angles to a deflecting field. The deflection coils are illustrated in view A of figure 3-7. View B shows the **N-S** windings in schematic form.

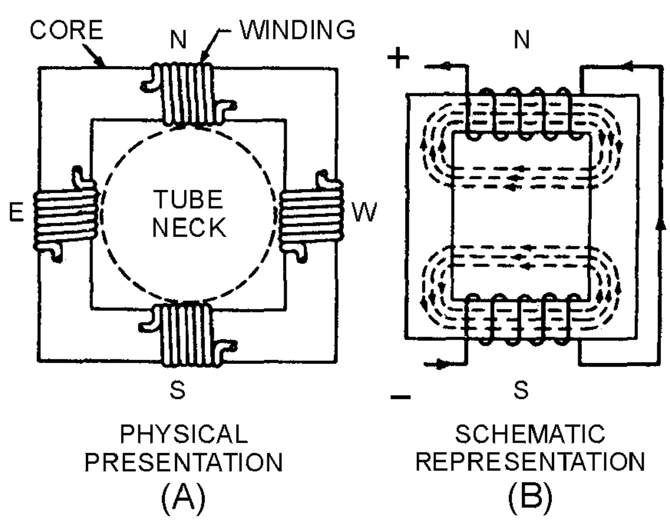

Figure 3-7.—Deflection yoke.

Electron deflection in the electromagnetic crt is proportional to the strength of the magnetic fields. Magnetic field strength depends on current in the coils. The sweep circuits associated with electromagnetically deflected cathode-ray tubes must provide currents, rather than voltage, to produce the desired beam deflection.

A sawtooth current is required to produce a linear trace. A deflection coil may be considered equivalent to the circuit shown in view A of figure 3-8. Because of the inductance of the coil, a trapezoidal voltage must be applied across the coil to produce a sawtooth of current through it. This is illustrated in view B. (Refer to NEETS, Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits*, for a review of wave shaping.)

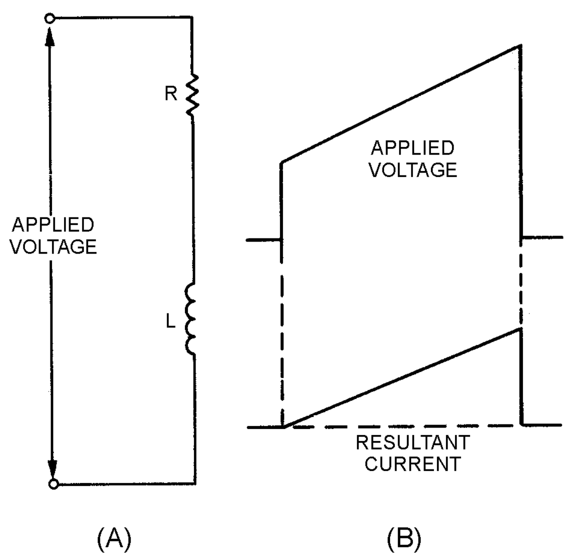

Figure 3-8.—Deflection coil equivalent circuit and waveform.

Sweep Rotation

Azimuth indication of the ppi requires that the range trace rotate about the center of the screen. A very simple means of achieving sweep rotation is to cause the deflection coil to rotate about the neck of the crt in synchronization with the antenna motion. This method, however, has the disadvantages of inaccuracy and maintenance complications inherent to any mechanical gear-train assembly.

Most modem ppi systems employ fixed deflection coils and use special circuits to electronically rotate the magnetic field. Figure 3-9 illustrates a method of electronically producing a rotating sweep. In view A, a range sweep current, i, is applied to the vertical deflection coils only. The resulting magnetic field, represented by ! , lies along the axis of these coils. The resulting range trace, shown by the short straight line, is vertical because the electron beam is deflected perpendicular to the magnetic field. In view B, range sweep currents are applied to both sets of coils, and the resultant magnetic field takes a position between the axes of the two sets of coils. Because of this shift of the magnetic field, the range trace is rotated 45 degrees clockwise from its previous position. In view C, the sweep current is applied to the horizontal deflection coils only, and the range trace lies 90 degrees clockwise from its original position. Further rotation is obtained if the polarities of the deflection coil currents are varied in proper sequence, as illustrated in views D and E.

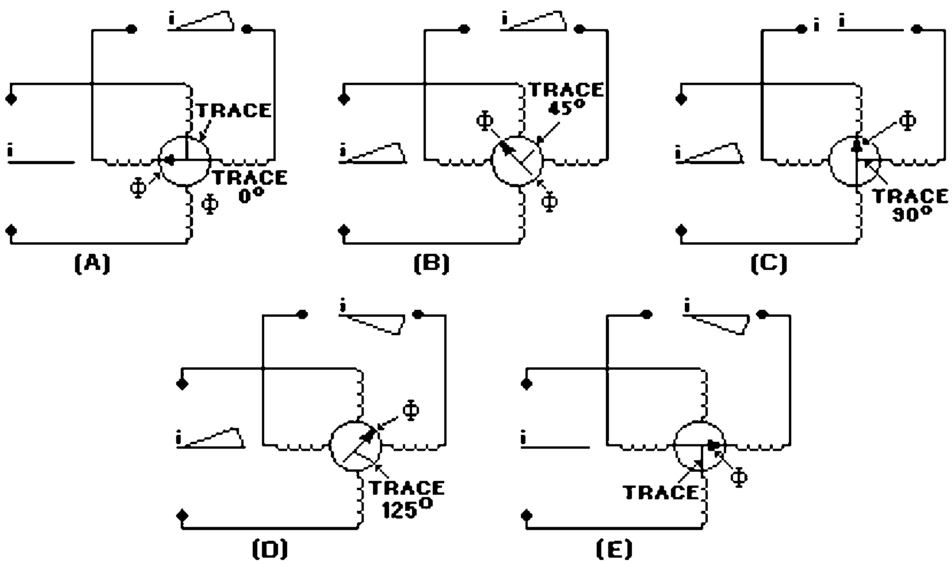

Figure 3-9.—Trace rotation.

To synchronize sweep rotation with antenna rotation, you must convert antenna azimuth (bearing) information into electrical signals. These signals, usually provided by synchros, control the amplitudes and polarities of the sawtooth sweep currents applied to the deflection coils.

Figure 3-10 illustrates the waveforms of current required to produce a rotating range sweep. The amplitudes of the sawtooth sweep currents are varied sinusoidally (like a sine wave), corresponding to the rotation of the antenna. Notice that there is a 90 degree phase difference between the amplitude variations of the horizontal and vertical waveforms.

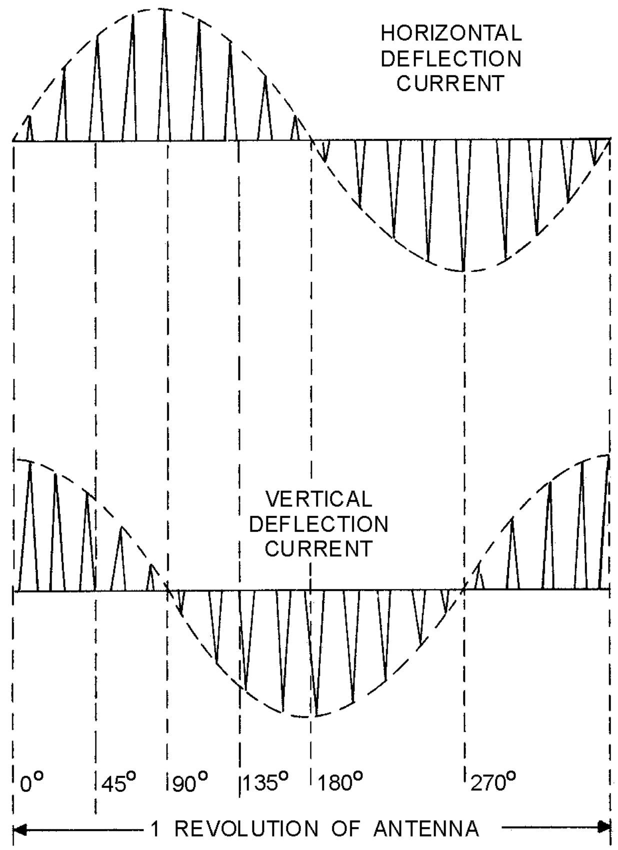

Figure 3-10.—Deflection coil currents.

CRT Screen Persistence

A ppi requires a crt in which the screen is coated with a long-persistence phosphor. This is necessary because each target reflects energy for only a short period of time during each rotation of the antenna. Therefore, the target indication on the face of the crt must be able to continue to glow during the portion of antenna rotation when the target is not reflecting energy.

Q4. What coordinates are presented on a ppi scope?

Q5. What type of deflection is preferred for a crt electron beam?

Q6. Which of the two types of deflection coils (fixed or rotating) is used most often?

RANGING CIRCUITS

The accuracy of target-range data provided by a radar varies with the use of the radar. For example, a weapons systems radar operating in a search mode is required to be accurate within a small percentage of its maximum range. However, an intercept radar, operating in a tracking mode, must supply range data that is even more accurate; it must be within a few yards of the actual range.

In some applications of radar, the indicator sweep is calibrated by a transparent overlay with an engraved range scale. This overlay enables the operator to estimate the range of targets. In other applications, electronic range marks are supplied to the indicator. They usually appear as vertical pulses on A-scopes and as concentric circles on ppi scopes. The distance between range marks is generally determined by the type of equipment and its mode of operation.

In a weapons systems radar that requires extremely accurate target-range data, a movable range marker may be used. The range marker is obtained from a range-marker generator and may be a movable range gate or range step. When a ppi scope is used, a range circle of adjustable diameter may be used to measure range accurately. In some cases, movement of the range marker is accomplished by adjusting a calibrated control from which range readings are obtained.

The following discussion describes the operation of three types of range-marker generators: the RANGE-GATE GENERATOR, the RANGE-MARKER GENERATOR, and the RANGE-STEP GENERATOR. The range-gate generator, used in conjunction with a blocking oscillator, generates a movable range gate. The range-marker generator and the range-step generator, used in conjunction with an astable multivibrator, generate fixed range marks and a movable range step, respectively.

Range-Gate Generator

Figure 3-11 shows a simplified block diagram of a typical range-gate generator. The pulse-repetition frequency is controlled by a master oscillator, or multivibrator, in which the output is coupled to a trigger thyratron (both in the synchronizer). The output of the trigger thyratron is used to trigger the radar modulator and the scope sweep circuits, thus starting the transmitter pulse and the range sweep at the same instant, referred to as time T0.

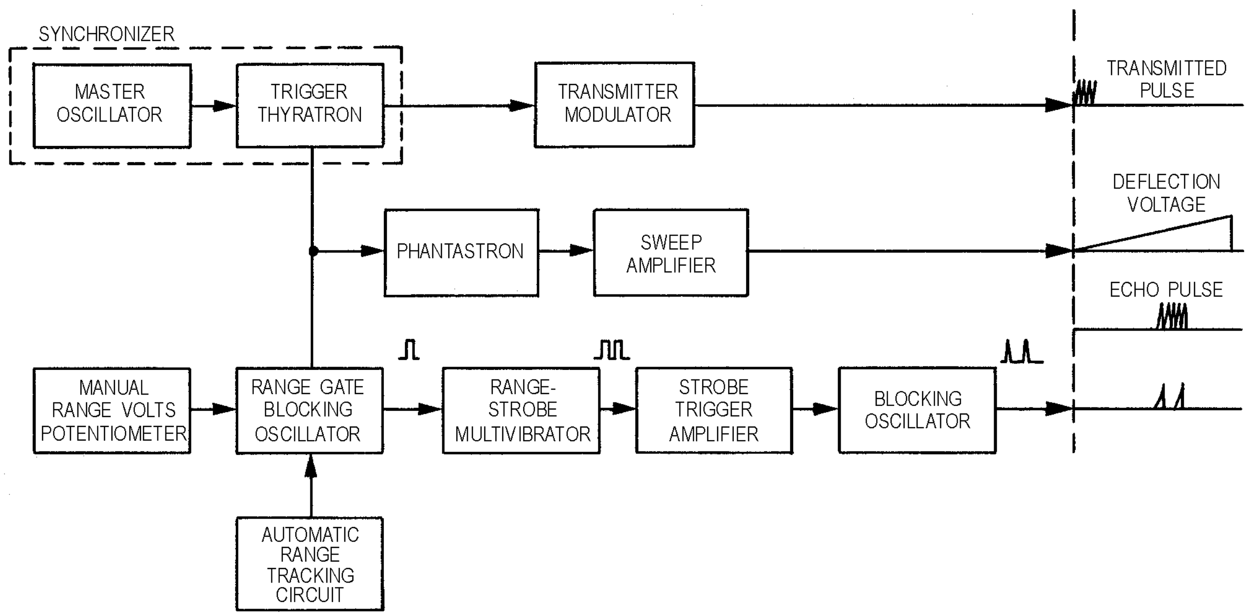

Figure 3-11.—Range-gate generator.

The PHANTASTRON in the sweep circuits is a variable timing circuit that supplies a sweep sawtooth to the sweep amplifier. The width of the gate and sawtooth is dependent upon the range selected by the radar operator.

The range-gate circuit receives its input pulse from the trigger thyratron and generates a delayed range-gate pulse. The delay of this pulse from time **T0** is dependent on either the range of the target when the radar is tracking, or the manual positioning of the range-volts potentiometer when the radar is not tracking (in the search mode). The range-gate triggers the range-strobe multivibrator, from which the output is amplified and sent to the blocking oscillator (which sharpens the pulses), as shown in figure 3-11. This range gate is used to select the target to be tracked. When in the track mode, the range gate brightens the trace or brackets the blip (depending on the system) to indicate what target is being tracked. Range-gate generators are used most often in weapons-control track radar A-scope presentations, but they can also be used with ppi presentations. When used with a ppi presentation, the range gate must be movable in both range and bearing.

The range-gate generator can easily be modified to produce a range strobe instead of a range gate. A range strobe is simply a single brightened spot that is movable both in range and bearing. In operation, the range strobe or range gate control also controls a dial or digital readout to provide a range readout to the operator.

Range-Marker Generator

Several types of range-marker generators are in common use. Figure 3-12 shows a simplified version of a circuit that produces both range markers and the basic system timing triggers. The master oscillator in this case is a blocking oscillator that operates at a frequency of 80.86 kilohertz. By dividing 80.86 kilohertz into 1 (t = 1/frequency), we find the time required for one cycle of operation is 12.36 microseconds. Thus the blocking oscillator produces pulses 1 radar mile apart. These are fed to the 5:1 divider circuit. Five of the 1-mile marks are required to produce an output from the divider circuit. These five-mile marks are sent to the indicator for display and to the 10:1 divider circuit. In the latter case, ten of the five-mile marks are required to produce an output from the 10:1 divider. Thus the output triggers are 50 miles apart. These basic timing triggers are for a radar with a range of fifty miles. The period between triggers could be extended through the use of additional dividers for use with longer range systems.

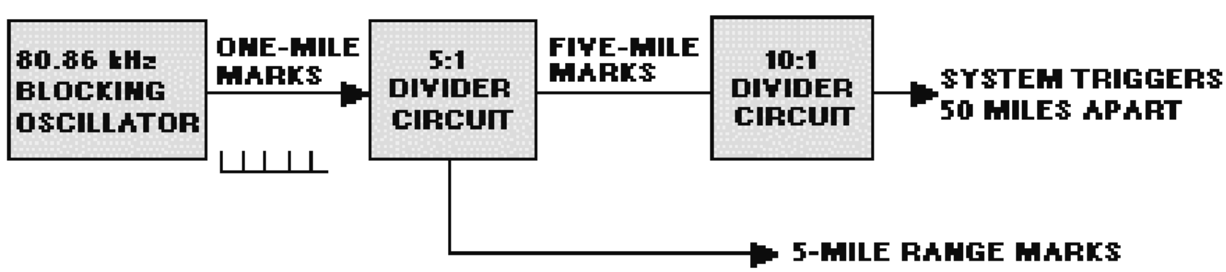

Figure 3-12.—Range-marker generator.

Another version of a range-mark generator is shown in figure 3-13. This circuit provides range marks at 1,000-, 2,000-, or 3,000-yard intervals. Generation of the marks begins with the ringing oscillator, which is started by a delayed master trigger from the synchronizer. A ringing oscillator produces a sinusoidal output of a fixed duration and frequency when triggered. The output is synchronized to the input trigger. In this circuit, the trigger causes the oscillator to produce a 162-kilohertz signal that lasts for 4 1/2 cycles. The emitter follower isolates the ringing oscillator from the countdown multivibrator and clips the oscillator output signals. This action allows only the positive half of each sine wave to reach the multivibrator. The positive triggers from the ringing oscillator are at 1,000-yard intervals. This input signal results in an output from the countdown multivibrator of 1,000-, 2,000-, or 3,000-yard range marks, depending on the position of the RANGE MARK SELECT SWITCH.

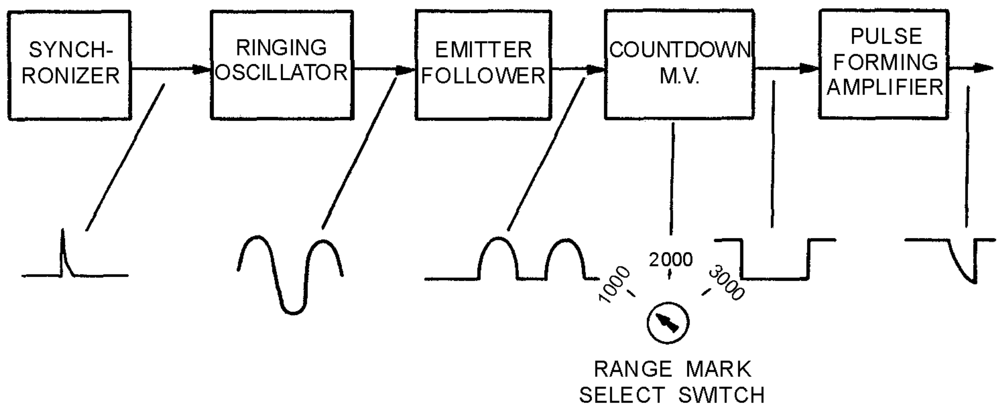

Figure 3-13.—Range-marker generator.

Range-Step Generator

The range step is often used to determine target range on an A-scope presentation. The appearance of a range step on an A-scope is illustrated in figure 3-14.

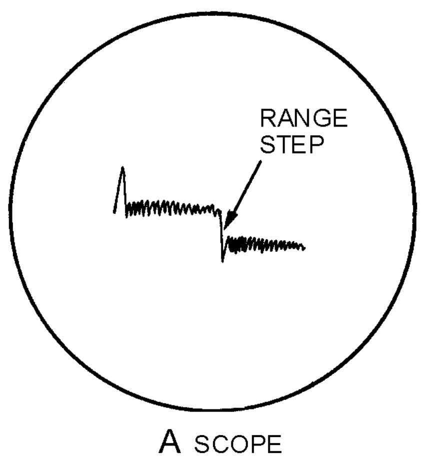

Figure 3-14.—Range-step presentation.

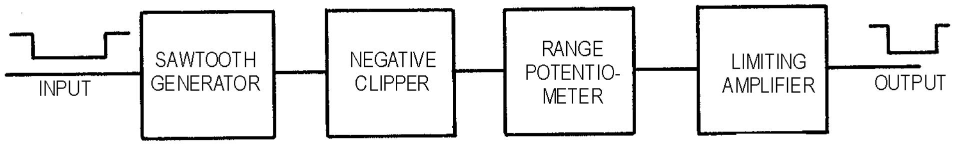
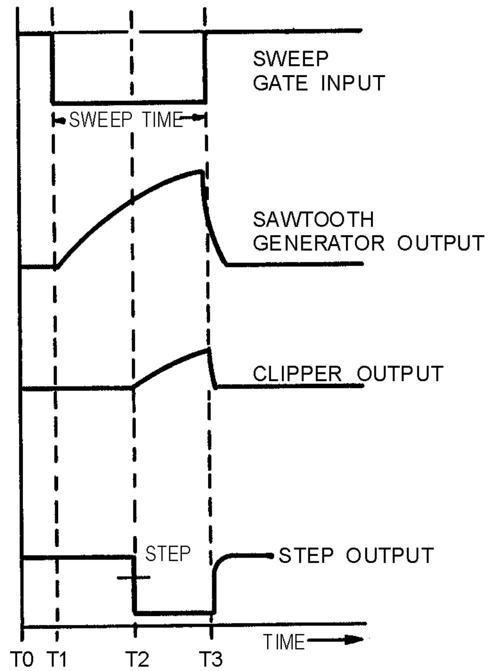
View A of figure 3-15 is a block diagram of a simple range-step generator consisting of a sawtooth generator, a negative clipper, a range potentiometer, and a limiting amplifier. The position of the range step along the indicator's time base is controlled by the range potentiometer. When the range step coincides with the leading edge of a target's echo pulse, the range can be read directly from a calibrated readout associated with the potentiometer.



(A)



(B)

Figure 3-15.—Range-step generation.

View B shows the time relationships of the voltage waveforms produced by the range-step generator. During the sweep gate, the sawtooth generator produces a sawtooth voltage that is sent to the clipper. The point at which the sawtooth is clipped is controlled by the range potentiometer. The clipped sawtooth is shaped in the limiting amplifier to produce the output voltage waveform. The portion of the output waveform from T1 to T3 is applied to the vertical-deflection plates of the indicator crt to produce the display shown in figure 3-14.

Q7. What type of ranging circuit is most often used with a radar that requires extremely accurate range data?

Q8. The range sweep in a range-gate generator is started at the same time as what other pulse?

Q9. Range-marker generators produce pulses based on what radar constant?

Q10. What radar scope uses a range step for range measurement?

RADAR ANTENNAS

In this section, we will briefly review the requirements of radar antennas. Antenna characteristics are discussed in detail in NEETS, Module 10, *Introduction to Wave-Generation, Transmission Lines, and Antenna* and in Module 11, *Microwave Principles*. A review of these modules would be helpful at this point to prepare you for the following radar antenna discussion.

Antennas fall into two general classes, OMNIDIRECTIONAL and DIRECTIONAL. Omnidirectional antennas radiate rf energy in all directions simultaneously. They are seldom used with modern radars, but are commonly used in radio equipment, in iff (identification friend or foe) equipment, and in countermeasures receivers for the detection of enemy radar signals. Directional antennas radiate rf energy in patterns of LOBES or BEAMS that extend outward from the antenna in one direction for a given antenna position. The radiation pattern also contains minor lobes, but these lobes are weak and normally have little effect on the main radiation pattern. The main lobe may vary in angular width from one or two degrees in some radars to 15 to 20 degrees in other radars. The width depends on the system's purpose and the degree of accuracy required.

Directional antennas have two important characteristics, DIRECTIVITY and POWER GAIN. The directivity of an antenna refers to the degree of sharpness of its beam. If the beam is narrow in either the horizontal or vertical plane, the antenna is said to have high directivity in that plane. Conversely, if the beam is broad in either plane, the directivity of the antenna in that plane is low. Thus, if an antenna has a narrow horizontal beam and a wide vertical beam, the horizontal directivity is high and the vertical directivity is low.

When the directivity of an antenna is increased, that is, when the beam is narrowed, less power is required to cover the same range because the power is concentrated. Thus, the other characteristic of an antenna, power gain, is introduced. This characteristic is directly related to directivity.

Power gain of an antenna is the ratio of its radiated power to that of a reference (basic) dipole. Both antennas must have been excited or fed in the same manner and each must have radiated from the same position. A single point of measurement for the power-gain ratio must lie within the radiation field of each antenna. An antenna with high directivity has a high power gain, and vice versa. The power gain of a single dipole with no reflector is unity. An array of several dipoles in the same position as the single dipole and fed from the same line would have a power gain of more than one; the exact figure would depend on the directivity of the array.

The measurement of the bearing of a target, as detected by the radar, is usually given as an angular position. The angle may be measured either from true north (true bearing), or with respect to the bow of a ship or nose of an aircraft containing the radar set (relative bearing). The angle at which the echo signal returns is measured by using the directional characteristics of the radar antenna system. Radar antennas consist of radiating elements, reflectors, and directors to produce a narrow, unidirectional beam of rf energy. A pattern produced in this manner permits the beaming of maximum energy in a desired direction. The transmitting pattern of an antenna system is also its receiving pattern. An antenna can therefore be used to transmit energy, receive energy, or both. The simplest form of antenna for measuring azimuth (bearing) is a rotating antenna that produces a single-lobe pattern.

The remaining coordinate necessary to locate a target in space may be expressed either as elevation angle or as altitude. If one is known, the other can be calculated from basic trigonometric functions. A method of determining the angle of elevation or the altitude is shown in figure 3-16. The slant range is obtained from the radar scope as the distance to the target. The angle of elevation is the angle between the axis of the radar beam and the earth's surface. The altitude in feet is equal to the slant range in feet multiplied by the sine of the angle of elevation. For example if the slant range in figure 3-16 is 2,000 feet and the angle of elevation is 45 degrees, the altitude is 1,414.2 feet (2,000 × .7071). In some radar equipments that use antennas that may be moved in elevation, altitude determination is automatically computed.

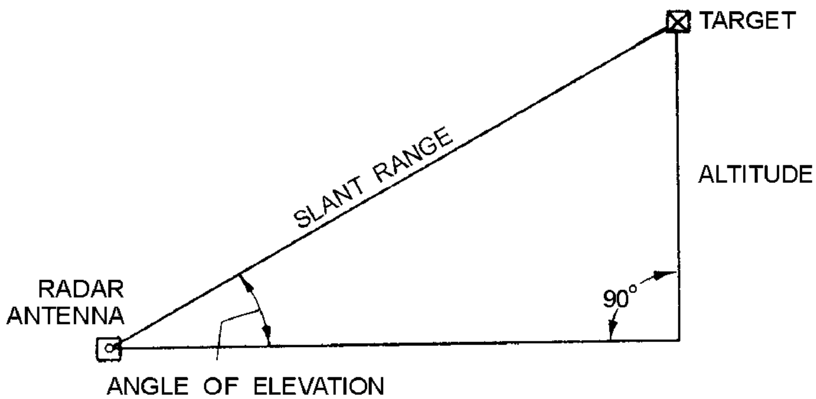


Figure 3-16.—Radar determination of altitude.

PARABOLIC REFLECTORS

A SPHERICAL WAVEFRONT spreads out as it travels and produces a pattern that is neither too sharp nor too directive. On the other hand, a PLANE wavefront does not spread out because all of the wavefront moves forward in the same direction. For a sharply defined radar beam, the need exists to change the spherical wavefront from the antenna into a plane wavefront. A parabolic reflector is one means of accomplishing this.

Radio waves behave similarly to light waves. Microwaves travel in straight lines as do light rays. They may be focused and/or reflected just as light rays can. In figure 3-17, a point-radiation source is placed at the focal point F. The field leaves this antenna with a spherical wavefront. As each part of the wavefront reaches the reflecting surface, it is shifted 180 degrees in phase and sent outward at angles that cause all parts of the field to travel in parallel paths. Because of the shape of a parabolic surface, all paths from F to the reflector and back to line XY are the same length. Therefore, all parts of the field arrive at line XY the same time after reflection.

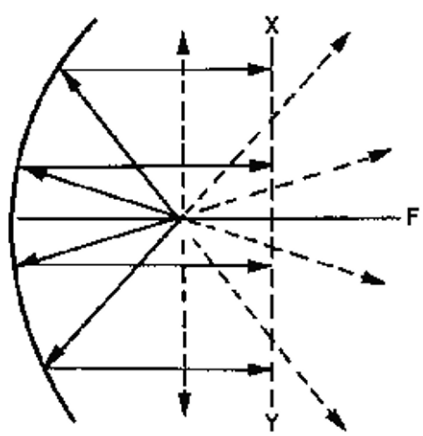

Figure 3-17.—Parabolic reflector radiation.

If a dipole is used as the source of radiation, there will be radiation from the antenna into space (dotted lines in figure 3-17) as well as toward the reflector. Energy that is not directed toward the paraboloid has a wide-beam characteristic that would destroy the narrow pattern from the parabolic reflector. This occurrence is prevented by the use of a hemispherical shield (not shown) that directs most radiation toward the parabolic surface. By this means, direct radiation is eliminated, the beam is made sharper, and power is concentrated in the beam. Without the shield, some of the radiated field would leave the radiator directly. Since it would not be reflected, it would not become a part of the main beam and thus could serve no useful purpose. The same end can be accomplished through the use of a PARASITIC array, which directs the radiated field back to the reflector, or through the use of a feed horn pointed at the paraboloid.

The radiation pattern of a parabola contains a major lobe, which is directed along the axis of revolution, and several minor lobes, as shown in figure 3-18. Very narrow beams are possible with this type of reflector. View A of figure 3-19 illustrates the parabolic reflector.

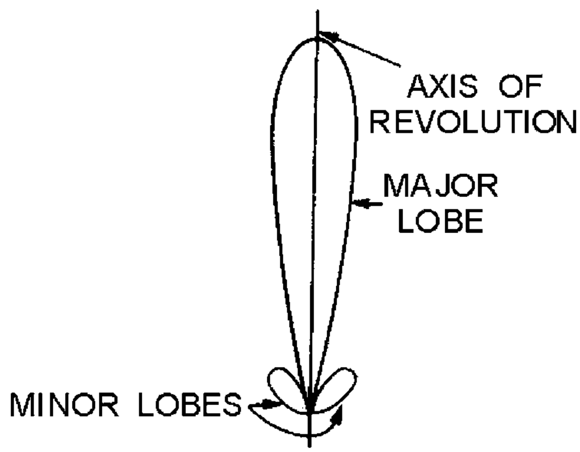

Figure 3-18.—Parabolic radiation pattern.

Truncated Paraboloid

View B of figure 3-19 shows a horizontally truncated paraboloid. Since the reflector is parabolic in the horizontal plane, the energy is focused into a narrow horizontal beam. With the reflector truncated, or cut, so that it is shortened vertically, the beam spreads out vertically instead of being focused. Since the beam is wide vertically, it will detect aircraft at different altitudes without changing the tilt of the antenna. It also works well for surface search radars to overcome the pitch and roll of the ship.

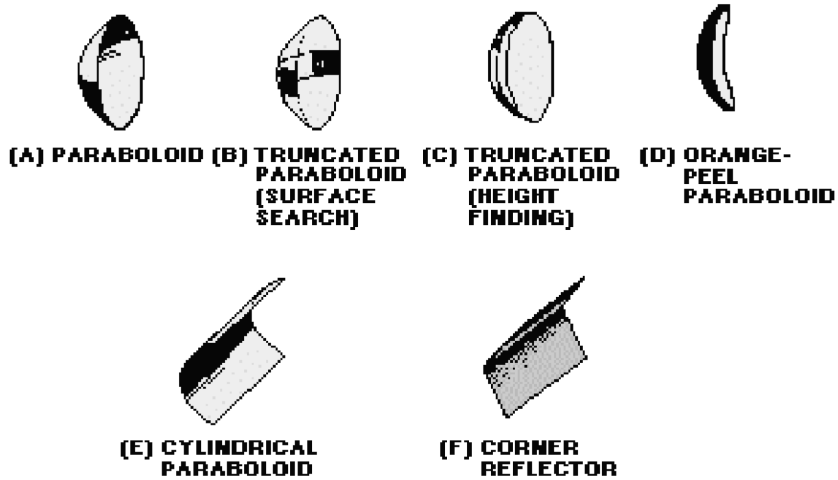

Figure 3-19.—Reflector shapes.

The truncated paraboloid reflector may be used in height-finding systems if the reflector is rotated 90 degrees, as shown in view C. Because the reflector is now parabolic in the vertical plane, the energy is focused into a narrow beam vertically. With the reflector truncated, or cut, so that it is shortened horizontally, the beam spreads out horizontally instead of being focused. Such a fan-shaped beam is used to determine elevation very accurately.

Orange-Peel Paraboloid

A section of a complete circular paraboloid, often called an ORANGE-PEEL REFLECTOR because of its shape, is shown in view D of figure 3-19. Since the reflector is narrow in the horizontal plane and wide in the vertical, it produces a beam that is wide in the horizontal plane and narrow in the vertical. In shape, the beam resembles a huge beaver tail. This type of antenna system is generally used in height-finding equipment.

Cylindrical Paraboloid

When a beam of radiated energy noticeably wider in one cross-sectional dimension than in the other is desired, a cylindrical paraboloidal section approximating a rectangle can be used. View E of figure 3-19 illustrates this antenna. A parabolic cross section is in one dimension only; therefore, the reflector is directive in one plane only. The cylindrical paraboloid reflector is either fed by a linear array of dipoles, a slit in the side of a waveguide, or by a thin waveguide radiator. Rather than a single focal point, this type of reflector has a series of focal points forming a straight line. Placing the radiator, or radiators, along this focal line produces a directed beam of energy. As the width of the parabolic section is changed, different beam shapes are obtained. This type of antenna system is used in search and in ground control approach (gca) systems.

Q11. Which of the two general classes of antennas is most often used with radar?

Q12. The power gain of an antenna is directly related to what other antenna property?

Q13. A parabolic reflector changes a spherical wavefront to what type of wavefront?

CORNER REFLECTOR

The corner-reflector antenna consists of two flat conducting sheets that meet at an angle to form a corner, as shown in view F of figure 3-19. This reflector is normally driven by a half-wave radiator located on a line which bisects the angle formed by the sheet reflectors.

BROADSIDE ARRAY

The desired beam widths are provided for some vhf radars by a broadside array, such as the one shown in figure 3-20. The broadside array consists of two or more half-wave dipole elements and a flat reflector. The elements are placed one-half wavelength apart and parallel to each other. Because they are excited in phase, most of the radiation is perpendicular or broadside to the plane of the elements. The flat reflector is located approximately one-eighth wavelength behind the dipole elements and makes possible the unidirectional characteristics of the antenna system.

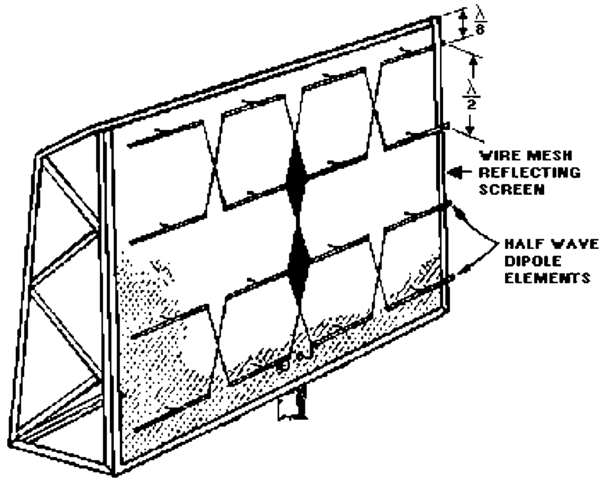

Figure 3-20.—Broadside array.

HORN RADIATORS

Horn radiators, like parabolic reflectors, may be used to obtain directive radiation at microwave frequencies. Because they do not involve resonant elements, horns have the advantage of being usable over a wide frequency band.

The operation of a horn as an electromagnetic directing device is analogous to that of acoustic horns. However, the throat of an acoustic horn usually has dimensions much smaller than the sound wavelengths for which it is used, while the throat of the electromagnetic horn has dimensions that are comparable to the wavelength being used.

Horn radiators are readily adaptable for use with waveguides because they serve both as an impedance-matching device and as a directional radiator. Horn radiators may be fed by coaxial or other types of lines.

Horns are constructed in a variety of shapes as illustrated in figure 3-21. The shape of the horn, along with the dimensions of the length and mouth, largely determines the field-pattern shape. The ratio of the horn length to mouth opening size determines the beam angle and thus the directivity. In general, the larger the opening of the horn, the more directive is the resulting field pattern.

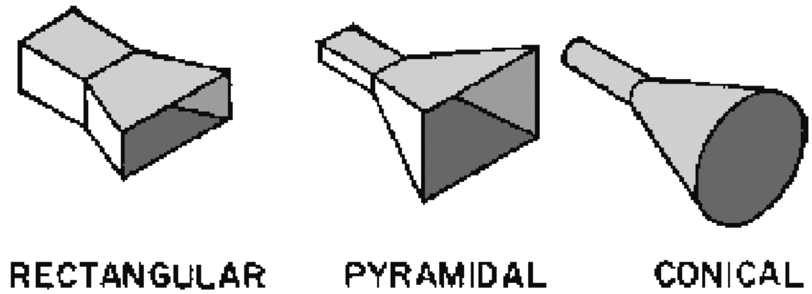

Figure 3-21.—Horn radiators.

FEEDHORNS

A waveguide horn, called a FEEDHORN, may be used to feed energy into a parabolic dish. The directivity of this feedhorn is added to that of the parabolic dish. The resulting pattern is a very narrow and concentrated beam. In most radars, the feedhorn is covered with a window of polystyrene fiberglass to prevent moisture and dirt from entering the open end of the waveguide.

One problem associated with feedhorns is the SHADOW introduced by the feedhorn if it is in the path of the beam. (The shadow is a dead spot directly in front of the feedhorn.) To solve this problem the feedhorn can be offset from center. This location change takes the feedhorn out of the path of the rf beam and eliminates the shadow. An offset feedhorn is shown in figure 3-22.

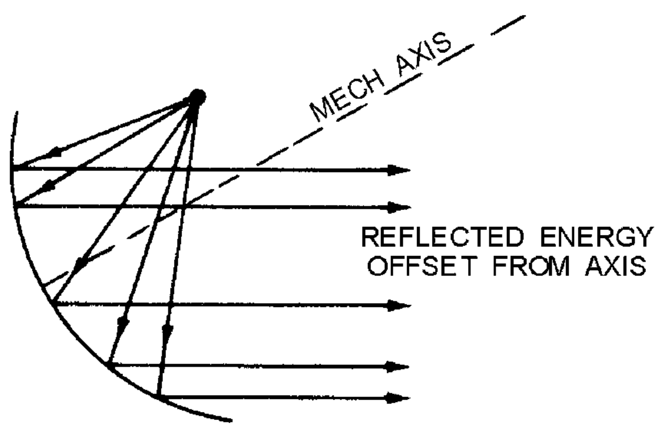

Figure 3-22.—Offset feedhorn.

AIRBORNE RADAR ANTENNAS

Airborne radar equipment is used for several specific purposes. Some of these are bombing, navigation, and search. Radar antennas for this equipment are invariably housed inside nonconducting radomes, not only for protection but also to preserve aerodynamic design. Some of these radomes are carried outside the fuselage, while others are flush with the skin of the fuselage. In the latter case, the radar antenna itself is carried inside the fuselage, and a section of the metallic skin is replaced by the nonconducting radome. The radar antenna and its radome must operate under a wide variety of temperature, humidity, and pressure conditions. As a result, mechanical construction and design must minimize any possibility of failure. Transmission lines are usually hermetically sealed to prevent moisture accumulation inside them. Such accumulation would introduce losses. Because the low air pressures encountered at high elevations are very conducive to arcing, pressurization of equipment is widely used (the pressure is maintained by a small air pump). In some airborne radar equipments, practically all of the equipment is sealed in an airtight housing, along with the antenna and transmission line. The antenna radome forms a portion of the housing.

Airborne radar antennas are constructed to withstand large amounts of vibration and shock; the radar antennas are rigidly attached to the airframe. The weight of the radar antenna, including the rotating mechanism required for scanning, is kept to a minimum. In addition, the shape of the radome is constructed so as not to impair the operation of the aircraft.

The airborne radar antenna must have an unobstructed view for most useful operation. Frequently, the antenna must be able to scan the ground directly under the aircraft and out toward the horizon. To meet this requirement, the antenna must be mounted below the fuselage. If scanning toward the rear is not required, the antenna is mounted behind and below the nose of the aircraft. If only forward scanning is needed, the antenna is mounted in the nose. When an external site is required, a location at the wing tip is common. A fire-control radar antenna is frequently located near the turret guns or in a special nacelle, where it can scan toward the rear or sides of the aircraft.

Q14. How many major lobes are produced by a paraboloid reflector?

Q15. What type of radiator normally drives a corner reflector?

Q16. The broadside array consists of a flat reflector and what other elements?

Q17. Horn radiators serve what purpose other than being directional radiators?

SUMMARY

The following is a brief summary of the important points of this chapter.

A radar **INDICATOR** presents the information (video) from the radar receiver in a usable manner. The display usually consists of one or more of the coordinates of range, bearing, and altitude.

The **CATHODE-RAY TUBE (crt)** is the best available device for displaying the two-dimensional relationship produced by radar coordinates. The most commonly used crt displays are the A-SCOPE, the RHI, and the PPI. The A-scope presents range information only. The rhi displays range and height information. The ppi is the most widely used radar display indicator and presents range and bearing.

The range of a radar contact is determined by special **RANGING CIRCUITS**. The following three basic types of ranging circuits are used.

RANGE-GATE GENERATORS produce a movable gate that measures range based on elapsed time and can be used on A-scope and ppi displays.

RANGE-MARKER GENERATORS produce fixed interval range marks that can be used to estimate the range to a detected target. Range marks appear as an intensified series of vertical dots on an rhi and as concentric circles on a ppi.

The **RANGE-STEP GENERATOR** produces a movable step that is displayed on an A-scope presentation.

RADAR ANTENNAS are usually directional antennas that radiate energy in a one directional lobe or beam. The two most important characteristics of directional antennas are directivity and power gain. Radar antennas often use parabolic reflectors in several different variations to focus the radiated energy into a desired beam pattern. Other types of antennas used with radar systems are the corner reflector, the broadside array, and horn radiators.

ANSWERS TO QUESTIONS Q1. THROUGH Q17.

A1. Range, bearing, and elevation.

A2. Triggers, video, and antenna information.

A3. Range and elevation.

A4. Range and bearing.

A5. Electromagnetic.

A6. Fixed.

A7. Range gate or range step.

A8. Transmitter.

A9. The radar mile (12.36 microseconds).

A10. The A scope.

A11. Directional.

A12. Directivity.

A13. Plane.

A14. One.

A15. Half-wave.

A16. Two or more half-wave dipoles.

A17. Waveguide impedance matching devices.

CHAPTER 4

RADAR SYSTEM MAINTENANCE

LEARNING OBJECTIVES

Upon completion of this chapter, the student will be able to:

1. Interpret the transmitter frequency spectrum in terms of frequency distribution, power output, receiver response, and an acceptable spectrum curve.
2. Describe the methods for measuring the average and peak power outputs of a radar transmitter.
3. Describe the methods of measuring receiver sensitivity.
4. Define receiver bandwidth in terms of the receiver response curve and state the most common methods of measuring tr tube recovery time.
5. List the support systems associated with a typical shipboard radar system and describe the basic function of each.
6. State the general rules for the prevention of personnel exposure to rf radiation and X-ray emissions.

INTRODUCTION TO RADAR MAINTENANCE

The effectiveness of your radar system depends largely upon the care and attention you give it. An improperly adjusted transmitter, for example, can reduce the accuracy of a perfectly aligned receiver; the entire system then becomes essentially useless. Maintenance, therefore, must encompass the entire system for best operation.

Because of the complexity of most radar systems, trying to detail step-by-step procedures for specific maintenance actions in this chapter is impractical. However, the basic procedures for some maintenance actions that are common to most radar systems will be discussed. Also, an overview of support systems for radars will be presented. This will include electrical power, dry-air systems, and liquid cooling systems. Finally, safety precautions inherent to radars are listed.

TRANSMITTER PERFORMANCE CHECKS

The transmitter of a radar is designed to operate within a limited band of frequencies at an optimum power level. Operation at frequencies or power levels outside the assigned band greatly decreases the efficiency of the transmitter and may cause interference with other radars. Therefore, transmitter performance must be monitored closely for both frequency and output power.

TRANSMITTER FREQUENCY

Whether of the fixed-frequency or tunable type, the radar transmitter frequency should be checked periodically. If the transmitter is of the fixed-frequency type and found to be operating outside its normal operating band, the problem is probably a defective part. The defective component must be replaced. If the transmitter is tunable, the transmitter must again be tuned to the assigned frequency.

Each time a radar transmitter generates an rf pulse, it produces electromagnetic energy. You should recall from your study of NEETS, Module 12, *Modulation Principles*, that the square wave used to modulate the transmitter carrier wave has (1) the fundamental square-wave frequency and (2) an infinite number of odd harmonics of the fundamental square wave frequency. When this square wave is used to modulate the transmitter carrier frequency, both the fundamental and odd harmonic frequencies of the square wave heterodyne with the transmitter carrier frequency. The heterodyning process produces in each transmitted rf pulse the following frequencies:

1. The fundamental carrier frequency
2. The sum and difference frequencies between the carrier and fundamental square-wave frequencies
3. The sum and difference frequencies between the odd harmonics of the square wave and the carrier frequencies

For a complete discussion of this process, you should review module 12.

Actually, the radar energy is distributed more or less symmetrically over a band of frequencies. This frequency distribution of energy is known as the FREQUENCY SPECTRUM. An analysis of frequency spectrum characteristics may be made with a SPECTRUM ANALYZER. The spectrum analyzer presents a graphic display of energy versus frequency. An extensive explanation of spectrum analyzer use can be found in the Electronics Installation and Maintenance Book (EIMB), *Test Methods and Practices*, NAVSEA 0967-LP-000-0130.

Spectrum Analysis

When properly performed and interpreted, a spectrum analysis will reveal misadjustments and troubles that would otherwise be difficult to locate. Therefore, you should be able to perform a spectrum analysis and understand the results.

You may be wondering why we are so interested in the frequency spectrum of an rf pulse. To better understand why, look at the spectrum of a transmitter as compared to the response curve of a receiver in figure 4-1. The receiver's response curve has a broader bandwidth than the transmitted spectrum, which ensures complete coverage. But the receiver responds best to frequencies in the middle of the bandwidth. This causes the receiver response to taper off from both sides of the center frequency until the response passes through the half-power points, as shown on the curve. Usually the receiver response beyond these points is too low to be useful and is not considered. Notice that the spectrum of the transmitter is centered inside the response curve of the receiver, thus yielding maximum efficiency.

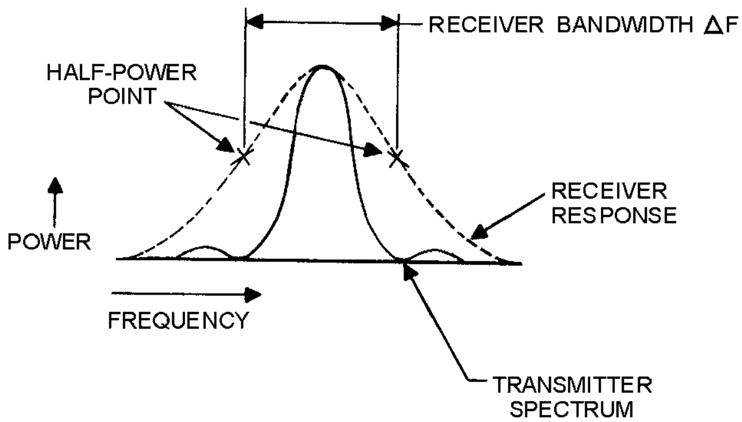

Figure 4-1.—Transmitter spectrum compared with receiver response.

Any frequency, when modulated by another frequency, will produce a base frequency with sideband frequencies (sum and difference). In other words, the output of a pulsed radar will contain more than one frequency. The output frequency spectrum of the pulsed radar transmitter does not consist of just a single frequency that is turned on and off at the pulse-repetition frequency (prf). Consider the spectrum as a base frequency (carrier) that is modulated by short rectangular pulses occurring at the prf of the radar. Two distinct modulating components are present: One component consists of the prf and its associated harmonics; the other component consists of the fundamental and odd-harmonic frequencies that make up the rectangular modulating pulse.

The distribution of power over the radar frequency spectrum depends on the amount of modulation. A pulsed radar spectrum is illustrated in figure 4-2. The vertical lines represent the modulation frequencies produced by the prf and its associated harmonics; the lobes represent the modulation frequencies produced by the fundamental pulse frequency and its associated harmonics. The amplitude of the main lobe falls to zero on each side of the carrier. The side lobes are produced by the odd harmonics of the fundamental pulse frequency. The zero points are produced by the even harmonics of the fundamental pulse frequency. In an ideal spectrum each frequency above the carrier has its counterpart in another frequency below the carrier. These frequencies are equally spaced and have equal power. Therefore, the pattern is symmetrical about the carrier. The main lobe, of course, contains the major portion of the transmitted rf energy.

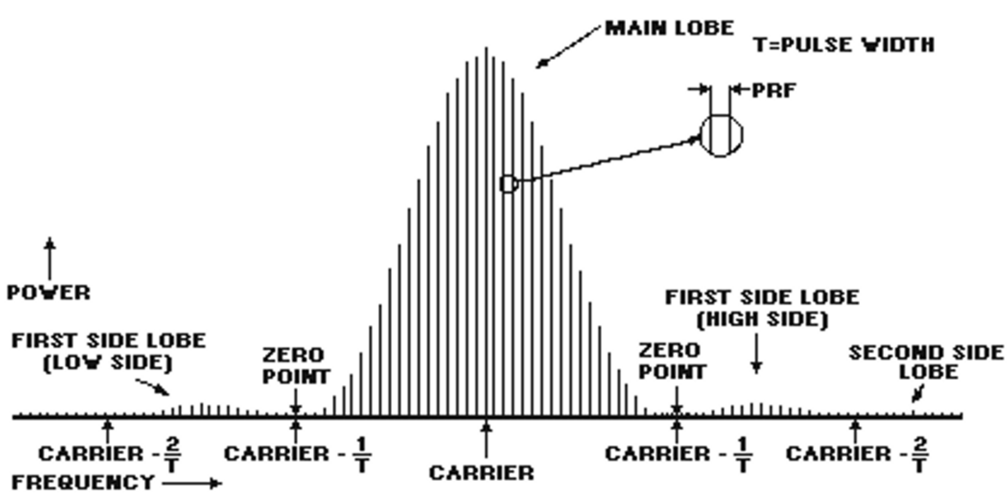

Figure 4-2.—Spectrum of a pulse-modulated carrier.

A radar transmitter in good condition should produce a spectrum curve similar to the curves shown in view A or B in figure 4-3. Good curves are those in which the two halves are symmetrical and contain deep, well-defined minimum points (minima) on both sides of the main peak.

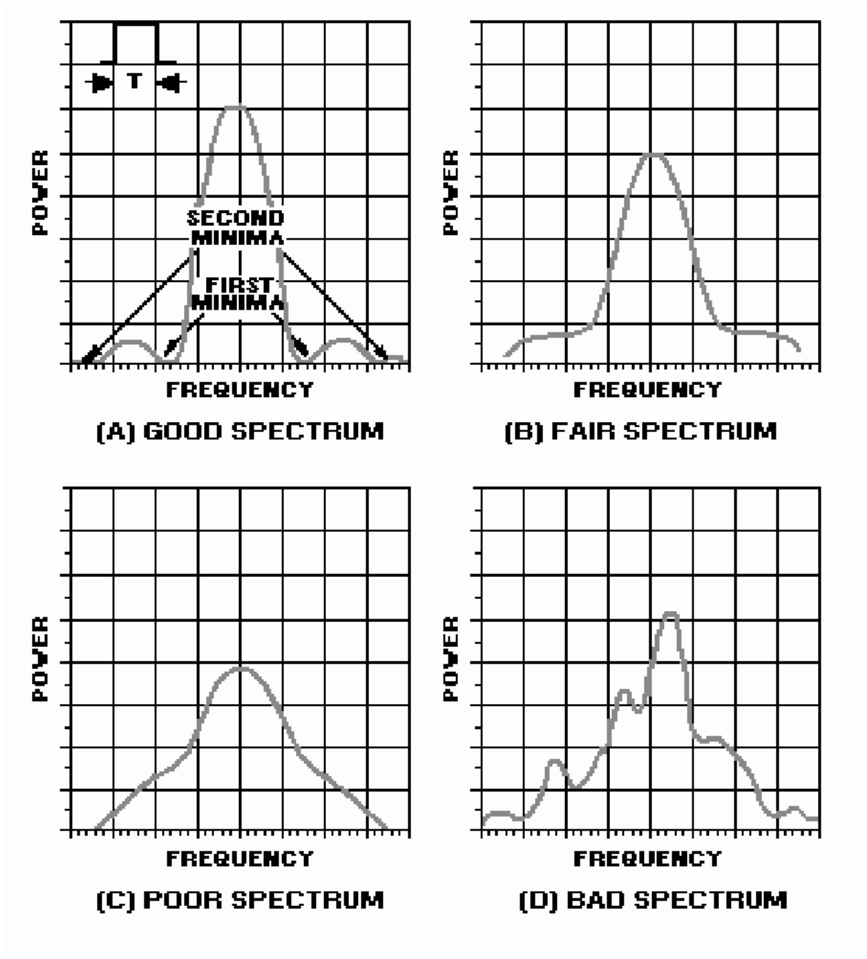

Figure 4-3.—Comparison of radar spectra.

A curve without well-defined minima, as in the curve shown in view C, indicates that the transmitter output is being frequency modulated during the pulse. This condition may occur when a pulse without sufficiently steep sides or a flat peak is applied to the transmitter. It may also occur when a transmitter tube is unstable or is operated without proper voltage, current, or magnetic field.

An extremely irregular spectrum, as in the curve in view D, is an indication of severe frequency modulation. This condition usually causes trouble with the receiver automatic frequency control (afc) as well as a general loss of signal strength. You can often improve a faulty spectrum by adjusting the transmission line stubs or by replacing the transmitter tube. When the spectrum has two large peaks that are quite far apart, it indicates that the transmitter tube is DOUBLE MODING (shifting from one frequency to another). This could be caused by standing waves in the transmission line or a faulty transmitter tube. Standing waves may be caused by a faulty line connection, a bad antenna rotating joint, or obstructions in the line. (Standing waves are described in NEETS, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas*.)

In the case of a good or fair spectrum curve with sharply defined minimum points on both sides of the main lobe, the distance between these two points is proportional to the duration of the transmitted pulse.

The device most commonly used to check the frequency spectrum of a radar transmitter is the spectrum analyzer.

Frequency-Measuring Devices

Devices used to determine the basic carrier frequency of a radar transmitter are the ELECTRONIC FREQUENCY COUNTER, the WAVEMETER, and the ECHO BOX. One or more of these devices may be included in a special RADAR TEST SET designed for a specific system or type of radar. Radar test sets quite often consist of several types of test equipment. This combination of test equipments enables both transmitter and receiver performance checks to be carried out with one test instrument. Electronic frequency counters, frequency meters, and wavemeters are discussed in NEETS, Module 16, *Introduction to Test Equipment*. The echo box is discussed in the next section. The specific equipments and procedures required to measure the frequency of any radar system are found in the associated system technical manuals and related PMS documents.

Q1. The spectrum of a radar transmitter describes what characteristic of the output pulse?

Q2. Where should the transmitter spectrum be located with respect to the receiver response curve?

Q3. The ideal radar spectrum has what relationship to the carrier frequency?

Q4. The display screen of a spectrum analyzer presents a graphic plot of what two signal characteristics?

The Echo Box

The ECHO BOX is an important test instrument for indicating the overall radar system performance. The echo-box test results reflect the combined relative effectiveness of the *transmitter* as a transmitter of energy and the receiver as a *receiver* of energy.

The echo box, or RESONANCE CHAMBER, basically consists of a resonant cavity, as shown in view A of figure 4-4. You adjust the resonant frequency of the cavity by varying the size of the cavity (the larger the cavity the lower the frequency). A calibrated tuning mechanism controls the position of a plunger and, therefore, the size of the cavity. The tuning mechanism is adjusted for maximum meter deflection, which indicates that the echo box is tuned to the precise transmitted frequency. The tuning mechanism also indicates on a dial (figure 4-5, view A) both the coarse transmitted frequency and a numerical reading. This reading permits the technician to determine the transmitted frequency with greater accuracy by referring to a calibration curve on a chart (figure 4-5, view B).

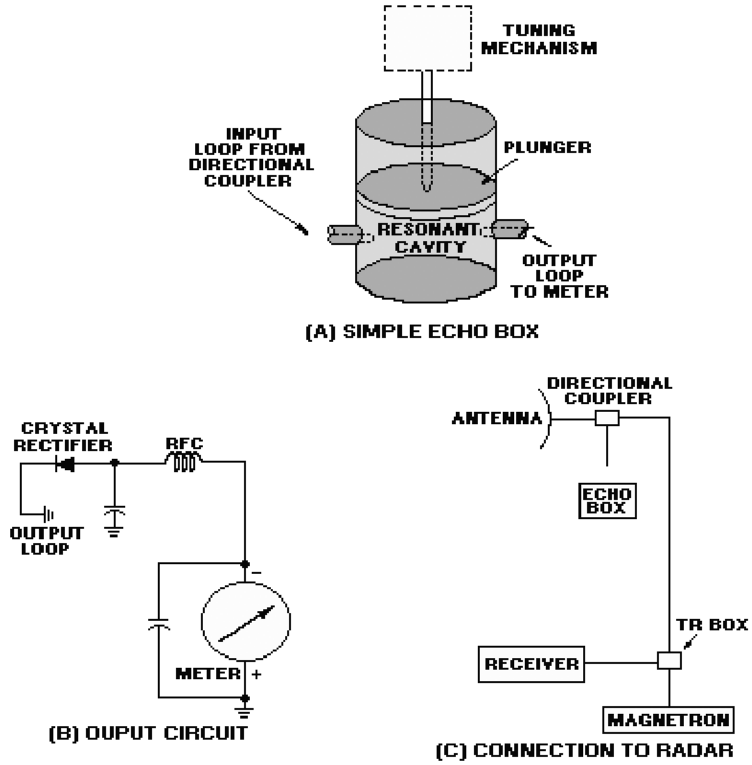

Figure 4-4.—Echo box.

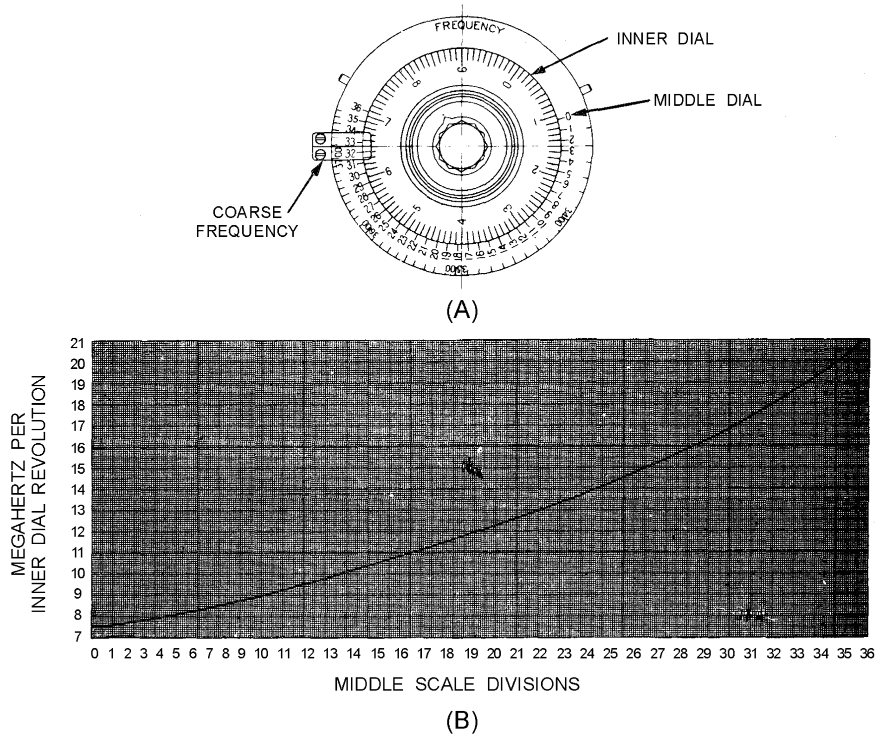

Figure 4-5.—Reading the echo box dial.

Energy is coupled into the cavity from the radar by means of an rf cable connected to the input loop. Energy is coupled out of the cavity to the rectifier and meter by means of the output loop. You can vary the amount of coupling between the echo box and the crystal rectifier by changing the position of the output loop. A schematic diagram of the output circuit is shown in figure 4-4, view B. The energy picked up by the loop is rectified, filtered, and applied to the meter. The method of connecting the echo box in a radar system is shown in figure 4-4, view C.

RING TIME MEASUREMENTS

Some of the energy generated by the radar transmitter is picked up by the echo box by means of the directional coupler. This energy causes oscillations (known as RINGING) within the echo box that persist for some time after the end of the radar pulse, much in the fashion of an echo that persists in a large room after a loud noise. As this echo dies down, a part of it is fed back into the radar receiving system, again by means of the directional coupler. The ringing causes a saturating signal to appear on the radar indicator (figure 4-6). The longer this ringing extends, the better the performance of the radar.

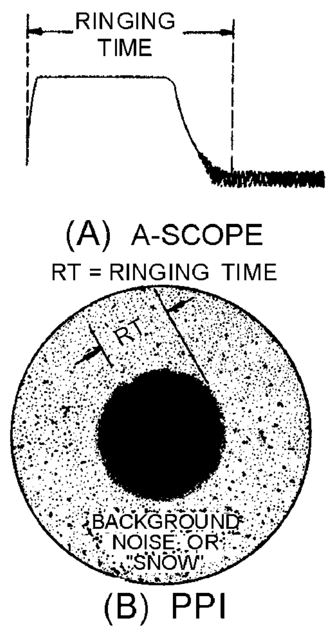

Figure 4-6.—Ring time saturation of A-scope and ppi.

The length of time the echo box *should* ring under the particular conditions of the test is called the EXPECTED RING TIME. You may determine whether or not the radar is performing well by comparing the expected ring time with the ring time observed.

The ring time to be expected on a good radar depends on the particular type of radar being tested; on the way the echo box is installed - that is, whether a directional coupler or a pickup dipole is used; on the length and type of cable used; on the individual ringing ability of the particular echo box in use; on the frequency of the radar; and on the temperature of the echo box at the time of the test. Corrections are made for all of these factors according to the procedure given in the technical manual for the echo box being used.

You may use an echo box without correction to detect a *change* in the performance of a radar. You simply log and compare the ring time from day to day. You should recognize that these readings do not permit the comparison of a particular radar with a standard of performance; however, you can use the readings to tell whether or not its performance is deteriorating.

Because ring time measurements are the most valuable single feature of the echo box, they must be measured properly. Ring time measurements are made on the A-scope or on the ppi.

In measuring the ring time, you should make sure the echo-box ringing (not some fixed-target echo or block of echoes) is being monitored. You can determine this condition by adjusting the radar gain control and noting if the ring time varies on the scope. The echo box ringing will change in duration; fixed target echoes, however, will not change duration.

To obtain the best results, you should repeat every ring time measurement at least four times; then average the readings. You should take special care to ensure that all readings are accurate. If two or more technicians use the same echo box, they should practice together until their ring time measurements agree.

TRANSMITTER POWER MEASUREMENT

Because high peak power and radio frequencies are produced by radar transmitters, special procedures are used to measure output power. High peak power is needed in some radar transmitters to produce strong echos at long ranges. Low average power is also desirable because it enables transmitter components to be compact, more reliable, and to remain cooler during operation. Because of these considerations, the lowest possible duty cycle (pw x prf) must be used for best operation. The relationships of peak power, average power, and duty cycle were described in chapter 1. Peak power in a radar is primarily a design consideration. It depends on the interrelationships between average power, pulse width, and pulse-repetition time.

You take power measurements from a radar transmitter by sampling the output power. In one sampling method, you use a pickup horn in front of the antenna. Air losses and weather conditions make the horn placement extremely critical and also affect the accuracy of the sample. A more accurate and convenient method can be used. In this method, you sample the output power through a directional sampling coupler located at the point in the transmitter where a power reading is desired. Power-amplifier transmitters usually have sampling couplers after each stage of amplification.

Some radar sets have built-in power-measuring equipment; others require the use of general purpose test equipment or a special test set. In any case, the measuring instruments are most often referenced to 1 milliwatt; readings are taken in dBm (a discussion of the decibel measurement system was presented in NEETS, Module 11, *Microwave Principles*).

When taking power measurements, you must allow for power losses. You must add the directional coupler attenuation factor and the loss in the connecting cable to the power meter reading. The sum is the total power reading. For example, the directional coupler has an attenuation factor of 20 dB, the connecting cable has a loss rating of 8 dB, and the reading obtained on the power meter is 21 dBm. Therefore, the transmitter has an output power that is 49 dBm (21 + 20 + 8). Power readings in dBm obtained by the above procedure are normally converted to watts to provide useful information. Although the conversion can be accomplished mathematically, the procedure is relatively complex and is seldom necessary. Most radar systems have a conversion chart, such as the one shown in figure 4-7, attached to the transmitter or the test equipment. As you can see on the chart, 49 dBm is easily converted to 80 watts average power.

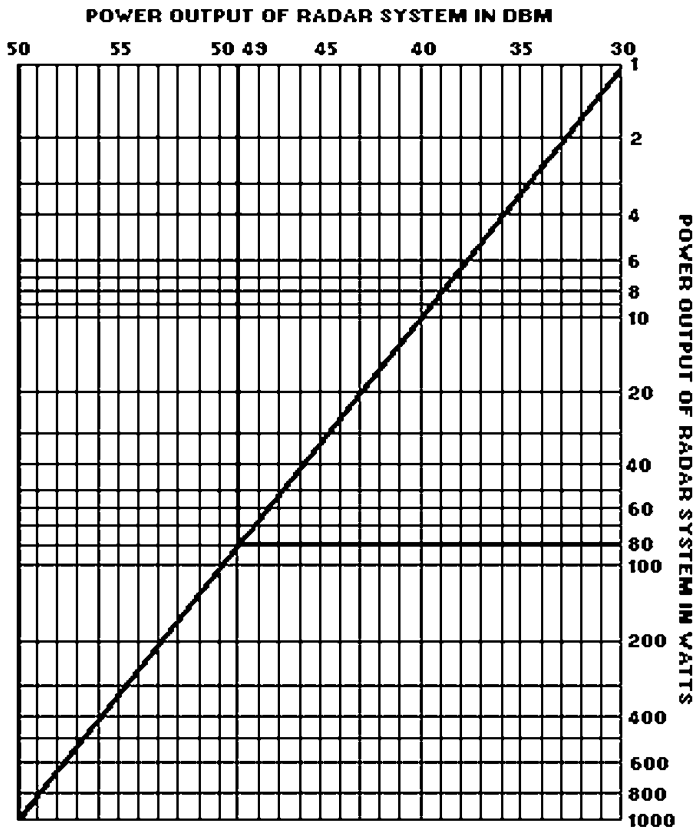

Figure 4-7.—Conversion of power in dBm to watts (average).

You can convert average power to peak power by dividing average power by the duty cycle of the radar. If the radar in the above example has a duty cycle of 0.001, then the peak power can be calculated with the following formula:

$$\text{peak power } (P_{pk}) = \frac{\text{average power } (P_{avg})}{\text{duty cycle}}$$

$$= \frac{80 \text{ watts}}{0.001}$$

$$= 80,000 \text{ watts or } 80 \text{ kilowatts}$$

Many radar systems have charts available to convert average power to peak power.

Q5. The peak power of a radar depends on the interrelationship of what other factors?

Q6. Transmitter power readings are most often referenced to what power level?

RECEIVER PERFORMANCE CHECKS

The performance of a radar receiver is determined by several factors, most of which are established in the design engineering of the equipment. In the paragraphs that follow, factors concerned with maintenance are considered. Important factors are (1) receiver sensitivity, which includes noise figure determination and minimum discernible signal (mds) measurement; (2) tr recovery time; and (3) receiver bandwidth.

Many radar systems contain circuits that serve special functions. Three of these special circuits are instantaneous automatic gain control (iagc), sensitivity time control (stc), and fast time constant (ftc). These circuits may be found in combination or alone, depending on the purpose of the radar. When the test methods and procedures about to be described are used, these special functions should not be used. If an automatic frequency control (afc) circuit is included in the radar, it may be permitted to operate during receiver tests. A good way you can check afc circuit operation is to complete the tests specified for manual tuning and then switch to afc. If the afc circuit operation is normal, test indications should not differ.

RECEIVER SENSITIVITY

Insufficient detection range in a radar system can be caused by decreased sensitivity in the radar receiver. This condition results mainly from the great number of adjustments and components associated with the receiver. A decrease of receiver sensitivity has the same effect on range performance as does a decrease of transmitter power. For example, a 6 dB loss of receiver sensitivity shortens the effective range of a radar just as much as a 6 dB loss in transmitter power. Such a drop in transmitter power is evident and is easy to detect. On the other hand, a 6 dB loss in receiver sensitivity, which can easily result from a slight misadjustment in the receiver, is difficult to detect unless accurate measurements are made.

Figure 4-8 shows a comparison of radar system performance versus maximum range. The system performance loss in dB includes both transmitter and receiver losses. You should note that with a loss of 5 dB in both receiver and transmitter (a total of 10 dB), only 55 percent of the maximum range of the system is realized.

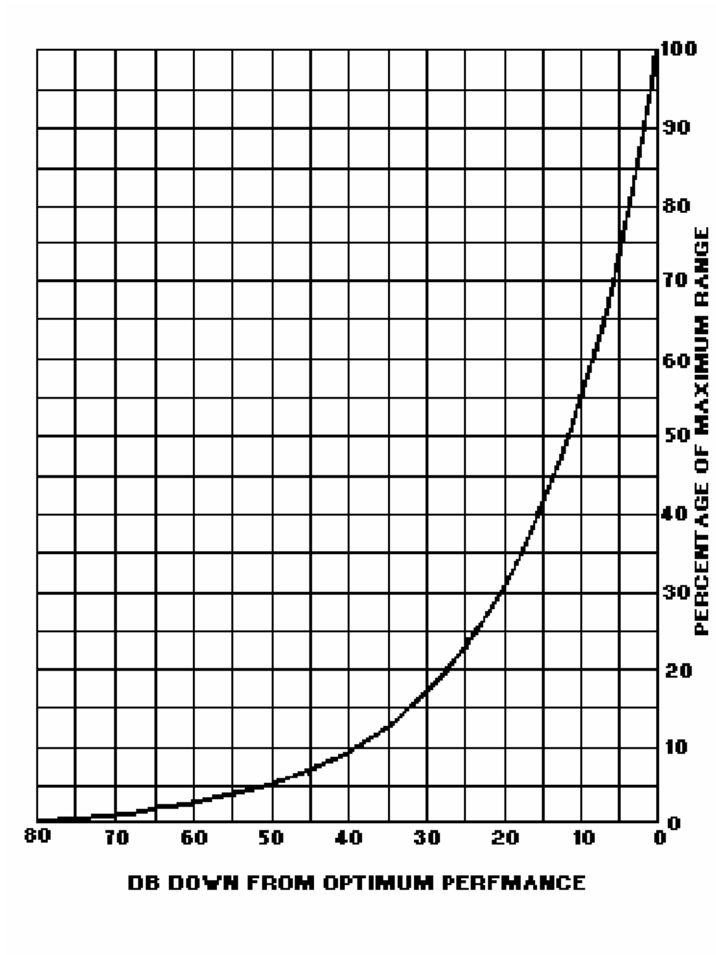

Figure 4-8.—System performance versus maximum range.

The sensitivity of the radar receiver is a measure of its ability to pick up weak signals. The greater the sensitivity of the receiver, the better the receiver picks up weak signals. You can determine receiver sensitivity by measuring the power level of the MINIMUM DISCERNIBLE SIGNAL (mds). Mds is defined as the weakest signal that produces a visible receiver output (on a scope). Its value is determined by the receiver output noise level (noise tends to obscure weak signals). Because mds measurement depends on the receiver noise level, measuring either mds or noise level (called NOISE FIGURE) will indicate receiver sensitivity.

Many radar systems have built-in receiver sensitivity test circuits. These test circuits indicate the sensitivity of the receiver to the technician or operator.

To measure the mds, you must measure the power of a test pulse in which the level is just sufficient to produce a visible receiver output. If a radar receiver has the mds level specified in the maintenance manual, then the noise figure should also be correct. Therefore, measurement of the mds is a satisfactory substitute for a noise-figure determination and is less complicated.

Because receiver sensitivity readings are taken periodically for comparison purposes, the identical pulse length must be used for each measurement. Maintenance instructions for the radar set usually specify the correct pulse length to be used in receiver sensitivity tests. In most cases, it is the same as the transmitter pulse length.

Before any measurements of receiver sensitivity can be made, the receiver must be accurately tuned to the transmitter frequency. If the receiver frequency differs from the transmitter frequency, the most likely cause is an improperly adjusted or malfunctioning local oscillator or transmitter frequency drift. Such problems can be caused by heat or aging components. Local oscillator tuning procedures differ widely according to the type of radar system; therefore, you should follow the tuning procedures in the system maintenance manuals.

Two basic methods are used to measure radar receiver sensitivity. One is the PULSE METHOD, in which a pulse of measured amplitude and width is coupled to the receiver. In the second method, you use an fm generator to vary the signal generator output frequency across the receiver bandwidth. This latter method ensures the test signal is within the bandpass of the receiver.

The sensitivity of the receiver is equal to the sum of the reading on the signal generator and the attenuations of the connecting cable and directional coupler. Receiver sensitivity is expressed as a negative dBm; for example, -90 dBm expresses the sensitivity of a receiver that can detect a signal 90 dB less than the 1-milliwatt reference level. A typical receiver sensitivity reading on a modern radar should be in the vicinity of -105 dBm.

RECEIVER BANDWIDTH TEST

Receiver bandwidth is defined as the frequency spread between the half-power points on the receiver response curve. Receiver bandwidth is specified for each radar, but wide variations are often tolerated. If either the bandwidth or the shape of the receiver response curve is not within tolerances, a detailed check of circuit components may be necessary. A considerable change in the value of circuit components is required to alter the response. You should check receiver response after any extensive repair to an IF amplifier.

Figure 4-9 shows a typical response curve of a radar receiver. The half-power points are shown as 3 dB below maximum response. Since the curve is plotted in terms of voltage, these points are also represented by the 70.7 percent voltage points as shown in the figure.

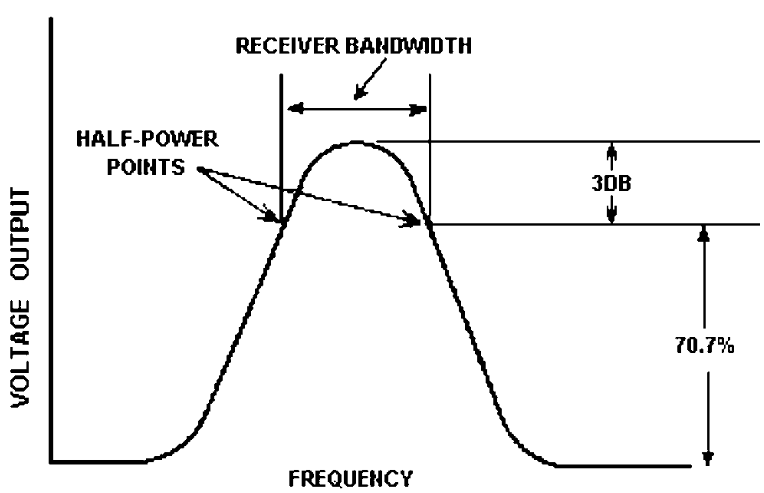

Figure 4-9.—Typical receiver response curve.

TR RECOVERY TIME

The time required for tr recovery is determined by the time taken by the tr switch (tube) to deionize after each transmitter pulse. It is usually defined as the time required for the receiver to return to within 6 dB of normal sensitivity after the end of the transmitter pulse. However, some manufacturers use the time required for the sensitivity to return to within 3 dB of normal sensitivity. Tr recovery time is a factor that limits the minimum range of a radar because the radar receiver is unable to receive until the tr switch is deionized. In various radars, the recovery time may differ from less than 1 microsecond to about 20 microseconds.

The primary function of the tr switch is to protect the sensitive crystal detectors from the powerful transmitter pulse. Even the best tr switches allow some power to leak through; but when the switch is functioning properly, leakage power is so small that it does not damage the crystal. However, the useful life of a tr tube is limited because the amount of leakage to the receiver increases with use.

To ensure efficient performance, some technicians make a policy of replacing the tr tube after a certain number of hours of use. A better practice is to measure the tr recovery time at frequent intervals and make a graph or chart. A graph or chart will immediately disclose any change in performance. Figure 4-10 shows how the recovery time is correlated with leakage power. Note that the end of the useful life of the tr tube is indicated by an increase in recovery time.

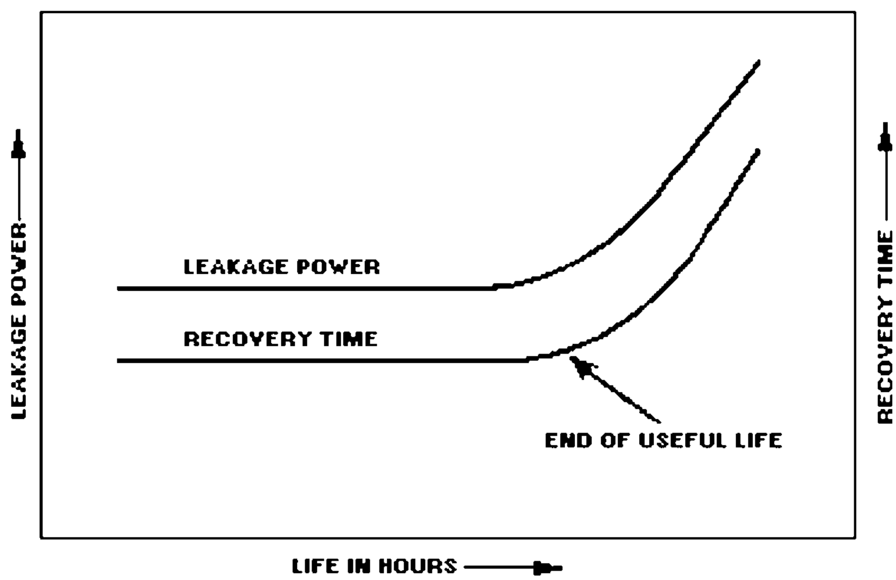

Figure 4-10.—Tr recovery time versus leakage power.

This method of checking the condition of a tr tube is reliable because recovery time increases before leakage power becomes excessive. In practice, a tr tube is replaced when any sharp increase in recovery time becomes apparent.

Ambient temperature also has an effect on recovery time. The colder a tr tube, the greater its recovery time. When tests are conducted under widely varying temperature conditions, this effect must be considered.

One method you can use in testing a tr tube is to measure the KEEP-ALIVE current. This current keeps the tr tube partially ionized, which makes the firing more instantaneous and thus helps protect the receiver crystals. The keep-alive current is normally about 100 microamperes but falls off as the end of the tr tube life approaches. You can also measure the keep-alive voltage between the plate of the tr tube and ground when the voltage source is known to have the correct output. You then record this voltage for use as a reference for future checks. However, these checks are not as reliable as recovery time testing.

Specific procedures for measuring tr leakage and recovery time can be found in the equipment technical manuals.

Q7. A loss of receiver sensitivity has the same effect on range performance as what other loss?

Q8. You determine receiver sensitivity by measuring the power level of what signal?

Q9. When measuring receiver sensitivity, what quantities must you add to the dBm reading obtained on the signal generator or test set?

STANDING WAVE MEASUREMENTS

(You may want to refer to NEETS, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas* for a review of standing waves before going further.) Measurements of standing waves can indicate the approximate operating frequency, the presence of defective transmission-line sections, and the condition of the antenna. Standing waves present on transmission lines and waveguides indicate an impedance mismatch between a transmitter or receiver and its antenna. When this condition occurs, the transfer of energy between these units becomes inefficient. Reflection of energy at the load end of a transmission line results in a wave that travels toward the generator end. This reflected wave varies continuously in phase in much the same way that the incident wave varies in phase. At certain points, a half wavelength apart, the two waves are exactly in phase; the resultant voltage is at maximum. At points a quarter wavelength from the maximums, the two waves are in opposition and voltage nodes (null points) are produced. The ratio of maximum-to-minimum voltage at such points is called the VOLTAGE STANDING WAVE RATIO (vswr). The ratio of maximum-to-minimum current along a transmission line is the same as the vswr. A high vswr (1.5 to 1 or higher) indicates that the characteristic impedance of a transmission line differs greatly from the terminating impedance; a low vswr (1 to 1 is best) indicates a good impedance match between the transmission line characteristic impedance and the terminating impedance.

For radar applications, a low vswr is desired for the following reasons: (1) Reflections in the transmission line cause improper transmitter operation and can result in faulty pulsing (this effect is most pronounced when the line is long, as compared with a wavelength of the transmitted energy); (2) arc-over may occur at the maximum voltage points; and (3) hot spots can occur in the transmission line and cause mechanical breakdown. Since transmission lines for radar equipment are normally coaxial cables or waveguides, slotted lines or directional couplers must be used for standing-wave measurements.

Q10. Receiver bandwidth is defined as those frequencies spread between what two points of the receiver response curve?

Q11. The end of the usefulness of a tr tube is indicated by an increase in what quantity?

SUPPORT SYSTEMS

When you think of radar equipment with its complex electronic circuitry and other sophisticated equipment, you may forget that the entire radar relies on other systems. These other systems are referred to as SUPPORT SYSTEMS and are not normally thought of as part of the radar. These support systems include ELECTRICAL POWER, DRY-AIR, and LIQUID-COOLING SYSTEMS. Without these support systems, radars could not function. Therefore, you must be aware of these support systems and understand their relationship to your radar equipment.

ELECTRICAL POWER

Let us now look at a typical ship's power distribution system. The power system on your ship or aircraft is probably similar in many ways. We will briefly discuss an overall power distribution system and the areas that are closely related to radar equipment.

Power Distribution System

Most ac power distribution systems in naval vessels are 440-volt, 60-hertz, 3-phase, 3-wire, ungrounded systems. The ac power distribution system consists of the power source, equipment to distribute the power, and the equipment which uses the power. A partial distribution chart is shown in figure 4-11.

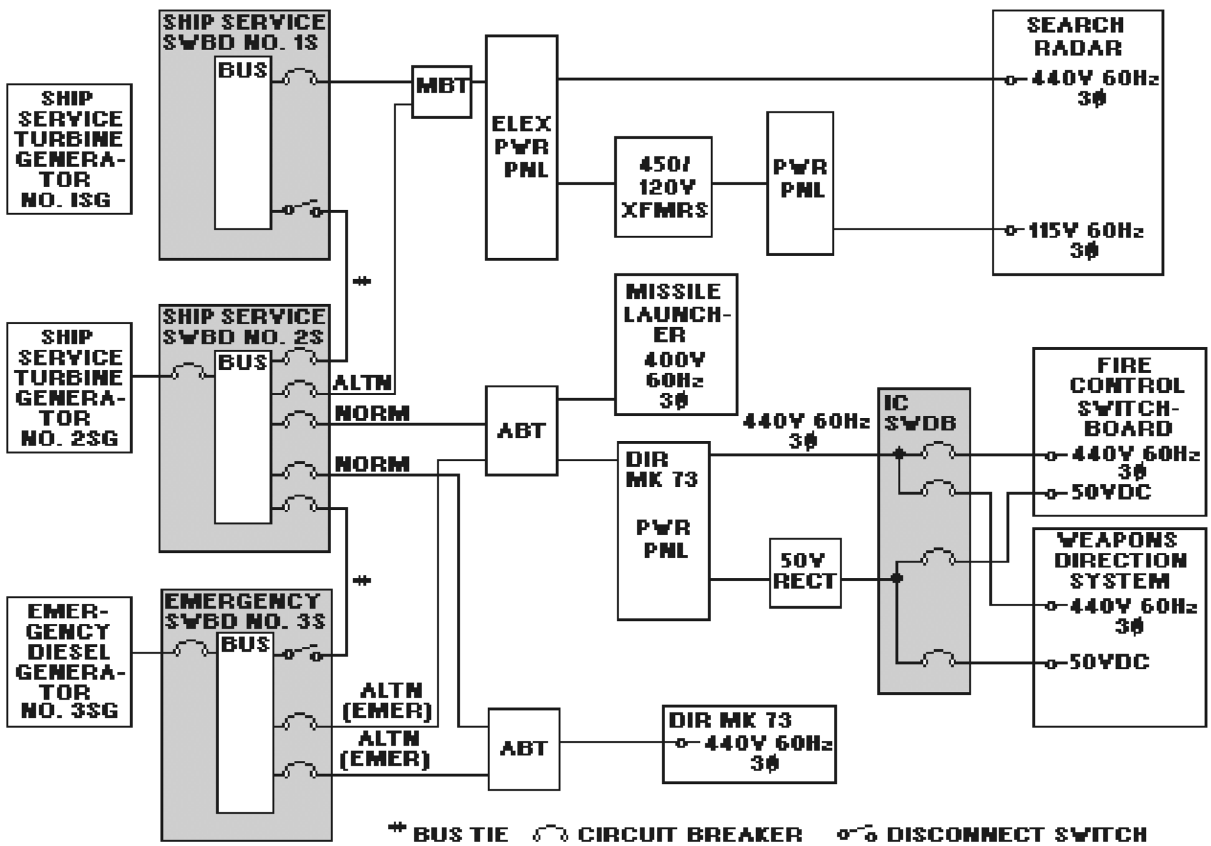

Figure 4-11.—60 Hz distribution.

The power source can be the ship service turbine generator or the emergency diesel generator. Power is normally distributed through the ship service distribution switchboards and power panels. Some large ships also use load centers (not shown) that function as remote switchboards.

Power is used by any equipment that requires electrical power for its operation (lights, motors, director power drives, radar equipment, weapon direction equipment, computers, etc.). The maintenance of the ship service generators, the emergency generators, and distribution switchboards is the responsibility of the ship's engineers (machinist's mates, electrician's mates, enginemen, etc.).

Emergency Power

If power from the ship service distribution system is interrupted, the emergency power distribution system is activated. The emergency system supplies an immediate and automatic source of electrical power to selected loads that are vital to the safety and defense of the ship. This system includes one or more emergency diesel generators and switchboards. The emergency generator is started automatically when a sensor detects the loss of normal power.

Bus Transfer Equipment

Bus transfer equipment is installed on switchboards, at load centers, on power panels, and on loads that are fed by both normal and alternate and/or emergency feeders (figure 4-11). Either the normal or alternate source of the ship's service power can be selected. Emergency power from the emergency distribution system can be used if an emergency feeder is also provided.

Automatic bus transfer (ABT) equipment is used to provide power to vital loads, while nonvital loads can be fed through manual bus transfer (MBT) equipment. For example, the interior communications (IC) switchboard is fed through an ABT in which the alternate input is from the emergency switchboard. A search radar might be fed through an MBT.

Miscellaneous Power

Many other supply voltages are used in radar systems and subsystems. They are usually used as reference voltages for specific functions. When you are missing a power input to your equipment, work backwards from the load to the source. Usually, the power panels and bus transfer units that feed the equipment are located nearby, possibly in the same space or in a passageway.

Keep in mind that technicians have corrected many suspected casualties merely by restoring a minor power input or signal reference, sometimes after hours of troubleshooting.

Q12. Most shipboard distribution systems use ac power that has what number of phases?

Q13. How is emergency power applied when normal power is lost?

Q14. What device is used to switch power from the normal source to an alternate source for nonvital users?

Q15. What procedure should you use when a power input to your equipment is missing?

DRY-AIR SYSTEMS

Some radars depend on inputs of dry air for proper operation. Radar dry air is normally supplied by the ship's central dry-air system. This system produces high-pressure (hp) air and low-pressure (lp) dry air for distribution to user equipment, such as a search or a fire control radar.

Electronics Dry-Air Branch

The electronics dry-air branch is fed from the vital service lp air main through the Type II (desiccant) or Type III (combination refrigerant and desiccant) dehydrators, as shown in figure 4-12. The purpose of the electronics dry-air branch is to provide several electronic equipments with air that is dry enough for proper operation. Microwave components, such as waveguides, cavities, and power amplifiers, require dry air to prevent arcing and internal corrosion. The electronics dry-air branch must satisfy the dry-air requirements of the electronic user equipment. Dry air of less than the required specifications will degrade equipment performance. It may also incur major repairs, overhaul, or replacement of expensive electronic components.

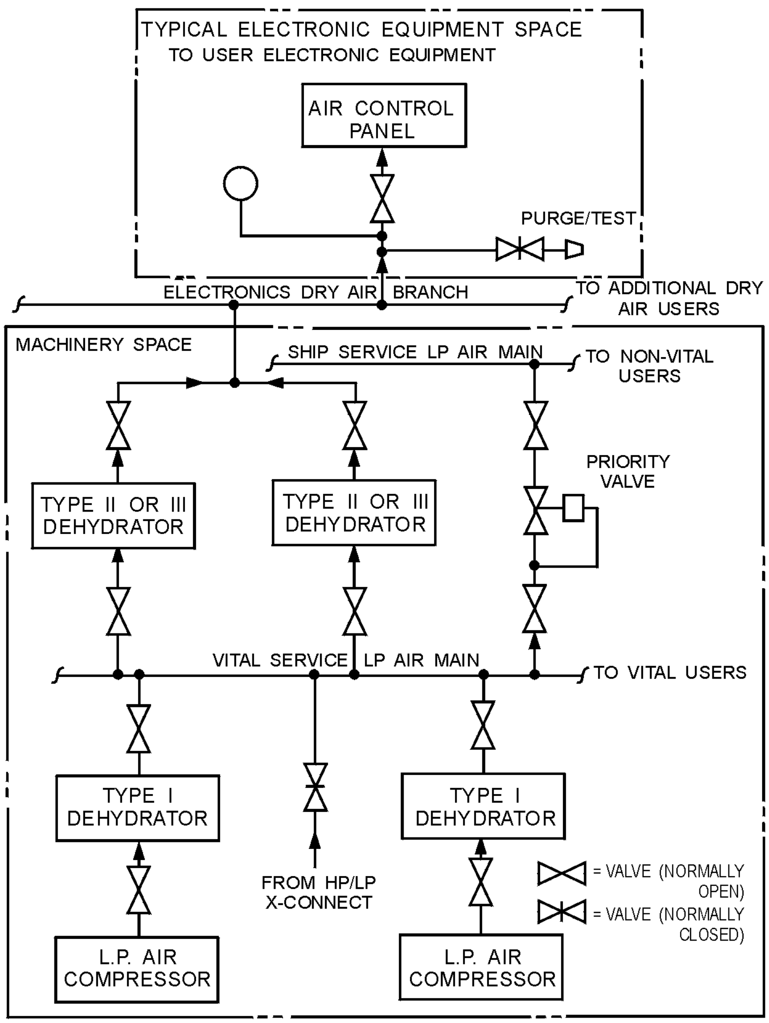

Figure 4-12.—Typical lp air system layout.

Air Control Panel

The dry-air distribution system (figure 4-12) delivers dry air to each air control panel of the user equipment. The air control panels are used to control and regulate the dry-air pressure to that required by the electronic user equipment.

The air control panel (figure 4-13) provides a means of monitoring the dry-air supply to the user equipment. The type of control panel used varies, depending on the outlet pressure and flow rate required.

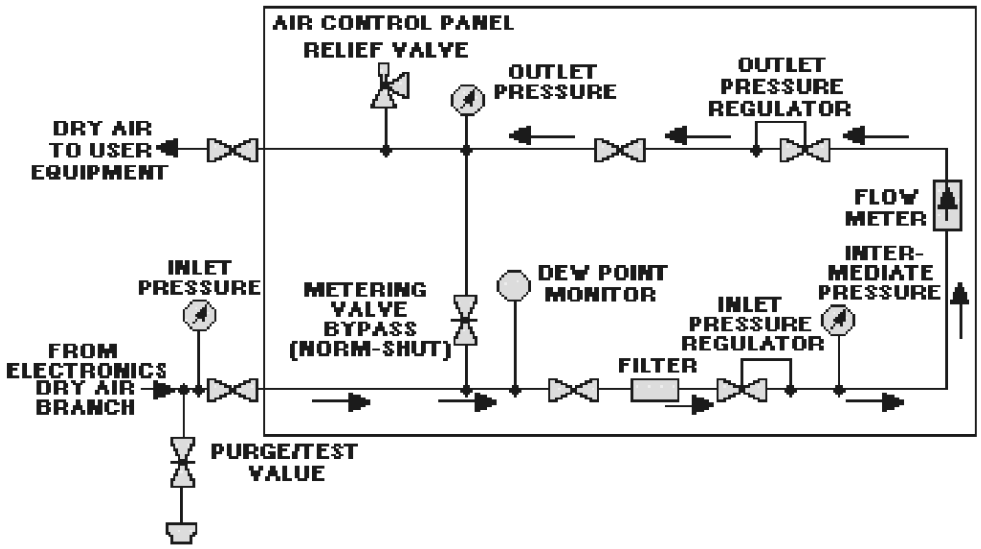

Figure 4-13.—Air control panel flow diagram.

The dew point (related to moisture content) and the flow of the lp dry air can be monitored at the air control panel. Also, the dry-air pressure can be monitored at the input to the control panel, at the input to the flowmeter (in which accuracy is calibrated at a certain pressure), and at the output of the control panel. A filter is installed to trap particles that affect proper pressure regulation. A metering valve bypass and a pressure relief valve are provided in case of malfunctions. The metering valve bypass permits manual control of air pressure to the user equipment.

Electronic Equipment Dehydrators.

Dehydrators or compressor-dehydrators are supplied as part of various radars. Many of them were provided prior to installation of properly configured central dry-air systems. These dehydrators are intended for emergency use in the event of the failure of the central dry-air system. In a typical configuration (figure 4-14), the outlet air from the local dehydrator is connected between the air control panel outlet and the user equipment or radar by a three-way valve.

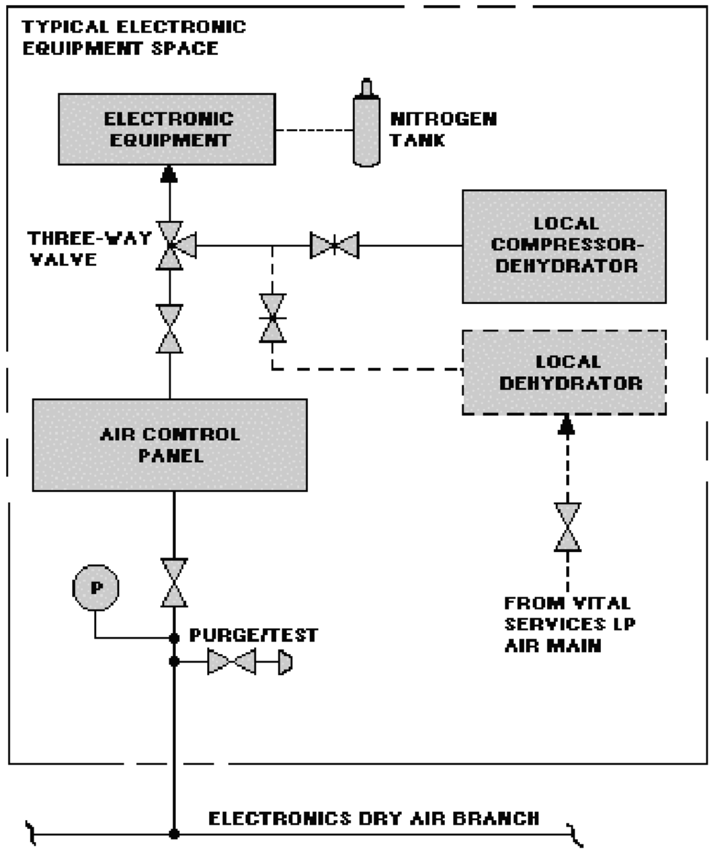

Figure 4-14.—Typical local dehydrator interface.

Local dehydrators depend on the ship's lp air for an inlet supply, while the local compressor-dehydrators can operate independently of the ship's air supply. Some units of electronic equipment that have local dehydrator units are pressure interlocked within the dehydrator unit. When the outlet air pressure is below a set value, the interlock prevents the equipment from going to a full OPERATE condition. When the central dry-air system is used, the pressure interlock is bypassed.

Some radars provide a tank of nitrogen as an emergency source that can be connected in place of dry air. Special safety precautions must be taken when you handle compressed gases because of the possibility of explosion. Nitrogen does not support life; when released in a confined space, it can cause asphyxiation.

Q16. What is the normal source of dry air for a radar system?

Q17. What is the major difference between the electronics dry-air branch and the vital service lp air main?

Q18. What is the air control panel designed to control?

COOLING SYSTEMS

Radar equipment, particularly the high-power transmitters, generate large amounts of heat. This heat must be dissipated to prevent damage to the equipment and to prevent erratic circuit operation. Most radar equipment rooms have high-capacity air-conditioning systems to control the ambient room temperature;

however, equipment cabinets must have additional cooling to control the internal temperature. In the case of transmitters (and other high-voltage circuits), individual components may require cooling.

Cabinets that generate relatively small amounts of heat may only require a system of fans or blowers to maintain constant air circulation. In some cases the air is circulated through a liquid-cooled heat exchanger located inside the cabinet.

Most low-power amplifier tubes are air cooled; most high-power tubes, such as klystrons, crossed-field amplifiers, and magnetrons, are liquid cooled.

The main source of power and heat in a power amplifier package is the high-voltage power supply. Part of the power produced by the power amplifier is transmitted in the form of rf energy; the remainder of the power eventually converts to heat, and cooling is required to dissipate the heat.

Radars that use blowers for cooling will usually have an airflow sensing switch. If the blower fails, the switch will open and remove power from appropriate power supplies. Radars employing liquid cooling normally distribute the liquid into a large number of separate paths, because the flow requirements are quite dissimilar. Each of the various paths will have a low flow interlock. If one of the liquid cooling paths becomes restricted, the low flow interlock switch will open and remove power from the radar.

Liquid cooling systems also include pressure gauges and switches, temperature gauges, and overtemperature switches. Many systems have pressure or flow regulators. Some systems include audio and/or visual alarms that energize before damage actually occurs. In some cases this allows the problem to be corrected without turning off the equipment.

Figure 4-15 illustrates a typical transmitter cooling system showing the many protective devices.

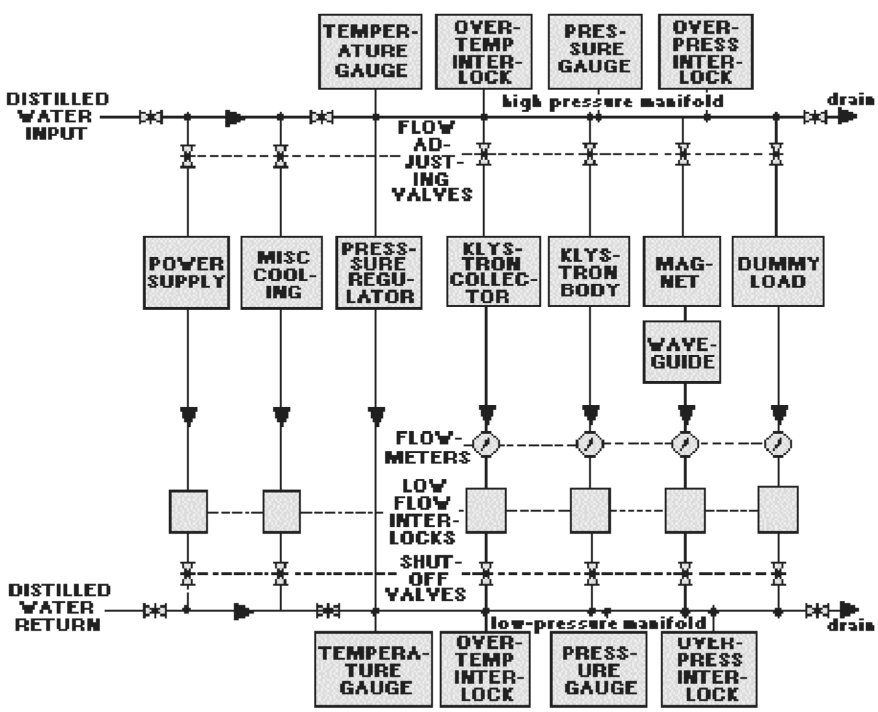

Figure 4-15.—Typical transmitter cooling system.

Distilled water is one of the best mediums for cooling high-power components, and, in many cases, the only medium that may be used.

For a distilled-water-cooling system to operate satisfactorily, the temperature, quantity, purity, flow, and pressure of the water must be controlled. This control is provided by various valves, regulators, sensors, meters, and instruments that measure the necessary characteristics and provide the required regulation.

Liquid-cooling systems consist of a sea water or a chilled (fresh) water section that cools the distilled water circulating through the electronic equipment. The main components of cooling systems are piping, valves, regulators, heat exchangers, strainers, circulating pumps, expansion tanks, gages, and demineralizers. Other specialized components are sometimes necessary to monitor cooling water to the electronic equipment.

A typical liquid-cooling system is composed of a PRIMARY LOOP and a SECONDARY LOOP (figure 4-16). The primary loop provides the initial source of cooling water and the secondary loop transfers the heat load from the electronic equipment to the primary loop. The source of cooling water for the primary loop is either sea water from a sea water supply or chilled water from the ship's air-conditioning plant. The cooling water used in the secondary loop is distilled water. Ultrapure systems are maintained by a demineralizer and use double-distilled water obtained through the Navy Supply System.

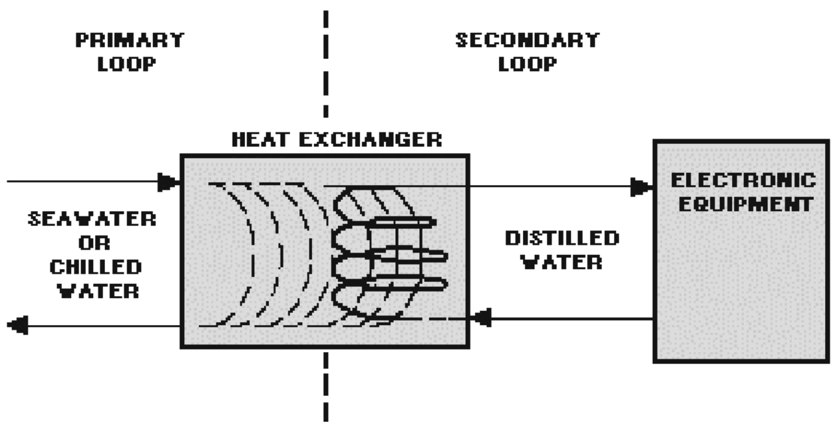

Figure 4-16.—Liquid cooling system block diagram.

Additional information about liquid cooling systems can be found in *Basic Liquid Cooling Systems for Shipboard Electronic Equipment Technician's Handbook*, NAVSEA 0948-LP-122-8010.

Q19. What type of cooling is used to control ambient room temperature?

Q20. A typical liquid-cooling system is composed of what loops?

Q21. What loop of a cooling system is often supplied by sea water?

SAFETY

Many safety and health hazards are involved with operating and maintaining high-power radars. These hazards result from high levels of rf radiation, X-ray emissions, the necessity of working aloft, and the generation of extremely high voltages.

Navy professionals are very safety conscious and, as a result, the number of accidents that occur on the job is small. Most of the safety precautions applicable to radar are published in radar technical manuals. Many of the safety regulations included in technical manuals are the result of actual experiences. Therefore, you should give them careful thought and strict observance.

RF RADIATION HAZARDS

Radar peak power may reach a million watts or more. Rf radiation hazards exist in the vicinity of radar transmitting antennas. These hazards are present not only in front of an antenna but also to the sides and sometimes even behind it because of spillover and reflection. At some frequencies, exposure to excessive levels of radiation will not produce a sufficient sensation of pain or discomfort to warn you of injury. If you suspect any injury, see your ship's doctor or corpsman. Be sure to acquaint yourself with the actual radiation hazard zones of the radars on your ship.

Personnel should observe the following precautions to ensure that persons are not exposed to harmful rf radiation:

- Visual inspection of feedhorns, open ends of waveguides, and any other opening that emits rf energy should not be made unless the equipment is properly secured and tagged for that purpose.
- Operating and maintenance personnel should observe all rf radiation hazard signs posted in the operating area.
- All personnel should observe rf radiation hazard (radhaz) warning signs (figure 4-17) that point out the existence of rf radiation hazards in a specific location or area. (You may encounter other types of rf radiation hazard signs, depending on the situation.)
- Ensure that radiation hazard warning signs are available and posted.
- Ensure that those radar antennas that normally rotate are rotated continuously while radiating or are trained to a known safe bearing.
- Ensure that those antennas that do not normally rotate are pointed away from inhabited areas (ships, piers, and the like) while radiating.
- Dummy loads should be employed where applicable in transmitting equipment during testing or checkout.

Figure 4-17.—Sample of one type of radhaz sign.

X-RAY EMISSIONS

X rays may be produced by the high-voltage electronic equipment in radars. X rays can penetrate human tissue and cause damage of a temporary or permanent nature. Unless the dosage is extremely high, no ill effects will be noticeable for days, weeks, or even years after the exposure.

The sources of these X rays are usually confined to magnetrons, klystrons, and cathode-ray tubes. Personnel should not linger near any of these types of equipments when the equipment covers have been removed. Klystrons, magnetrons, rectifiers, or other tubes that employ an excitation of 15,000 volts or more may emit X rays out to a few feet; thus, unshielded personnel standing or working close to the tubes will be endangered.

When performing maintenance on X-ray emitting devices, you should take the following precautions:

- Observe all warning signs (figure 4-18) on the equipment and all written precautions in the equipment technical manuals.

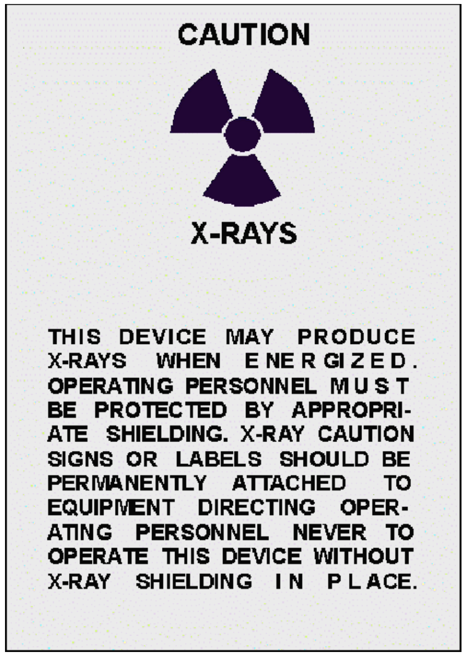

Figure 4-18.—X-ray caution label.

- Unless called for in the technical manual, do not bypass interlocks to permit the servicing of operating equipment with the X-ray shield removed.

- Be sure to replace all protective X-ray shielding when servicing is complete.

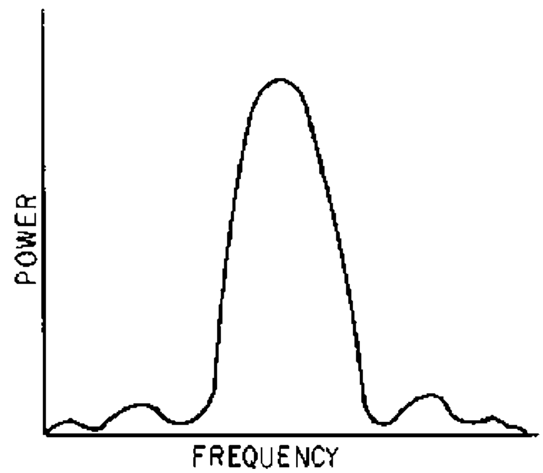
SUMMARY

This chapter has presented information on radar maintenance procedures. The information that follows summarizes the important points of this chapter.

Transmitter **PERFORMANCE CHECKS** are essential for you to maintain an efficient radar system. The transmitter output must be monitored closely for both frequency and power.

Transmitter energy is distributed symmetrically over a band of frequencies known as the **SPECTRUM**.

A **SPECTRUM CURVE** for a transmitter in good condition is shown in the illustration.



The **SPECTRUM ANALYZER** and the ECHO BOX are two instruments used to check transmitter performance.

One of the more important measurements that can be performed with the echo box is RING TIME. Ring time gives a relative indication of both transmitter output power and receiver sensitivity.

Transmitter **OUTPUT POWER MEASUREMENTS** are a good indication of overall transmitter operation. POWER MEASUREMENTS are usually of average power read in dBm. The average power dBm reading must be converted to watts and the peak power calculated. The formula for peak power is:

$$\text{peak power } (P_{pk}) = \frac{\text{average power } (P_{avg})}{\text{duty cycle}}$$

RECEIVER PERFORMANCE CHECKS determine receiver sensitivity, tr recovery time, and receiver bandwidth.

You usually measure receiver sensitivity by measuring the MINIMUM DISCERNIBLE SIGNAL (mds) using the pulse method.

TR RECOVERY time is the time required for the tr tube to DEIONIZE after each transmitted pulse. You should keep a graph of tr recovery time to determine when the tr tube should be replaced. If not replaced in a timely manner, a weak tr tube will allow damage to the radar receiver.

Few radars can function without SUPPORT SYSTEMS. These support systems include ELECTRICAL POWER, DRY-AIR, and LIQUID-COOLING SYSTEMS.

The radar technician should learn the source and distribution routes for NORMAL and EMERGENCY POWER for the radar.

The **DRY AIR** needed for electronic equipment can be supplied by the ship's electronics dry-air system through an air control panel or from local dehydrators.

Radar transmitters generate large amounts of heat. Most of this heat is dissipated by a combination of AIR CONDITIONING, CABINET AIR BLOWERS, and a DISTILLED-WATER COOLING system.

Personnel working on radars should always be aware of the hazards of RF RADIATION and X-RAY EMISSION.

All posted SAFETY PRECAUTIONS should be strictly observed.

ANSWERS TO QUESTIONS Q1. THROUGH Q21.

A1. Frequency distribution.

A2. In the center.

A3. Symmetrical above and below the carrier frequency.

A4. Power and frequency.

A5. Average power, pulse width, and prt.

A6. 1 milliwatt.

A7. Transmitter power loss.

A8. Minimum discernible signal (mds).

A9. Attenuations of the directional coupler and the connecting cable.

A10. Half-power points.

A11. Recovery time.

A12. Three.

A13. Automatically.

A14. Manual bus transfer (MBT) unit.

A15. Work backwards from the load to the source.

A16. Ship's central dry-air system.

A17. Degree of dehydration.

A18. Pressure.

A19. Air conditioning.

A20. Primary and secondary.

A21. The primary loop.

APPENDIX I

GLOSSARY

A-SCOPE—A radar display on which slant range is shown as the distance along a horizontal trace.

ACQUISITION—Operational phase of a fire- control or track radar during which the radar system searches a small volume of space in a prearranged pattern.

AIR-CONTROL PANEL—Panel that monitors the dry-air input at each user equipment.

ALTITUDE—Vertical distance of an aircraft or object above a given reference, such as ground or sea level.

AMBIGUOUS RETURNS—Echoes that exceed the prt of a radar and appear at incorrect ranges.

AMPLITRON—See Crossed-Field Amplifier.

ANTENNA BEAM WIDTH—Width of a radar beam measured between half-power points

ANTENNA SYSTEM—Routes rf energy from the transmitter, radiates the energy into space, receives echoes, and routes the echoes to the receiver.

ANTIJAMMING CIRCUIT—Electronic circuit used to minimize the effects of enemy countermeasures, thereby permitting radar echoes to be visible on the indicator.

ANTITRANSMIT-RECEIVE TUBE (atr)—Tube that isolates the transmitter from the antenna and receiver. Used in conjunction with tr tube.

ARTIFICIAL TRANSMISSION LINE—An LC network that is designed to simulate characteristics of a transmission line.

ASYMMETRICAL MULTIVIBRATOR—Multivibrator that generates rectangular waves.

AUTOMATIC GAIN CONTROL—Circuit used to vary radar receiver gain for best reception of signals that have widely varying amplitudes.

AVERAGE POWER—Output power of a transmitter as measured from the start of one pulse to the start of the next pulse.

AZIMUTH—Angular measurement in the horizontal plane in a clockwise direction.

BALANCED MIXER—Waveguide arrangement that resembles a T and uses crystals for coupling the output to a balanced transformer.

BEAM—See Lobe.

BEARING RESOLUTION—Ability of a radar to distinguish between targets that are close together in bearing.

BEAT FREQUENCIES—Difference and sum frequencies which result from combining two different frequencies.

BLIP—See Pip.

BLOCKING—A condition in an amplifier, caused by overdriving one or more stages, in which the amplifier is insensitive to small signals immediately after reception of a large signal.

BROADSIDE ARRAY—An antenna array in which the direction of maximum radiation is perpendicular to the plane of the array.

BUFFER AMPLIFIER STAGE—Amplifier stage that isolates one circuit from another.

CARRIER FREQUENCY—The frequency of an unmodulated transmitter output.

CARRIER-CONTROLLED APPROACH—Shipboard radar system used to guide aircraft to safe landings in poor visibility conditions.

CLUTTER—Confusing, unwanted echoes that interfere with the observation of desired signals on a radar indicator.

COHERENCE—A definite phase relationship between two energy waves, such as transmitted frequency and reference frequency.

COHERENT OSCILLATOR—In cw radar this oscillator supplies phase references to provide coherent video from target returns.

CONICAL SCANNING—Scanning in which the movement of the beam describes a cone, the axis of which coincides with that of the reflector.

CONTACT—In radar, an object that reflects rf energy; target.

CORNER REFLECTOR—Two flat reflectors that meet at an angle and are normally fed by a half-wave radiator.

CROSSED-FIELD AMPLIFIER—High-power electron tube that converts dc to microwave power by a combination of crossed electric and magnetic fields.

CYLINDRICAL PARABOLIC REFLECTOR—A parabolically shaped reflector that resembles part of a cylinder.

DEFLECTION COILS—In a cathode-ray tube, coils used to bend an electron beam a desired amount.

DEIONIZATION TIME—In a spark gap, the time required for ionized gas to return to its neutral state after the spark is removed.

DESIGNATION—Operational phase of a fire- control or track radar during which the radar is directed to the general direction of a desired target.

DIFFERENCE FREQUENCY—See Beat Frequency.

DIODE DETECTOR—A demodulator that uses one or more diodes to provide a rectified output with an average value that is proportional to the original modulation.

DIRECTIONAL ANTENNA—An antenna that radiates most effectively in only one direction.

DIRECTIVITY—Ability of an antenna to radiate or receive more energy in some directions than in others. The degree of sharpness of the antenna beam.

DISCRIMINATOR—A circuit in which amplitude variations are derived in response to phase or frequency variations.

DISTILLED WATER—Water that has been purified through a process of evaporation and condensation.

DOPPLER EFFECT—In radar, the change in frequency of a received signal caused by the relative motion between the radar and the target.

DOPPLER FREQUENCY—Difference between transmitted and reflected frequencies; caused by the Doppler effect.

DOUBLE-MODING—In a transmitter output tube, the abrupt and random change from one frequency to another.

DRY-AIR SYSTEM—Provides dehumidified air for electronic equipment that is moisture critical.

DUCTING—Trapping of an rf wave between two layers of the earth's atmosphere or between an atmospheric layer and the earth.

DUPLEXER—A radar device that switches the antenna from the transmitter to the receiver and vice versa.

DUTY CYCLE—In a transmitter, ratio of time on to time off.

ECHO—The rf signal reflected back from a radar target.

ECHO BOX—A resonant cavity device that is used to check the overall performance of a radar system. It receives a portion of the transmitted pulse and retransmits it back to the receiver as a slowly decaying transient.

ELECTRICAL POWER SYSTEM—Provides the necessary input power.

ELECTRONIC COUNTER-COUNTERMEASURES (ECCM) CIRCUITS—See Antijamming Circuits.

ELECTRONIC EQUIPMENT DEHYDRATOR—Provides alternate dry-air input in the event of failure of the central dry-air system. May include a compressor.

ELECTRONIC FREQUENCY COUNTER—An instrument that counts the number of cycles (pulses) occurring during a precise time interval.

ELECTRONIC SCANNING—Scanning in which the axis of the beam is moved, relative to the antenna axis, in a desired pattern.

ELECTRONICS DRY-AIR BRANCH—A common line for providing dry air to various electronic equipment, such as search radar, fire-control radar, and repeaters.

ELEVATION ANGLE—The angle between the horizontal plane and the line of sight.

EMERGENCY POWER—Temporary source of limited electrical power used upon the loss of the normal power source.

EXTERNALLY SYNCHRONIZED RADAR—Radar system in which timing pulses are generated by a master oscillator external to the transmitter.

FAST-TIME-CONSTANT CIRCUIT—Differentiator circuit in the first video amplifier that allows only the leading edges of target returns, no matter how small or large, to be used.

FEEDBACK—The return of a portion of the output of a circuit to its input.

FEEDHORN—A horn radiator used to feed a reflector.

FIRST DETECTOR—See Mixer.

FREQUENCY COMPENSATION NETWORK—Circuit modification used to improve or broaden the linearity of its frequency response.

FREQUENCY SCANNING—Varying the output frequency to achieve electronic scanning.

FREQUENCY SPECTRUM—In a radar, the entire range of frequencies contained in an rf pulse or signal.

FREQUENCY SYNTHESIZER—A bank of oscillators in which the outputs can be mixed in various combinations to produce a wide range of frequencies.

GAIN—Any increase in the strength of a signal.

GATED AGC—Circuit that permits automatic gain control to function only during short time intervals.

GLOW DISCHARGE—Discharge of electricity through a gas in an electron tube.

GROUND CLUTTER—Unwanted echoes from surrounding land masses that appear on a radar indicator.

GROUND RANGE—The distance on the surface of the earth between a radar and its target. Equal to slant range only if both radar and target are at the same altitude.

GROUND-CONTROLLED APPROACH—Radar system used to guide aircraft to safe landings in poor visibility conditions.

GUIDANCE RADAR—System which provides information that is used to guide a missile to a target.

HALF-POWER POINT—A point on a waveform or radar beam that corresponds to half the power of the maximum power point.

HARD-TUBE MODULATOR—A high-vacuum electron tube modulator that uses a driver for pulse forming.

HEIGHT-FINDING RADAR—Radar that provides target altitude, range, and bearing data.

HITS PER SCAN—The number of times an rf beam strikes a target per antenna revolution.

HORIZONTAL PLANE—Imaginary plane that is tangent (or parallel) to the earth's surface at a given location.

HORN ANTENNA—See Horn Radiator.

HORN RADIATOR—A tubular or rectangular microwave antenna that is tapered and is widest at the open end.

HYBRID RING—A circular waveguide arrangement with four branches. When properly terminated, energy is transferred from any one branch into any two of the remaining three branches.

HYBRID MIXER—See Balanced Mixer.

IF AMPLIFIER—Usually a narrow-bandwidth IF amplifier that is tuned to one of the output frequencies produced by the mixer.

INDEX OF REFRACTION—The degree of bending of an rf wave when passing from one medium to another.

INDICATOR—Equipment that provides a visual presentation of target position information.

INSTANTANEOUS AUTOMATIC GAIN CONTROL (IAGC)—Circuit that can vary the gain of the radar receiver with each input pulse to maintain the output peak amplitude nearly constant.

INTERMEDIATE FREQUENCY (IF)—A lower frequency to which an rf echo is converted for ease of amplification.

KEEP-ALIVE CURRENT—See Keep-Alive Voltage.

KEEP-ALIVE VOLTAGE—Dc voltage applied to a tr gap electrode to produce a glow discharge that allows the tube to ionize faster when the transmitter fires.

KEYED-OSCILLATOR TRANSMITTER—A transmitter in which one stage is used to produce the rf pulse.

KEYER—See Synchronizer.

KLYSTRON POWER AMPLIFIER—Multicavity microwave electron tube that uses velocity modulation.

LIN-LOG AMPLIFIER—Amplifier in which the response is linear for weak signals and logarithmic for large signals.

LINE OF SIGHT—Straight line from a radar antenna to a target.

LINE-PULSING MODULATOR—Circuit that stores energy and forms pulses in the same circuit element, usually the pulse-forming network (pfn).

LIQUID-COOLING SYSTEM—Source of cooling for high-heat producing equipments, such as microwave components, radar repeaters, and transmitters.

LOBE—An area of greater signal strength in the transmission pattern of an antenna.

LOGARITHMIC RECEIVER—Receiver that uses a linear logarithmic amplifier (lin-log) instead of a normal linear amplifier.

LOW-NOISE AMPLIFIER—See Preamplifier.

MAGIC T—See Balanced Mixer.

MAGNETRON OSCILLATOR—Electron tube that provides a high power output. Theory of operation is based on interaction of electrons with the crossed electric and magnetic fields in a resonant cavity.

MASTER OSCILLATOR—In a transmitter, the oscillator that establishes the carrier frequency of the output.

MECHANICAL SCANNING—The reflector, its feed source, or the entire antenna is moved in a desired pattern.

MINIMUM DISCERNIBLE SIGNAL (MDS)—The weakest signal that produces a usable signal at the output of a receiver. The weaker the signal, the more sensitive the receiver.

MIXER—In radar, a circuit that combines the received rf signal with a local-oscillator signal to effectively convert the received signal to a lower IF frequency signal.

MODE SHIFTING—In a magnetron, shifting from one mode to another during a pulse.

MODE SKIPPING—Rather than firing on each successive pulse as desired, the magnetron fires randomly.

MODES—Operational phases (of a radar).

MODULATOR SWITCHING DEVICE—Controls the on (discharge) and off (charge) time of the modulator.

MODULATOR—Produces a high-voltage pulse that turns the transmitter on and off.

MONOPULSE (SIMULTANEOUS) LOBING—Radar receiving method using two or more (usually four) partially overlapping lobes. Sum and difference channels locate the target with respect to the axis of the antenna.

MONOPULSE RADAR—A radar that gets the range, bearing, and elevation position data of a target from a single pulse.

MONOPULSE RECEIVER—See Monopulse Lobing.

MOISTURE LAPSE—Abnormal variation of moisture content at different altitudes because of high moisture located just above large bodies of water.

MOVING TARGET INDICATOR—A device that limits the display of radar information to moving targets.

NAUTICAL MILE—The length of a minute of arc of a great circle of the earth (6,076 ft.)

NAUTICAL RADAR MILE—See Radar Mile.

NOISE—In radar, erratic or random deflection or intensity of the indicator sweep that tends to mask small echo signals.

NOISE FIGURE—The ratio of output noise to input noise in a receiver.

NUTATING—Moving an antenna feed point in a conical pattern so that the polarization of the beam does not change.

OMNIDIRECTIONAL ANTENNA—An antenna that radiates equally in all directions (nondirectional).

ORANGE-PEEL PARABOLOID—A section of a complete circular paraboloid that is narrow in the horizontal plane and wide in the vertical plane.

PARABOLIC REFLECTOR—An antenna reflector in the shape of a parabola. It converts spherical wavefronts from the radiating element into plane wavefronts.

PARALLEL-CONNECTED DUPLEXER—Configuration in which the tr spark gap is connected across the two legs of the transmission line one-quarter wavelength from the Tjunction.

PARASITIC ARRAY—An antenna array containing one or more elements not connected to the transmission line.

PEAK POWER—Maximum power of the rf pulse from a radar transmitter.

PERSISTANCE—The length of time a phosphor dot glows on a crt before disappearing.

PHANTASTRON—A variable-length sawtooth generator used to produce a sweep on an A-scope.

PIP (BLIP)—On a crt display, a spot of light or a base-line irregularity representing the radar echo.

PLANE WAVEFRONTS—Waves of energy that are flat, parallel planes and perpendicular to the direction of propagation.

PLANNED-POSITION INDICATOR—A radar display in which range is indicated by the distance of a bright spot or pip from the center of the screen and the bearing is indicated by the radial angle of the spot.

POWER GAIN—In an antenna, the ratio of its radiated power to that of a reference.

POWER-AMPLIFIER (CHAIN) TRANSMITTER—Transmitter that uses a series of power amplifiers to create a high level of power.

PREAMPLIFIER (PREAMP)—An amplifier that raises the output of a low-level source for further processing without appreciable degradation of the signal-to-noise ratio.

PRIMARY LOOP—In a cooling system, the primary source of cooling for the distilled water.

PROBE COUPLER—A resonant conductor placed in a waveguide or cavity to insert or extract energy.

PULSE WIDTH—Duration of time between the leading and trailing edges of a pulse.

PULSE-FORMING NETWORK (PFN)—An LC network that alternately stores and releases energy in an approximately rectangular wave.

PULSE-REPETITION RATE (PRR)—Average number of pulses per unit of time; pulse rate.

PULSE-REPETITION FREQUENCY (PRF)—The rate at which pulses are transmitted, given in hertz or pulses per second; reciprocal of pulse-repetition time.

PULSE-REPETITION TIME (PRT)—Interval between the start of one pulse and the start of the next pulse; reciprocal of pulse-repetition frequency.

RADAR—An acronym for RAdio Detecting And Ranging.

RADAR ALTIMETER—Airborne radar that measures the distance of the aircraft above the ground.

RADAR BEAM—The space in front of a radar antenna where a target can be effectively detected or tracked.

RADAR DISTRIBUTION SWITCHBOARD—An electrical switching panel used to connect inputs from any of several radars to repeaters.

RADAR MILE—Time interval (12.36 microseconds) for rf energy to travel out from a radar to a target and back to the radar; radar nautical mile.

RADAR TEST SET—Combination of several test circuits and equipment used to test various characteristics of a radar.

RANGE—The length of a straight line between a radar set and a target.

RANGE-HEIGHT INDICATOR—A radar display on which slant range is shown along the X axis and height along the Y axis.

RANGE-GATE—A movable gate used to select radar echoes from a very short-range interval.

RANGE MARKER—A movable vertical pulse on an A-scope or ring on a ppi scope used to measure the range of an echo or to calibrate the range scale.

RANGE RESOLUTION—Ability of a radar to distinguish between targets that are close together.

RANGE STEP—On an A-scope sweep, vertical displacement used to measure the range of an echo.

RECEIVER—In radar, a unit that converts rf echoes to video and/or audio signals.

RECEIVER SENSITIVITY—The degree to which a receiver can usefully detect a weak signal; the lower limit of useful signal input to the receiver.

RECOVERY TIME—In a radar, the time interval between the end of the transmitted pulse and the time when echo signals are no longer attenuated by the tr gap.

REFLECTING OBJECT—In radar, an air or surface contact that provides an echo.

REFLEX KLYSTRON—A microwave oscillator that is tuned by changing the repeller voltage.

REFRACTION—The bending of rf waves as the waves pass through mediums of different density.

REFRACTIVE INDEX—In a wave-transmission medium, the ratio between the phase velocity in free space and in the medium.

REGENERATION—See Feedback.

RELATIVE BEARING—Bearing of target measured in a clockwise direction from "dead ahead" of a ship or plane.

RESONANCE CHAMBER—See Echo Box.

RETURN—The rf signal reflected back from a radar target; echo.

RF RADIATION HAZARD—Health hazard caused by exposure to electromagnetic radiation or high-energy particles (ions). Abbreviated RADHAZ.

RING TIME—In radar, the time during which the output of an echo box remains above a specified level.

RINGING—Rf oscillations caused by shock excitation of a resonant circuit (cavity).

SCANNING—Systematic movement of a radar beam to cover a definite pattern or area in space.

SEA CLUTTER—Unwanted echoes from the irregular surface of the sea that appear on a radar indicator.

SEARCH RADAR SYSTEM—Early-warning device that searches a fixed volume of space.

SECOND DETECTOR DEMODULATOR—The part of the receiver that separates the audio or video component from the modulated intermediate frequency.

SECOND-SWEEP ECHOES—See Ambiguous Returns.

SECONDARY LOOP—In a cooling system, the loop that transfers the heat from the heat source (electronic equipment) to the primary loop; usually distilled water.

SELF-SYNCHRONIZED RADAR—A type of radar in which the timing pulses are generated within the transmitter.

SENSITIVITY TIME CONTROL (STC)—A circuit that varies the gain of a receiver as a function of time.

SERIES-CONNECTED DUPLEXER—Configuration in which the tr spark gap is connected in series in one leg of the transmission line one-half wavelength away from the T- junction.

SHADOW—A dead spot (minimum radiation) caused by the physical obstruction of transmitted waves by a feed horn.

SINGLE-ENDED MIXER—See Unbalanced Crystal Mixer.

SINGLE, STATIONARY-LOBE SCANNING SYSTEM—Antenna (with a single, stationary beam) that is rotated to obtain 360-degree coverage.

SLANT RANGE—See Range.

SPECTRUM ANALYZER—A test instrument that provides a visual display of the frequency distribution of a transmitter output.

SPHERICAL WAVEFRONTS—Waves of energy that spread out in concentric circles.

STABILITY—In a magnetron, the ability to maintain normal operating characteristics.

STATUTE MILE—I5,280 ft.

STUB—A short section of transmission line connected in parallel with the main transmission line.

SCINTILLATION—Apparent change in target reflectivity. Motion of the target causes radar pulses to bounce off different parts of the target, such as fuselage and wingtip.

SUPERHETERODYNE RECEIVER—A type of receiver that uses a mixer to convert the rf echo to an IF signal for amplification.

SUPPORT SYSTEM—For a radar, a system that provides an auxiliary input, such as dry air, electrical power, or liquid cooling.

SYMMETRICAL MULTIVIBRATOR—Circuit that generates square waves.

SYNCHRONIZER—Circuit that supplies timing signals to other radar components.

TARGET—In radar, a specific object of radar search or detection.

TARGET RESOLUTION—The ability of a radar to distinguish between two or more targets that are close to each other.

THREE-DIMENSIONAL RADAR (3D)—Measures the range, bearing, and altitude of a target.

THYRATRON—Gas tube used as a modulator switching device.

TIMER—See Synchronizer.

TR RECOVERY TIME—Time required for a fired tr or atr tube to deionize to a normal level of conductance.

TRACK—Operational phase of a fire-control or track radar during which the radar beam is kept on the target.

TRACK RADAR—Radar that provides continuous range, bearing, and elevation data by keeping the rf beam on the target.

TRANSMIT-RECEIVE TUBE (TR)—Gas-filled rf switch that is used as a duplexer.

TRANSMITTER—Equipment that generates, amplifies, and modulates electromagnetic energy.

TRANSMITTER FREQUENCY (CARRIER FREQUENCY)—The frequency of the unmodulated output of a transmitter.

TRAVERSE (BEARING) SIGNAL—In a monopulse radar system, the combination of individual lobe signals that represents target offset direction and amplitude from the antenna axis.

TRIGGER GENERATOR—See Synchronizer.

TRIGGER PULSES—In radar, pulses that are used to initiate specific events.

TRUE BEARING—Angle between a target and true north measured clockwise in the horizontal plane.

TRUE NORTH—Geographic north.

TRUNCATED PARABOLOID—A paraboloid reflector that has been cut away at the top and bottom to increase beam width in the vertical plane.

TWO-DIMENSIONAL RADAR (2D)—Measures the range and bearing to a target.

UNBALANCED CRYSTAL MIXER—Circuit consisting of a section of coaxial transmission line one-half wavelength long that is tuned to the difference (intermediate) frequency between the local oscillator and rf echo signals.

VERTICAL PLANE—Imaginary plane that is perpendicular to the horizontal plane.

VIDEO ENHANCEMENT FEATURES—See Antijamming Circuits.

VOLTAGE STANDING WAVE RATIO (VSWR)—In a waveguide, the ratio of the electric field at a maximum point to that of an adjacent minimum point.

WAVEGUIDE DUPLEXER—Consists of tr and atr tubes housed in a resonant cavity attached to a waveguide system.

WAVEMETER—An instrument for measuring the wavelength of an rf wave.

X-RAY EMISSION—Penetrating radiation similar to light, but with shorter wavelength, that can penetrate human tissue.

X

ASSIGNMENT 1

Textbook assignment: Chapter 1, “Radar Fundamentals,” pages 1-1 through 1-45.

1-1. Radar uses what form of energy to detect ships, planes, and land masses?

1. Sound waves
2. Visible light
3. Infrared radiation
4. Electromagnetic energy

1-2. What radar measurement of an object is referenced to true north?

1. Height
2. Surface angle
3. Vertical angle
4. One-way distance

1-3. The elevation angle to the target is the angle between which of the following references?

1. Ship's heading and line of sight
2. Vertical plane and line of sight
3. Horizontal plane and line of sight
4. Vertical plane and horizontal plane

1-4. Electromagnetic energy travels through air at approximately what speed?

1. 984 feet per microsecond
2. 186,000 statute miles per second
3. 162,000 nautical miles per second
4. Each of the above is correct

1-5. For an object that is detected 15 miles from a radar set, what is the approximate time required for the rf energy to travel to and return from the object?

1. 7 microseconds
2. 185 microseconds
3. 271 microseconds
4. 927 microseconds

1-6. The minimum range of a radar depends on the length of time of the transmitter pulse (pulse width) and recovery time. During this period, the radar can NOT receive energy. A radar set with a pulse width of 5 microseconds and a recovery time of 0. 2 microseconds has a minimum range of approximately

1. 614 yards
2. 787 yards
3. 852 yards
4. 4,100 yards

1-7. Of the following radar characteristics, which has NO effect on maximum range capability?

1. Recovery time
2. Carrier frequency
3. Receiver sensitivity
4. Pulse-repetition frequency

1-8. Which of the following characteristics of a radar system determines the degree to which the radiated energy is affected by atmospheric conditions?

1. Pulse peak power
2. Carrier frequency
3. Receiver sensitivity
4. Pulse-repetition frequency

1-9. Pulse-repetition time is described as the

1. reciprocal of pulse width
2. period of time from the beginning to the end of a transmitter pulse
3. period of time required for the pulse to travel to the target and return
4. period of time from the beginning of one transmitter pulse to the beginning of the next

1-10. Which of the following terms describes radar returns that exceed the prt of the radar?

1. Clutter
2. Ambiguous
3. Reciprocal
4. Acquisition

1-11. What type of transmitter power is measured over a period of time?

1. Peak
2. Return
3. Average
4. Reciprocal

1-12. Which of the following formulas can be used to compute the duty cycle of a radar set?

1. $\frac{\text{prt}}{\text{pw}}$

2. $\frac{\text{pw}}{\text{prt}}$

3. $\frac{\text{peak power}}{\text{average power}}$

4. $\text{average power} \times \text{peak power}$

IN ANSWERING QUESTIONS 1-13 AND 1-14, ASSUME THAT A RADAR SET HAS THE FOLLOWING CHARACTERISTICS:
AVERAGE POWER = 700 WATTS
PULSE WIDTH = 3. 5 MICROSECONDS
PRF = 400 HERTZ

1-13. What is the peak power (in kilowatts) for this radar set?

1. 500
2. 1,500
3. 2,000
4. 2,500

1-14. What is the pulse-repetition time (in microseconds) for this radar set?

1. 1,500
2. 2,000
3. 2,500
4. 4,000

1-15. For a radar set with a pulse width of 25 microseconds and a prf of 600 pulses per second, what is the duty cycle?

1. 0.015
2. 0.024
3. 0.15
4. 0.24

1-16. What is the maximum radar horizon distance for a radar set with an antenna 100 feet above the surface of the earth?

1. 8 miles
2. 12.5 miles
3. 80 miles
4. 125 miles

1-17. A radar set with a prf of 1,000 pps and an antenna rotation rate of 15 rpm produces what maximum number of pulses per degree?

1. 2.7
2. 11.1
3. 14.4
4. 36

1-18. The relative bearing of a radar echo is measured with respect to which of the following reference points?

1. True north
2. Magnetic north
3. Centerline of your own ship
4. The position of the antenna

1-19. Altitude- or height-finding radar systems require a beam with which of the following characteristics?

1. Narrow in the vertical plane
2. Narrow in the horizontal plane
3. Broad in the horizontal plane
4. Broad in the vertical plane

1-20. Target resolution is the ability of a radar to distinguish between targets that are at nearly the same range and/or bearing. Range resolution is dependent on which of the following factors?

1. Peak power and beam width
2. Pulse width and beam width
3. Pulse width and target size
4. Peak power and target size

1-21. What is the approximate range resolution (in yards) of a radar set with a pulse width of 15 microseconds and a peak power of 2 kilowatts?

1. 10
2. 24
3. 1,093
4. 2,460

1-22. The width of a radar beam and range to a detected object are the determining factors in which of the following radar system characteristics?

1. Range resolution
2. Bearing resolution
3. Beam half-power points
4. Altitude detection accuracy

1-23. Which of the following factors has/have the greatest effect on the accuracy of a pulse radar?

1. Resolution
2. Average power
3. Atmospheric conditions
4. Each of the above

1-24. To detect nearby objects, the output pulse of a radar transmitter should possess which of the following characteristic shapes?

1. Narrow and square
2. Narrow with a sloping trailing edge
3. Wide and trapezoidal
4. Wide and square

1-25. Refractions and speed changes are known to occur in electromagnetic wavefronts. These phenomena are caused by which of the following conditions?

1. Temperature
2. Vapor content
3. Atmospheric pressure
4. All of the above

1-26. Temperature inversions and/or moisture lapses in the atmosphere may extend or reduce the range of a radar by creating

1. ducts
2. ionic layers
3. surface waves
4. reflective layers

1-27. In a pulse radar system, which of the following components should you expect to find?

1. Synchronizer and transmitter
2. Duplexer and antenna system
3. Receiver and indicator
4. All of the above

1-28. In a pulse radar system, what component controls timing throughout the system?

1. Power supply
2. Synchronizer
3. Indicator
4. Receiver

1-29. What component of the transmitter supplies the trigger pulse, which acts as a switch to turn the klystron on and off?

1. Magnetron
2. Modulator
3. Indicator
4. Power supply

1-30. Which of the following radar components allows the use of one antenna for both transmitting and receiving radar energy?

1. Synchronizer
2. Modulator
3. Duplexer
4. Mixer

1-31. To make amplification of received rf energy easier, the returning rf signal is converted to a lower, intermediate frequency. What component of the radar system performs this function?

1. A duo-diode duplexer
2. A three-stage synchronizer
3. A cross-field amplifier
4. A superheterodyne receiver

1-32. The sweep frequency of a radar indicator is determined by what parameter of the radar system?

1. Duty cycle
2. Pulse width
3. Carrier frequency
4. Pulse-repetition frequency

1-33. The type and method of scanning used by a radar system depend upon which of the following radar system design considerations?

1. Antenna size
2. Type of radar
3. Purpose of the radar
4. All of the above

1-34. In a single stationary-lobe scanning system, complete azimuth coverage is achieved by which of the following methods?

1. Multiple overlapping beams
2. An omnidirectional antenna
3. A continuously rotating antenna
4. Very wide, flat beams

1-35. Which of the following methods can be used to achieve radar-beam scanning?

1. Mechanical
2. Electronic
3. Combined mechanical and electronic
4. Each of the above

1-36. In a conical-scan antenna, nutation of the radar beam is usually accomplished by which of the following methods?

1. By moving the reflector
2. By moving the feed point
3. By varying the signal phase at the feed point
4. By moving both the feed point and the reflector

1-37. At any given distance from the antenna, the radar beam axis of a conical-scan antenna follows what pattern?

1. A circle around the scan axis
2. An ellipse in the vertical plane
3. An ellipse in the horizontal plane
4. Two circles covering the scan axis in figure eights

1-38. In a monopulse scanning radar, the relative position of a target with respect to the radar-beam axis is determined by comparing which of the following signal components?

1. The phases of the radiated rf energy
2. The phases of the returning rf energy
3. The amplitudes of the returning rf energy in each horn
4. The amplitudes of the returning rf energy in each successive pulse

1-39. In a monopulse scanning system, which of the following feedhorn signal combinations makes up the bearing signal?

1. (A + D) - (A + C)
2. (A + B) - (C + D)
3. (A + C) - (B + D)
4. A + B + C + D

1-40. In a monopulse scanning system, which of the following combinations make up the range signal?

1. (A + D) - (A + C)
2. (A + B) - (C + D)
3. (A + C) - (B + D)
4. A + B + C + D

1-41. Monopulse receivers use what signal as a phase reference?

1. Range
2. Traverse
3. Elevation
4. Angle-tracking

1-42. In the cw radar transmission method, the Doppler effect provides which of the following target information?

1. Speed of the target
2. Presence of the target
3. Both 1 and 2 above
4. Relative bearing of the target

1-43. The frequency of the returned signal increases when a target is approaching and decreases when a target is moving away in which of the following types of radar systems?

1. Search
2. Doppler
3. Pulse-modulation
4. Frequency-modulation

1-44. Continuous-wave radar that uses the Doppler effect is best used in detecting which of the following types of targets?

1. Stationary
2. Past-moving
3. Targets with a high degree of range resolution
4. Targets with a high degree of bearing resolution

1-45. Range information can be obtained in a Doppler radar by which of the following methods?

1. Sweeping the transmitter frequency
2. Using two separate transmitters
3. Both 1 and 2 above
4. Using two separate antennas

1-46. Frequency-modulated radars transmit a wave that continuously changes in frequency about a center frequency. Using frequency modulation, the range to a target is determined by using which of the following methods?

1. By comparing the frequency of the transmitted signal with the returned frequency from the target
2. By comparing the magnitude of transmitted pulses with the magnitude of returned pulses
3. By comparing the velocity of the received energy with the velocity of the transmitted energy
4. By measuring the Doppler shift that occurs in the returning signal

1-47. Which of the following statements describes the advantage of using pulse modulation (pm) rather than continuous-wave (cw) in a radar system?

1. Pm may be used to detect moving targets; cw is effective only against stationary targets
2. Pm may be used to determine relative velocity much more accurately than cw
3. Pm does not require frequency stabilization of the carrier wave; cw does
4. Pm does not depend on target motion; cw does

1-48. In Doppler radar, some definite relationship must exist between the transmitted frequency and the reference frequency. For what purpose is this relationship used?

1. To detect the heterodyning signal
2. To detect the continuous-wave signal
3. To detect the Doppler shift of the received signal
4. To detect the frequency shift of the transmitted frequency

1-49. Which of the following JETDS classifications identifies a shipboard fire control radar set?

1. AN/SPS-39
2. AN/SPG-55
3. AN/APG-12
4. AN/MRC-20

1-50. For most military applications, which of the following radar systems is/are used?

1. Track radar only
2. Search radar only
3. Both track and search radars are used
4. Moving-target indicators

1-51. Detection of surface and low-altitude air targets is the primary purpose of which of the following types of radar?

1. Surface search
2. Height finding
3. Fire control
4. Air search

1-52. Which of the following are typical characteristics of surface-search radars?

1. High pulse-repetition rates
2. Narrow pulse widths
3. High frequencies
4. All of the above

1-53. Long-range aircraft detection is provided by which of the following types of radar?

1. Track
2. Air search
3. Fire control
4. Surface search

1-54. Which of the following are characteristics of a typical air-search radar?

1. Low frequency
2. Narrow pulse width
3. High pulse-repetition rate
4. All of the above

1-55. Which of the following types of radar provides accurate range, bearing, and altitude of aircraft?

1. Air search
2. Guidance
3. Height-finding
4. Surface search

1-56. Which of the following radars would most likely be used to direct CAP aircraft during an intercept?

1. Track radar
2. Fire-control radar
3. Surface-search radar
4. Three-coordinate radar

1-57. The range capability of a 3D radar is limited by which of the following characteristics?

1. Low prf
2. Long prt
3. Low output power
4. High operating frequency

1-58. Fire control radars must be directed to the general location of a desired target. This is because of which of the following characteristics?

1. Low output power level
2. Low degree of accuracy
3. Narrow beam pattern
4. Poor resolution

1-59. When a fire-control radar antenna approaches the general direction of a target, the radar enters which of the following modes of operation?

1. Acquisition
2. Designation
3. Lock-on
4. Track

1-60. Which of the following characteristics is/are typical of a fire-control radar?

1. Very high prf
2. Very narrow pw
3. Very narrow beam
4. All of the above

1-61. Complete control of a beam-rider missile requires what minimum number of radar beams?

1. 1
2. 2
3. 3
4. 4

ASSIGNMENT 2

Textbook assignment: Chapter 2, "Radar Subsystems," pages 2-1 through 2-51.

2-1. Which of the following units of a radar system determines timing for all units of the radar?

1. Automatic tracker
2. Synchronizer
3. Transmitter
4. Receiver

2-2. Which of the following classifications describes a radar system that uses a master oscillator to produce timing pulses?

1. Externally synchronized
2. Self-synchronized
3. Unsynchronized
4. Free-running

2-3. Which of the following oscillators may be used as the master oscillator in a radar system?

1. A stable multivibrator
2. Sine-wave oscillator
3. Blocking oscillator
4. Each of the above

2-4. Which of the following oscillators, used in a synchronizer to provide timing trigger pulses, does NOT require a pulse-shaping circuit in its output?

1. Phase-shift oscillator
2. Square-wave oscillator
3. Sine-wave oscillator
4. Blocking oscillator

2-5. A radar system in which timing triggers are determined by the pulse-repetition rate of the modulator uses what type of synchronization?

1. Self
2. External
3. Free-running
4. Stable blocked

2-6. Which of the following radar indicator functions is/are controlled by gate pulses from the synchronizer?

1. Sweep duration
2. Sweep initiation
3. Range-mark generator gating
4. All of the above

2-7. Indicator sweep voltage in a radar is normally initiated at which of the following times?

1. At the same time as the transmitter trigger
2. Before the transmitter trigger
3. After the transmitter trigger
4. Each of the above

2-8. The flyback retrace of a radar system indicator is prevented from appearing on the cathode-ray tube by removing the

1. negative-intensity gate pulse applied to the control grid
2. positive-intensity gate pulse applied to the control grid
3. negative-intensity gate pulse applied to the cathode
4. positive-intensity gate pulse applied to the cathode

2-9. Which of the following characteristics is NOT a requirement of a basic radar system timing circuit?

1. It must be free-funning
2. Frequency must be variable
3. It must develop random frequencies
4. It should provide a stable frequency

2-10. Which of the following circuits converts square waves to positive and negative triggers?

1. A negative limiter
2. A positive limiter
3. A long-time-constant RC differentiator
4. A short-time-constant RC differentiator

2-11. Which of the following circuits is used to remove either the negative or positive triggers from the output of a sine-wave oscillator?

1. A clipper
2. A limiter
3. An LC network
4. A differentiator

2-12. When the master oscillator in a multivibrator timer is asymmetrical, the output of the master oscillator is in the form of

1. rectangular waves
2. negative pulses
3. square waves
4. sine waves

2-13. The positive and negative output pulses of the astable multivibrator are sent to the indicator for which of the following purposes?

1. To intensify the crt beam
2. To gate the range-marker generator
3. Both 1 and 2 above
4. To gate the transmitter output

2-14. Which of the following oscillators generates sharp trigger pulses without additional circuitry?

1. Sine-wave oscillator
2. Wien-bridge oscillator
3. One-shot multivibrator
4. Single-swing blocking oscillator

2-15. A radar transmitter is triggered directly by high voltage pulses from what unit?

1. The timer
2. The antenna
3. The indicator
4. The modulator

2-16. The peak power of a transmitted rf pulse depends on which of the following factors?

1. Width of the modulator pulse
2. Amplitude of the modulator pulse
3. Prf of trigger pulses from the timer
4. Delay time between trigger and modulator pulse outputs

2-17. The transmitter range timing circuit must be triggered at the instant the transmitted pulse leaves the transmitter. For which of the following reasons is this timing so important?

1. To ensure accurate range
2. The ensure long range targets are detected
3. To ensure that the target is "painted" on the crt by each transmitted pulse
4. To keep the magnetron oscillating at a fixed frequency

2-18. For proper operation of the magnetron, the modulator pulse must have which of the following characteristics?

1. A flat top
2. A steep leading edge
3. A steep trailing edge
4. All of the above

2-19. In order that nearby targets may be detected, which of the following characteristics must the transmitted pulse have?

1. A steep leading edge
2. A steep trailing edge
3. A sloping leading edge
4. A sloping trailing edge

2-20. Compared to the hard-tube modulator, the line-pulsing modulator has which of the following advantages?

1. It is more complex
2. It is more efficient
3. It is more sensitive to voltage changes
4. It requires a higher power-supply voltage

2-21. The modulator of a radar basically consists of a power supply, a switch, a storage element, and a/an

1. IF strip
2. oscillator
3. transmitter
4. charging impedance

2-22. Which of the following devices can be used as the storage element in a radar modulator?

1. A capacitor
2. A pulse-forming network
3. An artificial transmission line
4. Each of the above

2-23. A signal introduced at the input end of an artificial transmission line moves through the circuit to the output end and is reflected back to the input. The output end of an artificial transmission line appears to the input signal as what type of circuit?

1. Open
2. Short
3. Inductive reactance
4. Capacitive reactance

2-24. The discharge pulse from the artificial transmission line causes a voltage of what magnitude to appear across the primary of the pulse transformer?

1. Twice the original charge voltage
2. One-half the original charge voltage
3. The same as the original charge voltage
4. One-fourth the original charge voltage

2-25. What parameter, if any, of the output pulse from an artificial transmission line is affected by the inductance and capacitance of each section of the line?

1. Width
2. Amplitude
3. Frequency
4. None of the above

2-26. A pulse-forming network exhibits electrical behavior similar to which of the following devices?

1. A resistance-capacitance network
2. An artificial transmission line
3. A capacitor
4. An inductor

2-27. The requirements of a modulator switch are to (1) reach full conduction quickly, (2) consume low power, (3) start and stop conduction suddenly, and (4) conduct high currents and handle high voltages. Which of the following tubes meets these requirements?

1. A tetrode
2. A thyratron
3. A magnetron
4. A beam-powered amplifier

2-28. What modulator circuit characteristic determines the charging rate of the storage element?

1. Resistance
2. Capacitance
3. Charging impedance
4. Pulse-repetition frequency

2-29. Which of the following types of instability are common to magnetron oscillators?

1. Mode skipping
2. Mode shifting
3. Both 1 and 2 above
4. Magnetic fluctuation

2-30. Which of the following magnetron characteristics can be caused by low magnetic field strength?

1. Low power output
2. Excessive plate current
3. Incorrect operating frequency
4. All of the above

2-31. Which of the following maximum tuning ranges is typical for a tunable magnetron?

1. ±10 percent around the center frequency
2. ±5 percent around the center frequency
3. 1 to 5 percent above the center frequency
4. 1 to 10 percent below the center frequency

2-32. Compared to the keyed-oscillator transmitter, power-amplifier transmitters are used more often with mti radar systems because power-amplifier transmitters provide

1. better stability
2. lower output power
3. higher output power
4. greater frequency range

2-33. Which of the following tubes should be used as the power amplifier in a radar transmitter?

1. The magnetron
2. The thyratron
3. The reflex klystron
4. The multicavity klystron

2-34. Which of the following components determines the pulse width of a power-amplifier transmitter?

1. The modulator
2. The mixer-amplifier
3. The local oscillator
4. The power-amplifier tube

2-35. The intermediate stages of a power-amplifier transmitter have operating power only during which of the following times?

1. When the coherent rf pulse is applied
2. When the local oscillator signal is applied
3. During the time the modulator pulse is applied
4. Immediately after the coherent rf pulse is removed

2-36. Using a frequency synthesizer instead of a heterodyning mixer as the frequency generating source for a power-amplifier transmitter is an advantage because the frequency synthesizer

1. is more stable
2. is simpler to construct
3. produces a single frequency
4. produces discrete frequencies over a wide band

2-37. Unwanted oscillations in an rf amplifier transmitter are prevented because of which of the following pulse relationships?

1. The rf pulse is wider than the modulator pulse
2. The rf pulse is narrower than the modulator pulse
3. The rf pulse frequency is equal to the local oscillator frequency
4. The rf pulse frequency is less than the local oscillator frequency

2-38. A power-amplifier transmitter that transmits a broad band of frequencies typically uses which of the following tubes as the final stage?

1. A crossed-field amplifier
2. A multicavity klystron
3. A magnetron
4. A twt

2-39. What is the primary function of the radar duplexing system?

1. To prevent the formation of standing waves in the waveguide system
2. To permit the use of one antenna for transmission and reception
3. To increase the effective range of the radar
4. To increase antenna directivity

2-40. A defective duplexer in a radar will most likely cause damage to which of the following components?

1. The receiver
2. The waveguide
3. The magnetron
4. The local oscillator

2-41. Why is it desirable that the duplexer quickly connect the receiver to the antenna after the transmitted pulse?

1. So that line-match will remain balanced
2. So that the transmitter power dissipated will be minimum
3. So that echoes from nearby targets will be received
4. So that echoes from nearby targets will not prolong ionization

2-42. The action of tr-atr circuits depends upon the impedance characteristics of which of the following lengths of transmission line segments?

1. 1 wave length
2. 1/2 wave length
3. 1/4 wave length
4. 1/8 wave length

2-43. Which of the following requirements is/are essential for proper tr spark gap operation?

1. High impedance during arc time
2. Low impedance during arc time
3. High impedance prior to arc time
4. Both 2 and 3 above

2-44. What is the purpose of introducing water vapor into a tr tube?

1. It increases recovery time
2. It prevents early ionization
3. It decreases deionization time
4. It increases the gap breakdown potential

2-45. Keep-alive voltage is applied to the tr tube for which of the following reasons?

1. To maintain ionization within the tube after the breakdown voltage is removed
2. To ensure that the tube will rapidly return to the deionized state
3. To maintain a glow discharge within the tube so that firing will occur rapidly
4. To prevent breakdown within the tube prior to pulse transmission so that firing will not be premature

2-46. Atr tubes generally have a longer duty life than tr tubes because atr tubes do NOT use

1. radioactive materials and chemically active gas
2. chemically active gas and keep-alive voltages
3. keep-alive voltages and radioactive materials
4. keep-alive voltages and pure inert gas

2-47. In a series-connected duplexer, what spark gap, if any, fires during reception?

1. The tr only
2. The atr only
3. Both the tr and atr
4. None of the above

2-48. Indirectly coupled waveguide duplexers are normally connected to the main waveguide by which of the following devices?

1. A two-wire line
2. A coaxial cable
3. A short quarter-wave stub
4. A short section of waveguide

2-49. The direct-coupled waveguide duplexer is connected to the waveguide at the location of

1. minimum current flow
2. minimum magnetic field intensity
3. maximum magnetic field intensity
4. maximum electric field intensity

2-50. In a hybrid-ring duplexer, the fields at the entrance of an arm must have what phase relationship to propagate energy down the arm?

1. 0 degrees
2. 90 degrees
3. 180 degrees
4. 270 degrees

2-51. Which of the following are requirements of a microwave receiver?

1. Amplify extremely high-frequency pulses
2. Detect and amplify pulses in the microvolt range
3. Detect pulses with a duration of a few microseconds
4. All of the above

2-52. The maximum range at which a radar receiver can detect an object is limited by which of the following factors?

1. Noise
2. Signal distortion
3. Receiver bandwidth
4. Transmitter frequency

2-53. An effective radar receiver should have a gain factor that is in which of the following ranges?

1. 10^1 to 10^2
2. 10^3 to 10^4
3. 10^6 to 10^8
4. 10^9 to 10^{10}

2-54. An overdriven amplifier stage in a receiver may cause which of the following conditions?

1. Blocking
2. Inaccurate ranges
3. Increased sensitivity
4. Large signal distortion

2-55. The intermediate frequency is produced in what stage of a microwave receiver?

1. The mixer
2. The IF amplifier
3. The second detector
4. The local oscillator

2-56. What section of a radar receiver usually determines the overall bandwidth?

1. The mixer
2. The IF amplifier
3. The video amplifier
4. The local oscillator

2-57. What component in a receiver afc circuit produces an output voltage proportional in amplitude and polarity to any change in the intermediate frequency?

1. The mixer
2. The IF amplifier
3. The discriminator
4. The local oscillator

2-58. An efficient local oscillator must have which of the following characteristics?

1. Tunable frequency
2. Stable output frequency
3. Operation in the 4,000 megahertz range
4. All of the above

2-59. Which of the following devices would be used as a local oscillator in a radar receiver?

1. A magnetron
2. A crystal diode
3. A reflex klystron
4. A parametric amplifier

2-60. Which of the following advantages is gained by using a crystal mixer in a microwave receiver?

1. Less noise
2. Reduced saturation
3. Increased overall gain
4. Improved oscillator stability

2-61. The resonant circuit at the output of an unbalanced crystal mixer serves which of the following purposes?

1. It amplifies the IF signal
2. It produces the IF signal
3. It eliminates unwanted signals
4. It amplifies the local oscillator signal

2-62. The balanced transformer connected to the crystals of a balanced mixer has a secondary that is tuned to what frequency?

1. The desired IF
2. The local oscillator frequency
3. The afc discriminator frequency
4. The transmitter carrier frequency

2-63. The IF amplifier stage of a radar receiver determines which of the following receiver characteristics?

1. The gain
2. The effective bandwidth
3. The signal-to-noise ratio
4. All of the above

2-64. The detector in a radar receiver converts the IF pulses into what form?

1. Video pulses
2. Square waves
3. Dc voltage levels
4. Continuous-wave signals

2-65. Agc automatically adjusts the gain of the receiver by controlling which of the following quantities?

1. Detector bias
2. IF amplifier bias
3. Mixer output signal level
4. Video amplifier output signal level

2-66. A radar receiver uses iagc for which of the following purposes?

1. To reduce the amplitude of echoes from distant targets
2. To prevent full amplification of strong signals
3. To permit full amplification of weak signals
4. Both 2 and 3 above

2-67. In a radar receiver, which of the following purposes is served by using stc?

1. Prevents full amplification of echoes from nearby targets
2. Permits full amplification of echoes from distant targets
3. Both 1 and 2 above
4. Prevents target echoes within a selected range from being received

2-68. In the input of the first video amplifier of a radar receiver, the differentiator circuit performs which of the following functions?

1. Ftc
2. Gagc
3. Afc
4. Iagc

2-69. The primary function of the mti system is to display which of the following types of targets?

1. Moving targets only
2. Motionless targets only
3. Moving and motionless targets during each sweep
4. Moving and motionless targets during alternate sweeps

2-70. Delaying the received signals in the mti system permits them to be combined with the next set of received signals so that only desired signals are displayed. The signals displayed are formed by which of the following methods?

1. Division
2. Addition
3. Subtraction
4. Multiplication

2-71. In the mti system, what is the purpose of the coho lock pulse?

1. To synchronize the coho and transmitted frequency phase relationship
2. To control the transmitter pulse-repetition frequency
3. To synchronize the phase of the timing circuits with the phase detector
4. To control the polarity of the coherent video

2-72. The amplitude of coherent video is determined by the phase difference between which of the following signals?

1. Coho reference and transmitted pulse
2. Coho reference and coho lock pulse
3. Coho reference and IF echo
4. IF echo and received echo

2-73. The purpose of the mti system timing circuits is to

1. synchronize the coho and transmitted frequency phase relationship
2. control the transmitter pulse-repetition frequency
3. synchronize the phase of the video balancer with the phase detector
4. select the polarity of the coherent video

2-74. The lin-log amplifier provides (a) a linear output voltage for what amplitude of input signal and (b) a logarithmic output voltage for what amplitude of input signal?

1. (a) Low (b) low
2. (a) Low (b) high
3. (a) High (b) high
4. (a) High (b) low

2-75. What channel in a monopulse receiver is used as the reference channel?

1. IF
2. Range
3. Bearing
4. Elevation

ASSIGNMENT 3

Textbook assignment: Chapter 3, “Radar Indicators and Antennas,” pages 3-1 through 3-22. Chapter 4, “Radar Maintenance,” pages 4-1 through 4-23.

3-1. Which of the following geometrical quantities is/are used as coordinates for radar displays?

1. Range
2. Bearing
3. Elevation
4. All of the above

3-2. Of the following target parameters, which would most likely be displayed on all radar sets?

1. Altitude
2. Slant range
3. Ground range
4. All of the above

3-3. Which of the following quantities determines total distance represented on a crt display.

1. Crt size
2. Sweep speed
3. Sweep length
4. Echo spacing

3-4. To correctly represent the location of a target, a radar repeater must receive which of the following quantities?

1. Video
2. Timing pulses
3. Antenna information
4. All of the above

3-5. The A-scope crt normally uses what type of sweep deflection?

1. Mechanical
2. Electrostatic
3. Electromagnetic
4. Electromechanical

3-6. The rhi scope provides the operator with information concerning the target's

1. range only
2. altitude only
3. range and altitude
4. range and bearing

3-7. Own ship position is at the center of the scope in which of the following radar displays?

1. A-scope
2. B-scope
3. Rhi scope
4. Ppi scope

3-8. Synchronization of events in ppi circuitry is of special importance for which of the following reasons?

1. To ensure that bearing readings are accurate
2. To ensure that range readings are accurate
3. To ensure the deflection coils do not overheat
4. To ensure the power supply is activated at the instant the transmitter fires

3-9. Pulses used to synchronize the ppi with the transmitter are developed in which of the following circuits?

1. Gate
2. Sweep control
3. Sweep generator
4. Intensity gate generator

3-10. Which of the following circuits produces currents that deflect the electron beam across the crt?

1. Gate
2. Sweep control
3. Sweep generator
4. Intensity gate generator

3-11. Electromagnetic deflection is preferred over electrostatic deflection in ppi scopes because it provides which of the following advantages?

1. Better control of the beam
2. Better beam position accuracy
3. Better deflection sensitivity
4. All of the above

3-12. Focusing is accomplished in an electromagnetic crt by varying the

1. potential on the deflection plates
2. potential between the first anode and the cathode
3. current through the coil around the neck of the tube
4. do bias current in the deflection coils

3-13. Because the electromagnetic crt uses magnetic deflection, the sweep circuits must provide the deflection coils with which of the following signals?

1. Linear trace current
2. Trapezoidal voltage
3. Sinusoidal voltage
4. Direct current

3-14. In a ppi scope that uses electromagnetic deflection, the amplitudes and polarities of the sawtooth currents are determined by which of the following inputs?

1. Target position and speed
2. Antenna rotation speed
3. Antenna position
4. Both 2 and 3 above

3-15. On the screen of a ppi scope, range markers appear as

1. vertical pulses
2. radial grid lines
3. concentric circles
4. horizontal grid lines

3-16. The range sweep in a range-gate generator is started at the same time the transmitter fires. A pulse from which of the following circuits causes this timing?

1. Receiver
2. Indicator
3. Transmitter
4. Synchronizer

3-17. When used with a ppi presentation, a range gate must have which of the following characteristics?

1. Movable in range
2. Movable in bearing
3. Both 1 and 2 above
4. Fixed in range and bearing

3-18. Range-markers are produced on the basis of which of the following timing constants?

1. Radar mile
2. Transmitter prf
3. Receiver bandwidth
4. Transmitter pulse width

3-19. To read range directly, the range step is placed in what position relative to an echo pulse?

1. The range step is centered on the echo pulse
2. The range step coincides with the leading edge of the echo pulse
3. The range step coincides with the trailing edge of the echo pulse
4. The range step covers the entire echo pulse

3-20. Compared to omnidirectional antennas, directional antennas provide which of the following advantages?

1. Power gain and selectivity
2. Power gain and directivity
3. Sensitivity and selectivity
4. Sensitivity and directivity

3-21. If the vertical beam width of a radar antenna is decreased, what will be the effect on (a) power gain and (b) vertical directivity?

1. (a) Decrease (b) decrease
2. (a) Decrease (b) increase
3. (a) Increase (b) increase
4. (a) Increase (b) decrease

3-22. An array of twelve dipoles are set in the same position as a reference dipole and are fed with the same line. The power gain will be

1. less than unity
2. one-twelfth the reference
3. twelve times the reference
4. dependent on the directivity of the array

3-23. If the slant range and altitude of a target are known, which of the following coordinates can be computed using trigonometric functions?

1. Elevation angle
2. True-bearing angle
3. Relative-bearing angle
4. All of the above

3-24. To convert diverging waves into parallel waves, where must the radiating element be placed in relation to a parabolic reflector?

1. At the focal point of the reflector
2. 1/4 wavelength from the reflector
3. 1/2 wavelength from the reflector
4. At the focal point of the hemispherical shield

3-25. What is the function of the hemispherical shield of the parabolic reflector?

1. To polarize all reflected waves in the vertical plane
2. To polarize all reflected waves in the horizontal plane
3. To convert the spherical waves radiated by the dipole into vertical lines of rf energy
4. To reflect rf energy radiated forward of the dipole back to the parabolic reflector

3-26. Which of the following types of parabolic reflectors has a focal line rather than a single focal point?

1. Truncated
2. Rotational
3. Orange-peel
4. Cylindrical

3-27. A broadside array causes maximum energy to be radiated perpendicular to the plane of the dipole for which of the following reasons?

1. Because dipoles are excited in phase with each other
2. Because dipoles are parallel to each other
3. Because dipoles are 1/2 wavelength apart
4. Because dipoles are 1/8 wavelength away from the reflector

3-28. The directivity of a horn radiator is dependent on which of the following physical dimensions of the horn?

1. The shape
2. The length
3. The mouth size
4. All of the above

3-29. Feedhorn shadows can be eliminated by taking which of the following actions?

1. By making the horn smaller
2. By making the reflector smaller
3. By offsetting the horn from the center of the reflector
4. By putting the horn behind the reflector

3-30. Airborne radars have unique physical design requirements. Which of the following functions is performed by the radome?

1. It serves as the antenna
2. It provides aerodynamic shape
3. It protects the antenna from low air pressure
4. All of the above

3-31. If a fixed-frequency radar transmitter is found to be off its normal operating band, which of the following corrective actions should be taken?

1. Retune the transmitter
2. Change the assigned frequency
3. Replace the defective part causing the error
4. Check the frequency again, an error has been made

3-32. If a transmitter carrier wave is modulated by a square wave, what maximum number of different frequencies will be produced?

1. An infinite number
2. 2
3. 3
4. 4

3-33. Which of the following statements describes a radar transmitter frequency spectrum?

1. The distribution of energy over a band of frequencies
2. The distribution of energy over time
3. The prf multiplied by the duty cycle
4. The pulse width versus peak power

3-34. What total number of modulating components are present in the output spectrum of a pulse radar transmitter?

1. 1
2. 2
3. 3
4. 4

3-35. An ideal radar frequency spectrum would be best described in which of the following ways?

1. It is symmetrical
2. It has a wide lobe
3. It has narrow side lobes
4. It has no minimum points

3-36. In a good spectrum curve the distance between the two minima is proportional to which of the following transmitter parameters?

1. Prt
2. Prf
3. Peak power
4. Pulse width

3-37. The echo box is a good instrument for measuring overall radar system performance because it indicates the combined effectiveness of which of the following components?

1. Antenna and duplexer
2. Transmitter and antenna
3. Transmitter and receiver
4. Receiver and synchronizer

3-38. Oscillations in an echo box are known as ringing. Which of the following conditions cause this ringing?

1. A weak transmitter
2. A saturated receiver
3. A normally operating receiver
4. A normally operating transmitter

3-39. What constitutes the single most useful measurement you can make with the echo box?

1. Ring time
2. Duty cycle
3. Power distribution
4. Frequency distribution

3-40. Desirable transmitter output power characteristics include what relative levels of (a) peak power and (b) average power?

1. (a) Low (b) low
2. (a) Low (b) high
3. (a) High (b) high
4. (a) High (b) low

3-41. Most transmitter power readings are referenced to which of the following quantities?

1. 1 microwatt
2. 1 milliwatt
3. 1 watt
4. 1 kilowatt

3-42. Which of the following factors determines the overall performance of a radar receiver?

1. Bandwidth
2. Sensitivity
3. Recovery time of the tr
4. All of the above

3-43. Of the following receiver special circuits, which one is used during sensitivity tests?

1. Afc
2. Agc
3. Ftc
4. Iagc

3-44. The ability of a receiver to detect weak signals can be determined by which of the following measurements?

1. Noise figure
2. Minimum discernable signal
3. Both 1 and 2 above
4. Bandwidth

3-45. When several mds checks are to be taken over a period of time, the length of the test pulse used in the tests should

1. be the same on each check
2. be different on each check
3. vary with the transmitter pulse length on each check
4. vary with the noise figure on each check

3-46. When expressing the sensitivity of a radar receiver, which of the following quantities is used?

1. The signal generator reading
2. The combined attenuation value of the connecting cable and directional coupler
3. The sum of both 1 and 2 above
4. The attenuation value of the signal generator

3-47. Tr recovery time places limits on which of the following quantities?

1. Minimum range
2. Maximum range
3. Receiver bandwidth
4. Receiver sensitivity

3-48. Which of the following methods is/are used to determine the effectiveness of a tr tube?

1. Measure the keep-alive current
2. Measure the keep-alive voltage
3. Graph the correlation between recovery time and leakage power
4. All of the above

3-49. The presence of standing waves on a transmission line indicates which of the following conditions?

1. Excessive output power
2. An impedance mismatch
3. Excessive pulse width
4. Excessive prf

3-50. Of the following conditions, which would be a likely indication of a high vswr?

1. Insufficient reflection
2. Cold spots in the transmission line
3. Arc-over at the maximum points
4. All of the above

3-51. Most primary shipboard ac distribution systems provide which of the following types of electrical power?

1. 60 Hz, 3 phase, ungrounded
2. 60 Hz, 1 phase, ungrounded
3. 400 Hz, 1 phase, ungrounded
4. 400 Hz, 3 phase, ungrounded

3-52. If your equipment is missing a certain voltage input, which of the following actions should you take first?

1. Call an electrician
2. Energize the emergency generator
3. Check the input to the switchboard
4. Check the power panel that feeds your equipment

3-53. What is the normal source of dry air for a shipboard radar system?

1. Compressed-air bottles
2. Central dry-air system
3. Dehumidifying ovens
4. Local dehydrators

3-54. The air control panel is designed to regulate

1. flow
2. purity
3. pressure
4. dew point

3-55. Which of the following units may be available as an emergency back-up to the central dry-air system?

1. Nitrogen tank
2. Local dehydrator
3. Local compressor-dehydrator
4. Each of the above

3-56. Which of the following methods is used to cool radar system components?

1. Air blowers
2. Liquid-cooling loops
3. Air-conditioning systems
4. Each of the above

3-57. A radar cooling system has a low-flow alarm in the sea-water loop. What is the primary purpose of this alarm?

1. It allows correction before damage occurs
2. It increases the flow in the distilled-water loop
3. It removes power from the system
4. It increases the sea-water pressure

3-58. Which of the following characteristics of cooling water for electronic equipment must be carefully controlled?

1. Purity
2. Pressure
3. Quantity
4. All of the above

3-59. For which of the following reasons do personnel sometimes develop a false sense of security concerning exposure to radiation?

1. Rf radiation does not always produce pain
2. Rf radiation is visible only at night
3. Only search radars are hazardous
4. Rf hazards occur only at night

3-60. Injury from X-rays would most likely result from which of the following actions?

1. Standing near unshielded high-voltage components
2. Working alone on low-voltage power supplies
3. Bypassing interlocks on shielded equipment
4. Working too close to a crt with a potential of 1,500 volts

NONRESIDENT
TRAINING
COURSE

Navy Electricity and Electronics Training Series

Module 19—The Technician's Handbook

NAVEDTRA 14191

Notice: NETPDTC is no longer responsible for the content accuracy of the NRTCs.

PREFACE

About this course:

This is a self-study course. By studying this course, you can improve your professional/military knowledge, as well as prepare for the Navywide advancement-in-rate examination. It contains subject matter about day-to-day occupational knowledge and skill requirements and includes text, tables, and illustrations to help you understand the information. An additional important feature of this course is its reference to useful information in other publications. The well-prepared Sailor will take the time to look up the additional information.

Training series information:

This is Module 19 of a series.

History of the course:

Sep 1998: *Original edition released. Prepared by TMCM Jack L. Formyduval.*
Jan 2004: *Administrative update released. Reviewed and revised by ETC(SW) Jack Weatherford. Minor revision to technical content.*

TABLE OF CONTENTS

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

CHAPTER 1

THE TECHNICIAN'S HANDBOOK

Here, in one compact module, you will be able to find essential information and reference material. Whether you want to know safety precautions, first aid, or any number of helpful pieces of information, you will find it indexed.

We have included electrical and electronic formulas, data tables, and general maintenance hints. In most cases you will find references to other more detailed sources included.

We solicit your suggestions, maintenance hints, and constructive criticism. You will receive credit in future editions of this handbook if your input is used.

MISHAP PREVENTION AND AFTERCARE

Most of us working with electricity take risks. Usually we get our jobs done without any harmful results. Mishaps or injuries usually result from not understanding a risk or danger.

The first part of this handbook is designed to help you eliminate or minimize mishaps. It also provides you with a good review of what to do in case of a mishap.

SAFETY OBSERVATIONS FOR THE ELECTRICAL AND ELECTRONICS TECHNICIAN

Working safely is the most important thing you can do. Because of their importance, several precautions are included as the first subject in this handbook. Of course there are more precautions, but these are some you should think about. The keyword here is *think*. Think safety.

- Never work alone.
- Never receive an intentional shock.
- Only work on, operate, or adjust equipment if you are authorized.
- Don't work on energized equipment unless absolutely necessary.
- Keep loose tools, metal parts, and liquids from above electrical equipment. Never use steel wool or emery cloth on electric and electronic circuits.
- Never attempt to repair energized circuits except in an emergency.
- Never measure voltage in excess of 300 volts while holding the meter wire or probe.
- Use only one hand when operating circuit breakers or switches.
- Use proper tag-out procedures for regular and preventive maintenance.

- Be cautious when working in voids or unvented spaces.
- Beware the dangers of working aloft. Never attempt to stop a rotating antenna manually.
- Keep protective closures, fuse panels, and circuit breaker boxes closed unless you are actually working on them.
- Never bypass an interlock unless you are authorized to do so by the commanding officer, and then properly tag the bypass.
- Use extreme caution when handling cathode-ray tubes. They implode violently if broken. The anode contact may have a residual electrical charge. Make sure you discharge the anode before handling.

You can find additional and more detailed information on safety in the Electronics Installation and Maintenance Book (EIMB), *General*, NAVSEA SE000-00-EIM-100, paragraph 3-4. Another excellent reference source is the Naval Electronics Systems Command's *Electronic Safety Handbook*, E0410-AA-HBK-010/00K ELEXSAFE.

FIRST AID

First aid is the emergency care you give to sick or injured persons. It consists only of providing temporary assistance or treatment until medical help is available. In addition to knowing what to do for a victim, you should also know what not to do.

This section should be used to reinforce the knowledge you already have about first aid. First aid is included in detail for the purposes of review, study, and ready reference.

First aid study classes are usually available through your medical department or the American Red Cross.

Your knowledge of first aid measures and their proper application may mean the difference between life and death, between rapid recovery and long hospitalization, or between temporary disability and permanent injury.

The objectives of first aid are to save life and prevent further injury. First aid is not a substitute, however, for proper medical treatment. Keep in mind the objectives of first aid. Everyone in the Navy must know when and how to apply first aid measures and must be prepared to give assistance to persons injured in battle, collision, fire, or accidents.

In administering first aid, you have three primary tasks:

- Maintain breathing
- Stop bleeding
- Prevent or reduce shock

The first step, of course, is to determine the extent of the victim's injuries. When you treat a victim, first consideration usually must be given to the most serious injury. In general, the order of treatment is to restore breathing, stop bleeding, and treat for shock.

Work quickly, but do not rush around frantically. Do not waste time looking for ready-made materials; do the best you can with whatever is at hand. Send for medical help as soon as possible.

Although each case involving injury or sickness presents its own special problems, the following general rules apply to practically all situations. Become familiar with these basic rules before you go on to first aid treatment for specific types of injuries.

1. Keep the victim lying down, head level with the body, until you have found out what kind of injury has occurred and how serious it is. If the victim shows one of the following difficulties, however, follow the rule given for that specific problem:
   a. Vomiting or bleeding about the mouth and semi-consciousness. If the victim is in danger of sucking in blood, vomited matter, or water, place the victim on his/her side or back with the head turned to one side and lower than the feet.
   b. Shortness of breath. If the victim has a chest injury or breathing difficulties, place the victim in a sitting or semi-sitting position.
   c. Shock. If the victim is in shock, place the person on his or her back with the head slightly lower than the feet.
2. Move the victim no more than is absolutely necessary. To determine the extent of the victim's injuries, carefully rip or cut the clothing along the seams. If done improperly, the removal of the victim's clothing could cause great harm, especially if fracture injuries are involved. When the clothing is removed, ensure that the victim does not become chilled. Shoes may also be cut off to avoid causing pain or increasing an injury.
3. The victim need not see the actual injury(ies). You can supply reassurance and make the victim more comfortable by ensuring him or her that the injuries incurred are understood and medical attention will be given as soon as possible.
4. Do not touch open wounds or burns with fingers or other objects, except when sterile compresses or bandages are not available and it is absolutely necessary to stop severe bleeding.
5. Do not try to give an unconscious person any solid or liquid substance by mouth. The person may vomit and get some of the material into the lungs when he or she breathes, causing choking and possibly death.
6. If a bone is broken, or you suspect that one is broken, do not move the victim until you have immobilized the injured part. This may prove life saving in cases of severe bone fractures or spinal cord injuries, because the jagged bone may sever nerves and blood vessels, damage tissues, and increase shock. Of course, threat of fire, necessity to abandon ship, or other similar situations may require that the victim be moved. But the principle that further damage could be done by moving the victim should always be kept in mind and considered against other factors.
7. When transporting an injured person, always see that the litter is carried feet forward no matter what the injuries are. This will enable the rear bearer to observe the victim for any respiratory obstruction or stoppage of breathing.
8. Keep the injured person comfortably warm — warm enough to maintain normal body temperature.

Very serious and mutilating injuries may require heroic first aid measures on your part. However, the greater the number of injuries, the more judgment and self-control you must exhibit to prevent yourself and well-intentioned bystanders from trying to do too much.

Electric Shock

Electric shock may cause anything from mild surprise to death. The effects of the shock are usually unknown. It is often hard to determine how an electrical shock victim has been affected.

SYMPTOMS OF ELECTRIC SHOCK.—When you find someone who has received a severe electric shock, the person's skin is usually very white or pale blue. In the case of victims with dark skin, it may be necessary to rely primarily on the color of the mucous membranes on the inside of the mouth or under the eye lid or under the nail bed. A person in or going into electric shock has a bluish color to these membranes instead of a healthy pink. The victim's pulse is very weak or absent. The person is unconscious, and usually the skin is burned. A stiffness of the body may happen in a few minutes. This is caused by the muscles reacting to shock. You should not consider this condition as rigor mortis. You should make sure the victim is no longer touching the live circuit and then start artificial respiration. People have recovered after body stiffness has set in.

RESCUE OF VICTIMS.—The rescue of a shock victim depends on your immediate administration of first aid.

WARNING

Do not attempt to administer first aid or come in physical contact with an electric shock victim before the power is shut off or, if the power cannot be shut off immediately, before the victim has been removed from the live conductor.

When attempting to administer first aid to an electric shock victim, proceed as follows:

Shut off the power.

If the power cannot be deactivated, remove the victim immediately, observing the following precautions:

—Protect yourself with dry insulating material. Use a dry board, a belt, dry clothing, or other available nonconductive material to free the victim (by pulling, pushing, or rolling) from the power-carrying object. DO NOT TOUCH the victim.

Immediately after you remove the victim from contact with the live circuit, administer artificial respiration/ventilation or cardiopulmonary resuscitation as necessary.

ANYONE WHO RECEIVES A SIGNIFICANT SHOCK SHOULD BE TAKEN TO SICK BAY OR A MEDICAL FACILITY AND OBSERVED FOR SEVERAL HOURS.

Artificial Ventilation

A person who has stopped breathing is not necessarily dead, but is in immediate critical danger. Life depends on oxygen that is breathed into the lungs and then carried by the blood to every body cell. Since body cells cannot store oxygen, and since the blood can hold only a limited amount (and only for a short time), death will surely result from continued lack of breathing.

The heart may continue to beat and the blood may still be circulated to the body cells for some time after breathing has stopped. Since the blood will, for a short time, contain a small supply of oxygen, the body cells will not die immediately. Thus, for a few minutes, there is some chance that the person's life may be saved. A person who has stopped breathing but who is still alive is said to be in a state of respiratory failure. The first aid treatment for respiratory failure is called artificial ventilation.

The purpose of artificial ventilation is to provide a method of air exchange until natural breathing is established. Artificial ventilation should be given only when natural breathing has stopped; it must NOT be given to any person who is still breathing. Do not assume that breathing has stopped merely because a person is unconscious or because a person has been rescued from the water, from poisonous gas, or from contact with an electric wire. Remember, **DO NOT GIVE ARTIFICIAL VENTILATION TO A PERSON WHO IS BREATHING NATURALLY**. If the victim does not begin spontaneous breathing after you use the head or jaw tilt techniques (discussed later) to open the airway, artificial ventilation must be attempted immediately. If ventilation is inadequate, one of the "thrust" methods of clearing the airway must be performed, followed by another attempt of artificial ventilation.

MOUTH-TO-MOUTH.—To perform this method of ventilation, clear the victim's mouth of obstructions (false teeth and foreign matter), place one hand under the victim's neck and the heel of the other hand on the forehead, and, using the thumb and index finger, pinch the nostrils shut. Tilt the head back to open the airway. Take a deep breath, cover the victim's mouth with your own, and blow into the victim's mouth. Then remove your mouth from the victim's to allow the victim to exhale. Observe the victim's chest for movement. If the victim has not started to breathe normally, start artificial ventilation with four quick ventilation in succession, allowing the lungs to only partially inflate. If the victim still does not respond, then you must fully inflate the victim's lungs at the rate of **12 TO 15 VENTILATIONS PER MINUTE, or ONE BREATH EVERY 5 SECONDS**.

MOUTH-TO-NOSE.—This type ventilation is effective when the victim has extensive facial or dental injuries or is very young, as it permits an effective air seal.

To administer this method, place the heel of one hand on the victim's forehead and use the other hand to lift the jaw. After sealing the victim's lips, take a deep breath, place your lips over the victim's nose, and blow. Observe the chest for movement and place your ear next to the victim's nose to listen for, or feel, air exchange. Again, you must continue your efforts at the rate of 12 to 15 ventilation per minute, or one breath every 5 seconds, until the victim can breathe without assistance.

NOTE: Sometimes during artificial ventilation, air enters the stomach instead of the lungs. This condition is called GASTRIC DISTENTION. It can be relieved by moderate pressure exerted with a flat hand between the navel and rib cage. Before applying pressure, turn the victim's head to the side to prevent choking on stomach contents that are often brought up during the process.

BACK PRESSURE ARM LIFT.—This method is an alternate technique used when other methods are not possible. Place the victim on the stomach, face to one side, neck hypo-extended, with hands under the head. Quickly clear the mouth of any foreign matter. Kneel at the victim's head and place your hands on the victim's back so that the heels of the hands lie just below a line between the armpits, with thumbs touching and fingers extending downward and outward. Rock forward, keeping your arms straight, and exert pressure almost directly downward on the victim's back, forcing air out of the lungs. Then rock backward, releasing the pressure and grasping the arms just above the elbows. Continue to rock backward, pulling the arms upward and inward (toward the head) until resistance and tension in the victim's shoulders are noted. This expands the chest, causing active intake of air (inspiration). Rock forward and release the victim's arms. This causes passive exiting of air (expiration). Repeat the cycle of *press, release, lift,* and *release* 10 to 12 times a minute until the victim can breathe naturally.

Cardiac Arrest and Cardiopulmonary Resuscitation

Cardiac arrest is the complete stoppage of heart function. If the victim is to live, action must be taken immediately to restore heart function.

In this situation, the immediate administration of cardiopulmonary resuscitation (CPR) by a rescuer using correct procedures greatly increases the chances of a victim's survival. To be effective, CPR must be started within 4 minutes of the onset of cardiac arrest. CPR consists of external heart compression and artificial ventilation. This compression is performed on the outside of the chest, and the lungs are ventilated either by mouth-to-mouth or mouth-to-nose techniques. The victim should be lying on a firm surface.

CAUTION

A rescuer who has not been properly trained should not attempt CPR. Everyone who works around electricity should be trained. (To learn CPR, consult a hospital corpsman.) Improperly done, CPR can cause serious damage. Therefore, it is never practiced on a healthy individual for training purposes; a training aid is used instead.

ONE RESCUER TECHNIQUE.—If a cardiac arrest is not witnessed, the rescuer must not assume that an arrest has occurred solely because the victim is lying on the floor and appears to be unconscious. First, try to arouse the victim. You can try shaking the victim's shoulders gently to obtain a response. Next, quickly check vital signs; if there is no response, apply artificial ventilation. Establish an open airway and ventilate the victim four times. Check the carotid (neck) pulse as shown in figure 1-1. If no pulse is felt and there are no visible signs of breathing, start CPR immediately.

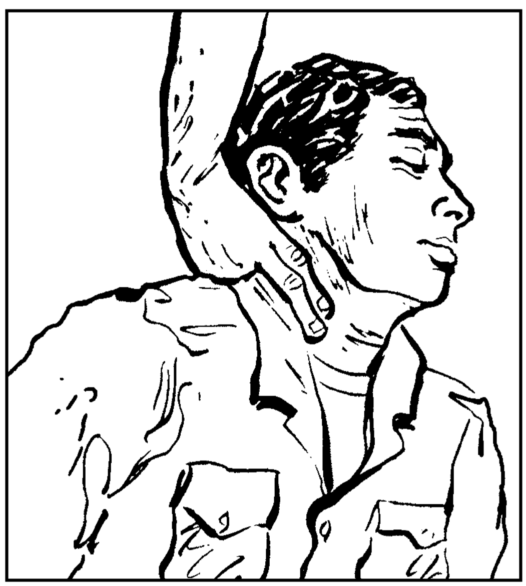

Figure 1-1.—Feeling for the carotid pulse

To start external cardiac compression, place the victim on the back, establish an open airway, and kneel at right angles to the victim's body. Then locate the victim's sternum (breastbone). You have a choice of two methods of doing this. One method is to bare the chest and locate the sternum by drawing an imaginary line from one nipple to the other to identify the proper area of the sternum, which is darkened in figure 1-2. The other method is to locate the lower tip of the sternum with the index and middle fingers, placing the heels of your hands above your fingers in the darkened area.

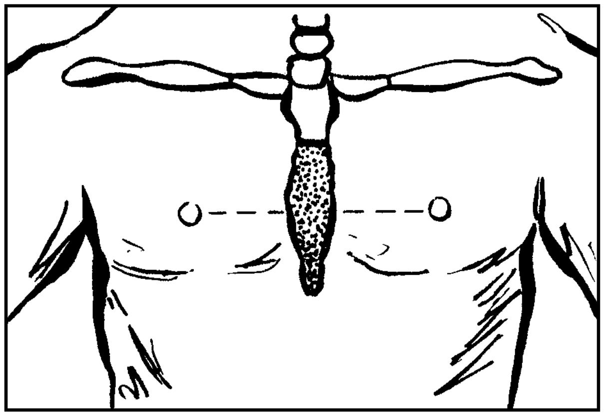

Figure 1-2.—Locating the sternum.

There is a small piece of cartilage at the lower end of the sternum (figure 1-2). A fracture of this area can damage the liver, causing hemorrhage (heavy bleeding) and death. When you place the heels of your hands on the victim's chest, make sure they are above the tip of the sternum.

Place the heel of one hand directly on the sternum and the heel of the other on top of the first. Figure 1-3, view A, shows this technique. Interlock your fingers and *keep them off the victim's chest!*

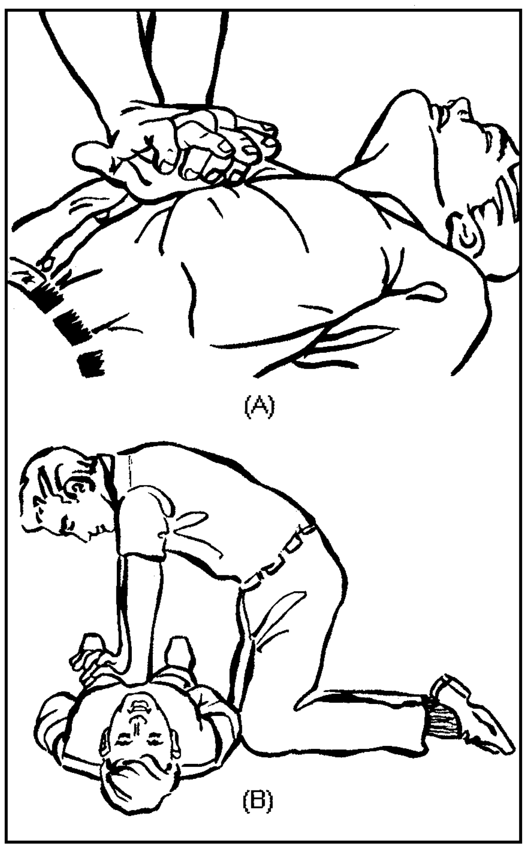

Figure 1-3.—Position for cardiac compression.

Lean or rock forward with elbows locked, and apply vertical pressure to depress the sternum (adult) 1 1/2 to 2 inches. View B depicts this. Then release the pressure, keeping hands in place. Administer 60 to 80 compressions per minute.

You will feel less fatigue if you use the proper technique, and a more effective compression will result.

Ineffective compression occurs when the elbows are not locked, the rescuer is not directly over the sternum, or the hands are improperly placed on the sternum.

When one rescuer performs CPR, as shown in figure 1-4, the ratio of compressions to ventilations is 15 to 2. After 15 compressions, you must give the victim 2 ventilations. This ratio must continue for four full cycles. Then check for pulse and breathing. If there are still no signs of recovery, continue CPR until the victim can breathe unassisted or you are relieved by medical personnel.

Figure 1-4.—One rescuer CPR technique.

Before reviewing the next technique, let's go over the steps to take in an unwitnessed cardiac arrest involving one rescuer.

1. Determine whether the victim is conscious.
2. Check the vital signs.
3. Ventilate four times (you may have to remove an airway obstruction at this time!).
4. Again check the vital signs; if none:
    a. Begin compression-ventilation rate of 15 to 2 for four complete cycles.
    b. Check pulse, breathing, and pupils. If no change
    c. Continue compression-ventilation rate of 15 to 2 until victim is responsive or you are relieved by medical personnel.

TWO RESCUER TECHNIQUE.—If two people trained in CPR are on the scene, one must perform compressions while the other performs artificial ventilation. The ratio for two-person CPR is 5 compressions to 1 ventilation. One rescuer is positioned at the chest area and the other beside the victim's head. The rescuers should be on opposite sides of the victim.

To avoid confusion, one rescuer must be designated the leader. The leader must make the preliminary checks of the victim's vital signs and perform the initial four ventilations. The second rescuer will perform the compressions.

When CPR is started, the compressions should be given in a constant, methodical rhythm. The rescuer giving the compressions counts them out loud. As the fifth compression is released, the other rescuer ventilates the victim. The compressions should be continued while ventilation is being given.

Hemorrhage

Blood is circulated throughout the body by means of three different kinds of blood vessels: arteries, veins, and capillaries. Arteries are large vessels that carry the blood away from the heart; veins are large vessels that carry the blood back to the heart; and capillaries form a connecting network of smaller vessels between the arteries and the veins.

Hemorrhage (escape of blood) occurs whenever there is a break in the wall of one or more blood vessels. In most small cuts, only capillaries are injured. Deeper wounds result in injury to veins or arteries. Bleeding which is severe enough to endanger life seldom occurs except when arteries or veins are cut.

The average adult body contains about 5 quarts (4.75 liters) of blood. One pint of blood can usually be lost without harmful effect—in fact, this is the amount usually given by blood donors. However, the loss of 2 pints (.95 liter) will usually cause shock; shock becomes greater and greater as the amount of blood loss increases (shock will be discussed later in this chapter). If half the blood in the body is lost, death almost always results.

Capillary blood is usually brick red in color. If capillaries are cut, the blood oozes out slowly. Blood from veins is dark red. If a vein is cut, the blood escapes in a steady, even flow. If an artery near the surface is cut, the blood will gush out in spurts that are synchronized with the heartbeats; but if the cut artery is deeply buried, the bleeding will appear to be a steady stream. Arterial blood is usually bright red in color.

In actual practice, you might find it difficult to decide whether bleeding is from a vein or an artery; but the distinction is not usually important. The important thing to know is that bleeding must be controlled as quickly as possible.

METHODS OF CONTROLLING BLEEDING.—The only way to stop serious bleeding is by the application of pressure. In practically all cases, bleeding can be stopped if **PRESSURE** is applied **DIRECTLY TO THE WOUND**. If direct pressure does not stop the bleeding, pressure should be applied at the appropriate pressure point. In those very rare cases where bleeding is so severe that it cannot be controlled by either of these methods, pressure can be applied by means of a tight, constricting band called a tourniquet.

PROCEDURES.—The actual procedures you should use to stop bleeding are detailed in the following paragraphs:

Direct Pressure.—In almost every case, bleeding can be stopped by the application of pressure directly on the wound. Figure 1-5 is an example of direct pressure. Place a dressing (sterile or clean, if possible) over the wound and firmly fasten it in position with a bandage. If bleeding does not stop, firmly secure another dressing over the first, or apply direct pressure with your hand to the dressing.

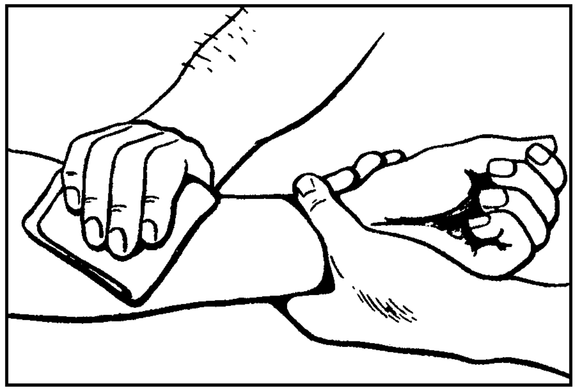

Figure 1-5.—Direct pressure.

In cases of severe hemorrhage, do not worry too much about the dangers of infection. The basic problem is to stop the flow of blood. If no material is available, simply apply pressure with your bare hand. Remember, **DIRECT PRESSURE** is the first method to use when you are trying to control hemorrhage.

Pressure Points.—Bleeding from a cut artery or vein may often be controlled by pressure applied to the appropriate pressure point. A pressure point is a place where the main artery to the injured part lies near the skin surface and over a bone. Pressure at such a point is applied with the fingers (digital pressure) or with the hand; no first aid materials are required. The object of the pressure is to compress the artery against the bone, thus shutting off the flow of blood from the heart to the wound.

There are 11 principal points on each side of the body where hand or finger pressure can be used to stop hemorrhage. These points are shown in figure 1-6.

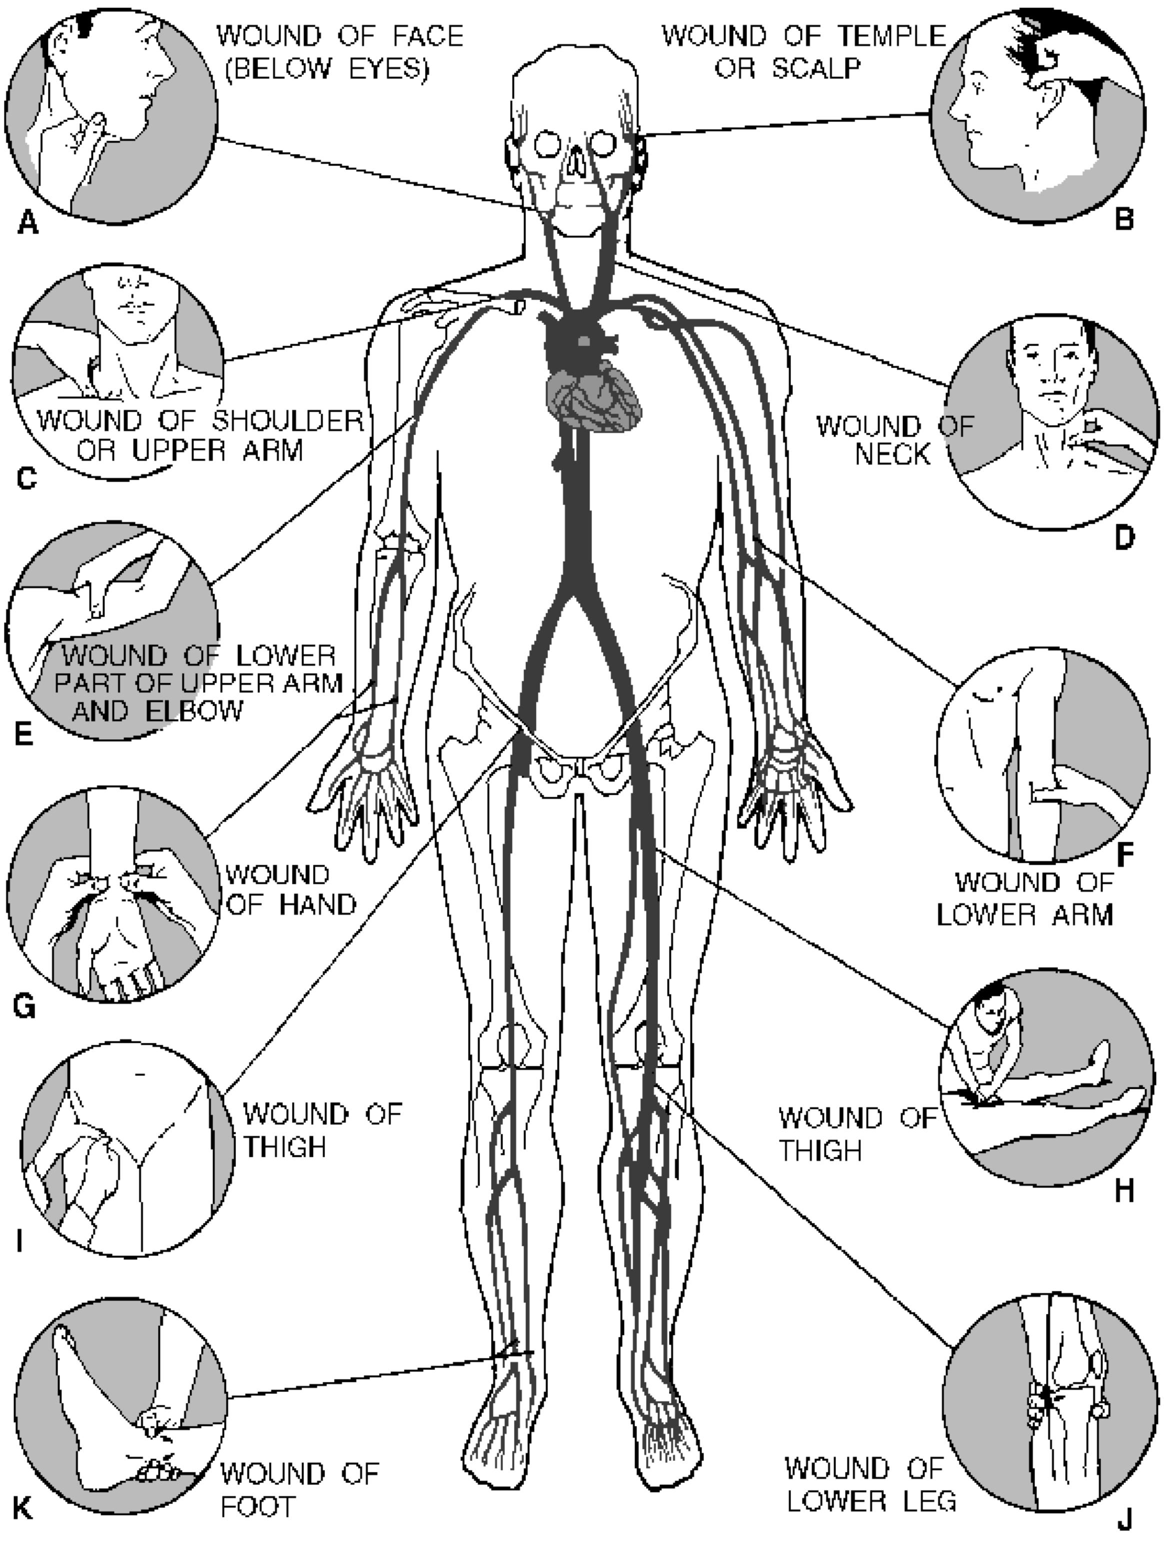

Figure 1-6.—Pressure points for control of bleeding.

You should memorize these pressure points so that you will know immediately which point to use for controlling hemorrhage from a particular part of the body. The correct pressure point is the one that is

(1) NEAREST THE WOUND and (2) BETWEEN THE WOUND AND THE MAIN PART OF THE BODY.

Applying finger pressure is very tiring, and it can seldom be maintained for more than 15 minutes. Pressure points are recommended for use while direct pressure is being applied to a serious wound. While pressure is being applied at the appropriate pressure point, an assistant can bandage the wound (or wounds). If available, a battle dressing should be used. Figure 1-7 shows the battle dressing and its use. After opening the dressing, be careful not to contaminate it. Place the compress portion over the wound, then bind it tightly in place with the attached straps. If bleeding continues to be severe even after direct pressure and pressure points have been used, you may have to apply a tourniquet.

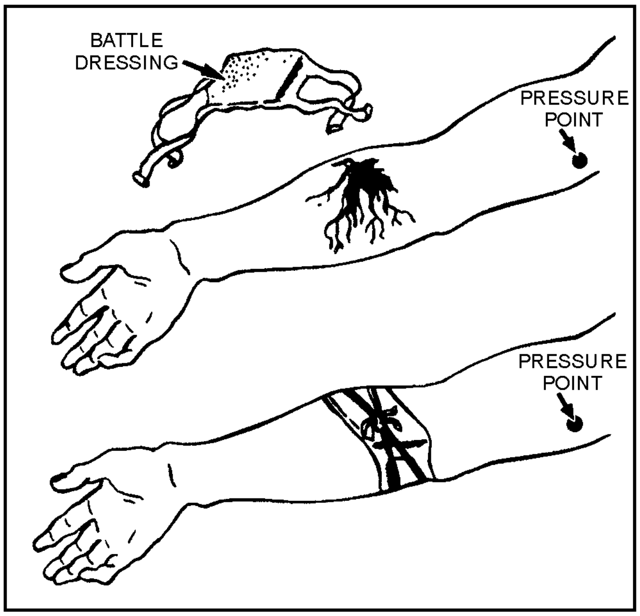

Figure 1-7.—Battle dressing.

Use of the Tourniquet.—A tourniquet is a constricting band that is used to cut off the supply of blood to an injured limb. It cannot be used to control bleeding from the head, neck, or trunk, since its use in these locations would result in greater injury or death. A tourniquet should be used *only* if the control of hemorrhage by other means proves to be impossible.

Basically, a tourniquet consists of a pad, a band, and a device for tightening the band so that the blood vessels will be compressed. There are several different kinds of ready-made tourniquets. A variety of materials can be used to improvise tourniquets. Any round, smooth pressure object may be used for the pad — a compress, a roller bandage, a stone, a rifle shell — and any long, flat material may be used as the band. However, the band must be flat: belts, stockings, flat strips of rubber, or neckerchiefs can be used; but rope, wire, string, or very narrow pieces of cloth should not be used because they will cut into the flesh. A short stick may be used to twist the band, thus tightening the tourniquet.

A tourniquet must always be applied *above* the wound — that is, toward the body — and it must be applied as close to the wound as practicable.

The best object to be used for the pad is either a bandage, a compress, or some similar pressure object. The pad goes under the band. It must be placed directly over the artery, or it will actually decrease the pressure on the artery and thus allow greater flow of blood. If a tourniquet placed over a pressure object does not stop the bleeding, the pressure object is probably in the wrong place. If this occurs, shift the object around until the tourniquet, when tightened, will control the bleeding. If no suitable pressure object is available, use the tourniquet without it.

To apply an emergency tourniquet made from something like a neckerchief, wrap the material once around the limb and tie an overhand knot; place a short stick on the overhand knot and tie a square knot over it. Then twist the stick rapidly to tighten the tourniquet. The stick may be tied in place with another strip of material. Figure 1-8 shows how to apply a tourniquet.

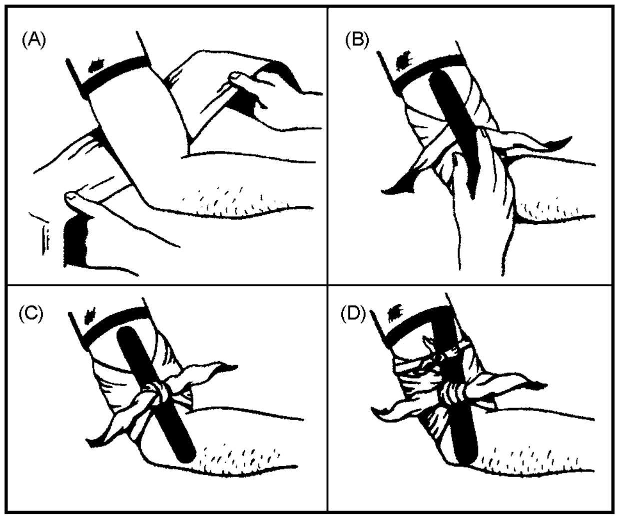

Figure 1-8.—Applying a tourniquet.

To be effective, a tourniquet must be tight enough to stop the blood flowing to the limb. If the pressure from the tourniquet is less than the arterial pressure, arterial bleeding will continue. Also, insufficient tourniquet pressure may actually increase the amount of bleeding from the veins. So be sure to draw the tourniquet tight enough to stop the bleeding. However, do not make it any tighter than necessary.

After you have brought the bleeding under control with the tourniquet, apply a sterile compress or dressing to the wound and fasten it in position with a bandage.

CAUTION

NEVER apply a tourniquet unless the hemorrhage is so severe that it cannot be controlled in any other way. By the time the tourniquet is required, the victim will have lost a considerable amount of blood; therefore, once a tourniquet has been applied, it should be released only by medical personnel.

Here are the points to remember when you use a tourniquet:

- Do not use a tourniquet unless you cannot control the bleeding by any other means.
- Do not use a tourniquet for bleeding from the head, face, neck, or trunk. Use it only on the limbs.
- Always apply a tourniquet *above the wound* and as close to the wound as possible.

- Be sure you draw the tourniquet tight enough to stop the bleeding, but do not make it any tighter than necessary.

- Do not loosen a tourniquet after it has been applied except in extreme emergency.

- Do not cover a tourniquet with a dressing. If you must cover the injured person in some way, make sure that all other people concerned with the case know about the tourniquet. Using crayon, magic marker, or blood, mark a large T on the victim's forehead or on a medical tag attached to the wrist.

Shock

If you've ever hit your finger with a hammer and felt — in addition to the pain — weak, dizzy, and nauseous, then you have experienced a mild form of shock. In such an instance, the symptoms appear immediately after the injury; but they may not show up for several hours.

Shock is a condition in which blood circulation is seriously disturbed. Crushed or fractured bones, burns, prolonged bleeding, and asphyxia all cause shock. It may be slight or it may be severe enough to cause death. Because all injuries will result in some form of shock, you must learn its symptoms and know how to treat the victim.

HOW TO RECOGNIZE SHOCK.—A person who is going into shock may show quite a few signs or symptoms, some of which are indicated in figure 1-9 and are discussed below. Remember, however, that signs of shock do not always appear at the time of the injury; indeed, in many serious cases they may not appear until hours later.

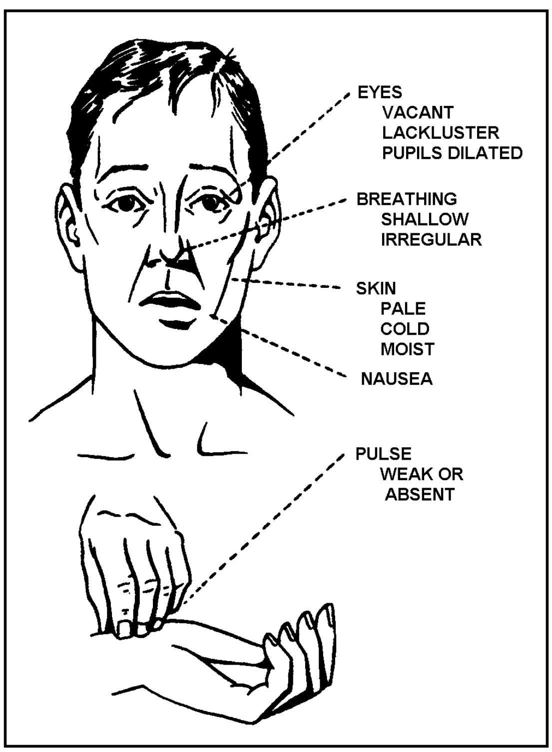

Figure 1-9.—Symptoms of shock.

The symptoms of a person suffering from shock are caused, directly or indirectly, by the disturbance of the circulation of the blood. The pulse is weak and rapid. Breathing is likely to be shallow, rapid, and irregular, because the poor circulation of the blood affects the breathing center in the brain. The temperature near the surface of the body is lowered because of the poor blood flow; so the face, arms, and legs feel cold to the touch. Sweating is likely to be very noticeable. A person in shock is usually very pale, but in some cases the skin may have a bluish or reddish color. As mentioned previously when we were discussing electric shock, in the care of victims with dark skin, it may be necessary to rely primarily on the color of the mucous membranes on the inside of the mouth or under the eyelid or under the nail bed. A person in or going into shock has a bluish color to these membranes instead of a healthy pink. The pupils of the eyes are usually dilated (enlarged).

A conscious person in shock may complain of thirst and have a feeling of weakness, faintness, or dizziness. The victim may feel nauseous, restless, frightened, and/or anxious. As shock deepens, these signs gradually disappear and the victim becomes less and less responsive to what is going on. Even pain may not arouse the shock victim. Finally, the victim may become unconscious.

You will not likely see all these symptoms of shock in any one case. Some of them appear only in late stages of shock when the disturbance of the blood flow has become so great that the person's life is in serious danger. Sometimes the signs of shock may be disguised by other signs of injury. You must know what symptoms indicate the presence of shock, but do not ever wait for symptoms to develop before beginning the treatment for shock. Remember, **EVERY SERIOUSLY INJURED PERSON IS LIKELY TO DEVELOP SERIOUS SHOCK**.

PREVENTION AND TREATMENT OF SHOCK.—You should begin treatment for shock as soon as possible. Prompt treatment may prevent the occurrence of shock or, if it has already developed, prevent its reaching a critical point. Keep the victim lying down and warm. If conscious, the victim should be encouraged and assured that expert medical help will arrive soon.

KEEP AN INJURED PERSON WARM ENOUGH FOR COMFORT, BUT DO NOT LET THE VICTIM BECOME OVERHEATED.

The best position to use for the prevention or the treatment of shock is one which encourages the flow of blood to the brain. If the injured person can be placed on his/her back on a bed, a cot, or a stretcher, you can raise the lower end of the support about 12 inches so that the feet will be higher than the head. The circumstances of the accident may prevent the use of a bed, a cot, or a stretcher. In such cases, you might still be able to raise the feet and legs enough to help the blood flow to the brain. Sometimes you can take advantage of a natural slope of ground and place the casualty so that the head is lower than the feet.

In every case, of course, you will have to consider what type of injury is present before you can decide on the best position. For example, a person with a chest wound may have so much trouble breathing that you will have to raise the head slightly. If the face is flushed rather than pale, or if you have any reason to suspect a head injury, do not raise the feet; instead, you should keep the head level with or slightly higher than the feet. If the person has broken bones, you will have to judge what position would be best both for the fractures and for shock. A fractured spine must be immobilized before the victim is moved at all, if further injuries are to be avoided. If you have any doubts about the correct position to use, have the victim lie flat on his/her back. **THE BASIC POSITION FOR TREATING SHOCK IS ONE IN WHICH THE HEAD IS LOWER THAN THE FEET**. Do the best you can under the particular circumstances to get the injured person into this position. In any case, never let a seriously injured person sit, stand, or walk around.

Liquids should be administered sparingly, and not at all if medical attention will be available within a short time. If necessary, small amounts of warm water, tea, or coffee may be given to a victim who is conscious. Persons having serious burns are an exception. Burn victims require large amounts of fluids. Water, tea, fruit juices, and sugar water may be given freely to a victim who is conscious, able to swallow, and has no internal injuries. Slightly salted water is also beneficial. Alcohol must never be given to a person in shock.

An injured person may or may not be in pain. The amount of pain felt depends in part on the person's physical condition and the type of injury. Extreme pain, if not relieved, can increase the degree of shock. Make the victim as comfortable as possible. Fractures should be immobilized and supported. Immobilization greatly reduces, and sometimes eliminates, pain. Normally, you should not administer drugs, but aspirin may be given for mild pain.

Heat is important in the treatment of shock to the extent that the injured person's body heat must be conserved. Exposure to cold, with resulting loss of body heat, can cause shock to develop or to become worse. You will have to judge the amount of covering to use by considering the weather and the general circumstances of the accident. Often a light covering will be enough to keep the casualty comfortable. Wet clothing should be removed and dry covering provided, even on a hot day. Use blankets or any dry material to conserve body heat. Artificial means of warming (hot water bottles, heated bricks, heated sand) should not ordinarily be used. Artificial heat may cause loss of body fluids (by sweating) and it brings the blood closer to the surface, thus defeating the body's own efforts to supply blood to the vital organs and to the brain. Also, the warming agent may burn the victim.

Burns

The seriousness of a burn depends on two factors: the extent of the burned area and the depth of the burn. Shock can be expected from burns involving 15 percent or more of the body. Burns involving 20 percent endanger life. Without adequate treatment, burns of over 30 percent are usually fatal. The depth of the injury determines whether it is a first, second, or third degree burn.

First degree burns are mildest. Symptoms are slight pain, redness, tenderness, and increased temperature of the affected area.

Second degree burns are more serious. The inner skin may be damaged, resulting in blistering, severe pain, some dehydration, and possible shock.

Third degree burns are worst of all. The skin is destroyed, and possibly also the tissue and muscle beneath it. The skin may be charred, or it may be white and lifeless (from scalds). After the initial injury, pain may be less severe because of destroyed nerve ends. The person may have chills. Some form of shock will result.

Probably the most important aspect is the extent of the burned area. A first degree burn covering a large area could be more serious than a small third degree burn. A sunburn, for example, ranging from mild to serious, is easily obtained, particularly if you are not accustomed to the exposure. If you were to fall asleep while sunbathing, second degree burns, or even third degree burns of a possibly fatal nature, could result.

The most effective immediate treatment of burns and of pain is to immerse the burned area in cold water or to apply cold compresses if immersion is impracticable. Cold water not only minimizes pain, but also reduces the burning effect in the deeper layers of the skin. Gently pat dry the area with lint-free cloth or gauze. Aspirin is also effective for the relief of pain. Continue treatment until no pain is felt when the burned area is exposed to the air.

Burn victims require large amounts of water, which should be slightly salted. Because of the nature of the injury, most burns are sterile. The best treatment for uninfected burns, therefore, is merely to protect the area by covering it with the cleanest (preferably sterile) dressing available. Never apply ointments to a burn nor use petrolatum gauze.

Do not attempt to break blisters or to remove shreds of tissue or adhered particles of charred clothing. Never apply a greasy substance (butter, lard, or petroleum jelly), antiseptic preparations, or ointments. These may cause further complications and interfere with later treatment by medical personnel.

Heatstroke

Sunstroke is more accurately called heatstroke since a person does not have to be exposed to the sun for this condition to develop. It is a less common but far more serious condition than heat exhaustion, since it carries a 20 percent fatality rate. The main feature of heatstroke is the extremely high body temperature, 105º F (41º C) or higher, that accompanies it. In heatstroke, the victim has a breakdown of the sweating mechanism and is unable to eliminate excessive body heat built up while exercising. If the body temperature rises too high, the brain, kidneys, and liver may be permanently damaged.

Sometimes the victim may have preliminary symptoms, such as headache, nausea, dizziness, or weakness. Breathing will be deep and rapid at first, later shallow and almost absent. Usually the victim will be flushed, very dry, and very hot. The pupils will be constricted (pinpoint) and the pulse fast and strong. Figure 1-10 compares these symptoms with those of heat exhaustion.

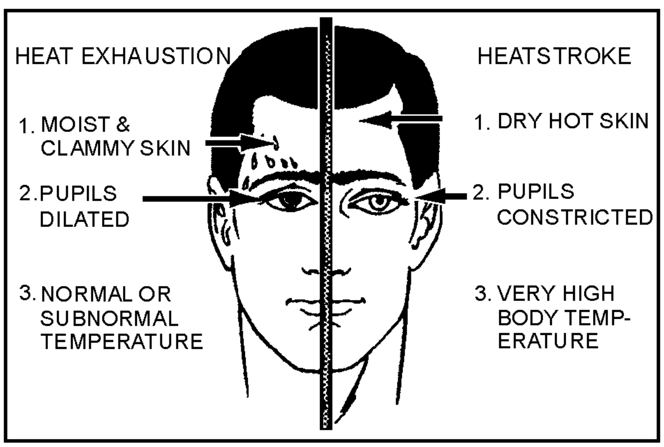

Figure 1-10.—Symptoms of heatstroke and heat exhaustion.

When you provide first aid for heatstroke, remember that this is a true life-and-death emergency. The longer the victim remains overheated, the higher the chances of irreversible body damage or even death occurring. First aid treatment for heatstroke is designed to reduce body heat.

Reduce body heat immediately by dousing the body with cold water, or applying wet, cold towels to the whole body. Move the victim to the coolest possible place and remove as much clothing as possible. Maintain an open airway. Place the victim on his/her back, with the head and shoulders slightly raised. If cold packs are available, place them under the arms, around the neck, at the ankles, and in the groin. Expose the victim to a fan or air-conditioner since drafts will promote cooling. Immersing the victim in a cold water bath is also effective. Give the victim (if conscious) cool water to drink. Do not give any hot drinks or stimulants. Get the victim to a medical facility as soon as possible. Cooling measures must be continued while the victim is being transported.

Heat Exhaustion

Heat exhaustion (heat prostration or heat collapse) is the most common condition caused by working or exercising in hot spaces. Heat exhaustion produces a serious disruption of blood flow to the brain, heart, and lungs. This causes the victim to experience weakness, dizziness, headache, loss of appetite, and nausea.

Signs and symptoms of heat exhaustion are similar to those of shock: the victim will appear ashen gray; the skin will be cold, moist, and clammy; and the pupils of the eyes may be dilated (enlarged). The vital (blood pressure, temperature, pulse, and respiration) signs usually are normal; however, the victim may have a weak pulse together with rapid and shallow breathing. Body temperature may be below normal.

You should treat heat exhaustion victims as if they were in shock. Loosen the clothing, apply cool wet cloths, move the victim to either a cool or an air-conditioned area, and fan the victim. Do not allow the person to become chilled. If the victim is conscious, administer a solution of 1 teaspoon of salt dissolved in a quart of cool water. If the victim vomits, do not give any more fluids. Transport the victim to a medical facility as soon as possible.

HELPFUL INFORMATION

The second part of this handbook has been compiled to provide the technician with a collection of helpful information. Included are many commonly used formulas, data tables, and general maintenance hints used in, with, and around electricity.

BASIC ELECTRICAL FORMULAS

Basic electrical formulas are included to aid you in solving electrical problems. These formulas are for capacitance, current, inductance, power, reactance, impedance, resistance, voltage, and transformers. Additional formulas can be found in the appropriate NEETS module.

Capacitance

The property of an electrical device to store energy is **CAPACITANCE**. This energy is stored in a way to oppose a change in voltage. A **CAPACITOR** is used to store this electrical energy. The **FARAD** is the basic unit of measurement of capacitance.

Formulas for capacitance:

$$C = \frac{Q}{E}$$

C = capacitance in farads

Q = coulombs (a unit of charge equal to 6.28×10^{18} electrons)

E = volts

$$C = 0.2249 \frac{(kA)}{d}$$

A = area of one plate, in square inches

C = capacitance in picofarads

d = distance between the plates in inches

k = dielectric constant of the insulating material

0.2249 is a constant resulting from conversion from metric to British units

Common insulating materials for capacitors and their dielectric constant are:

MATERIAL	CONSTANT
Vacuum	1.0000
Air	1.0006
Paraffin paper	3.5
Glass	5 to 10
Mica	3 to 6
Rubber	2.5 to 35
Wood	2.5 to 8
Glycerine (15º C)	56
Petroleum	2
Pure Water	81

The time to charge a capacitor to 63.2 percent of applied voltage or discharge it to 36.8 percent of its initial voltage is known as the TIME CONSTANT (t) of the circuit. Figure 1-11 shows an RC time constant chart. One time constant (t) in seconds equals R × C, with R in ohms and C in farads.

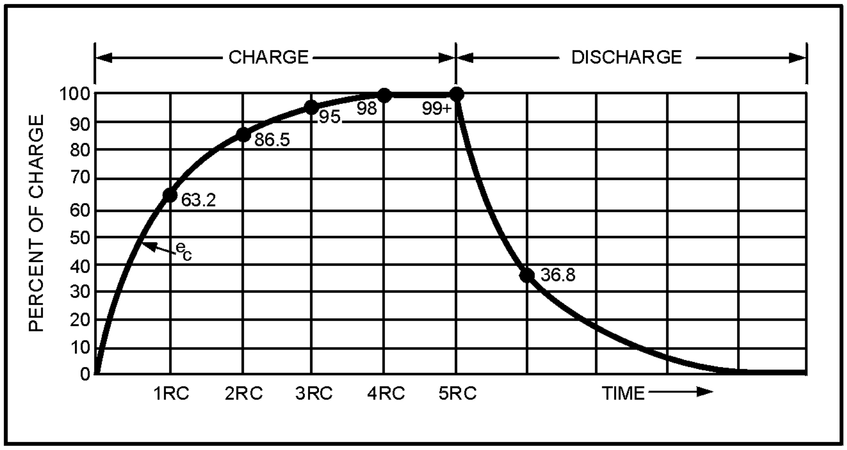

Figure 1-11.—RC time constants.

Figure 1-12 is a universal time constant chart for RC and LR circuits. One time constant (t) in seconds equals R × C, with R in ohms and C in farads, or L/R with L in henries and R in ohms.

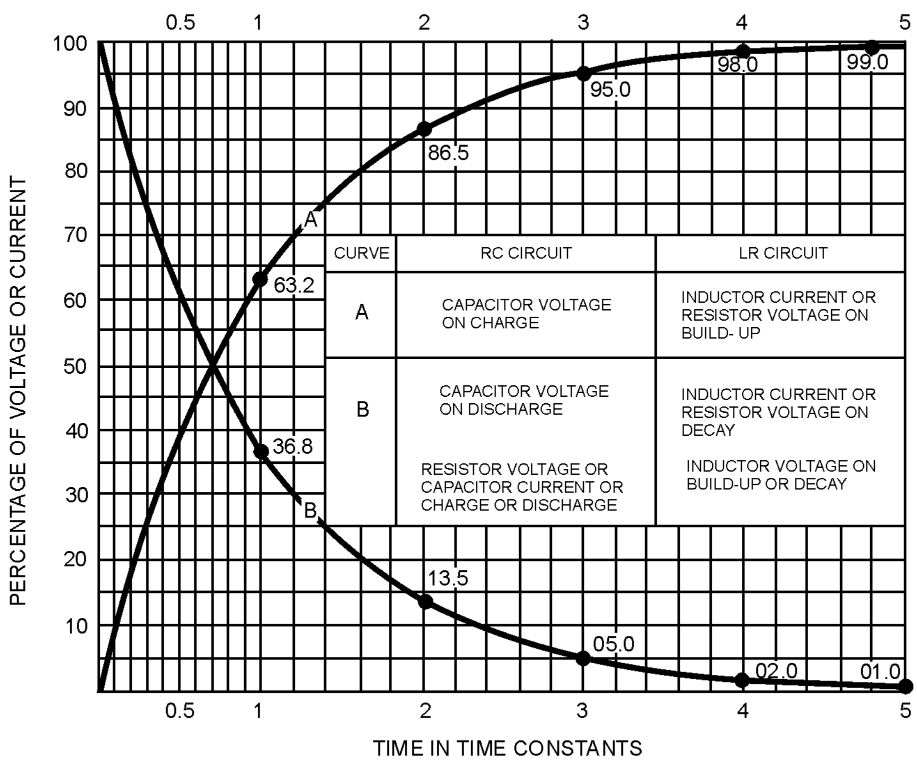

Figure 1-12.—Universal time constant chart for RC and LR circuits.

Adding capacitors in series:

If only two capacitors are used:

$$C_T = \frac{C_1 \times C_2}{C_1 + C_2}$$

If more than two capacitors are used:

$$C_T = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} \ldots + \frac{1}{C_n}}$$

Adding capacitors in parallel:

$$C_T = C_1 + C_2 + C_3 + \ldots + C_n$$

CAUTION

Capacitors retain an electrical charge. Be sure to discharge all capacitors and circuits containing capacitors before working on them.

A more detailed description of capacitors and capacitance can be found in NEETS, Module 2, *Introduction to Alternating Current and Transformers.*

Current

Electrons (negative charges) move through a conductor when an electric field is applied. Electron current is defined as the directed flow of electrons from negative to positive.

Current is measured in AMPERES (AMP). One amp of current flows when one coulomb (6.28×10^{18} electrons) passes a point in one second.

The Ohm's law formulas for current are:

$$I = \frac{E}{R}$$

I = current in amps

E = voltage in volts

R = resistance in ohms

$$I = \sqrt{\frac{P}{R}}$$

P = power in watts

$$I = \frac{P}{E}$$

Ac current formulas are:

Average current

$$I_{avg} = 0.636 \times I_{max}$$

Effective current

$$I_{eff} = 0.707 \times I_{max}$$

Maximum current

$$I_{max} = 1.414 \times I_{eff}$$

Ohm's law

$$I_{eff} = \frac{E_{eff}}{R}$$

$$I_{avg} = \frac{E_{avg}}{R}$$

$$I_{max} = \frac{E_{max}}{R}$$

Ohm's law for reactive circuits:

$$I = \frac{E}{X_L} \text{ or } I = \frac{E}{X_C}$$

Ohm's law for circuits containing resistance and reactance:

$$I = \frac{E}{Z}$$

Current across the primary (I_p) of a transformer:

$$I_p = \frac{E_S I_S}{E_p}$$

Current across the secondary (I_s):

$$I_S = \frac{E_p I_p}{E_S}$$

NOTE

Human reaction to electrical shock is determined by the amount of current flowing through the body. A 100-milliampere shock for 1 second is usually fatal!

More information about current can be found in NEETS, Module 1, *Introduction to Matter, Energy, and Direct Current.*

Inductance

Inductance is the characteristic of an electrical conductor that opposes a change in electrical current. The symbol for inductance is L and the basic unit of measurement is the *HENRY(H)*.

An inductor has an inductance of 1 henry if an electromotive force (emf) of 1 volt is induced in the inductor when the current through the inductor is changing at the rate of one ampere per second.

Mathematically:

$$E_{ind} = L\frac{\Delta I}{\Delta t}$$

E_{ind} = induced voltage
L = inductance in henrys
ΔI = change in current in amperes
Δt = change in time in seconds

Mutual inductance:

$$M = K\sqrt{L_1 L_2}$$

M = mutual inductance in henrys
K = coefficient of coupling
$L_1 L_2$ = inductance of coils in henrys

Series inductors without magnetic coupling:

$$L_T = L_1 + L_2 + L_3 \ldots + L_n$$

L_T = total inductance in henrys
L_1, L_2, L_3 = inductance of each inductor
L_n = any number of additional inductors (L_4, L_5, and so forth) that could be used

Series inductors with magnetic coupling:

$$L_T = L_1 + L_2 \pm 2_M$$

M = mutual inductance between two inductors; plus sign is used when the magnetic fields of two inductors aid each other and minus when they oppose.

Parallel inductors without coupling:

$$\frac{1}{L_T} = \frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} \ldots + \frac{1}{L_n}$$

Provided the coefficient of coupling between inductors is zero.

Resistive/inductive circuit:

The time required for the current in an inductor to increase to 63.2 percent of its final value or decrease to 36.8 percent is known as the time constant.

Mathematically expressed:

$$t = \frac{L}{R}$$

$$t = \text{seconds}$$

$$L = \text{henrys}$$

$$R = \text{ohms}$$

Figure 1-13 shows an L/R time constant chart.

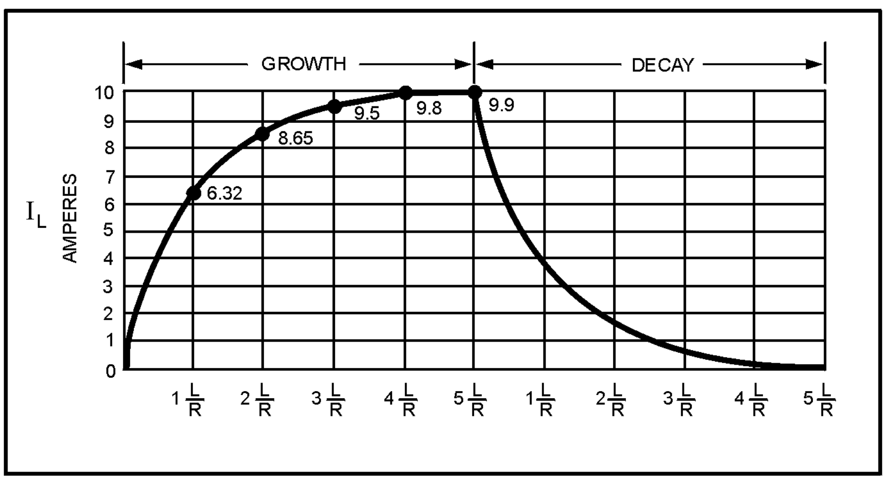

Figure 1-13.—L/R time constant.

You may want to refer back to figure 1-12, which shows the L/R relationship using the universal time constant chart.

Inductive reactance:

$$X_L = 2\pi f L$$
$$X_L = \text{reactance in ohms}$$
$$\pi = 3.1416$$
$$f = \text{frequency in hertz}$$
$$L = \text{inductance in henrys}$$

Ohm's law for reactive circuit:

$$I = \frac{E}{X_L}$$

You can find more information about inductance in NEETS, Module 2, *Introduction to Alternating Current and Transformers*.

Power

Electrical **POWER** pertains to the rate at which work is being done. Work is done whenever a force causes motion. The instantaneous rate at which work is done is called the electric power rate and is measured in **WATTS**.

Formulas for power in dc circuits are:

$$P = I E$$
$$P = I^2 R$$
$$p = \frac{E^2}{R}$$

For ac circuits:

True power:

$$P = (I_R)^2 R$$

True power is measured in watts.

I_R = resistive current in amperes.

R = resistance in ohms.

Reactive power:

$$Q = (I_X)^2 X$$

Reactive power is measured in volt-amperes-reactive.

I_X = reactive current in amps.

X = total reactance in ohms.

Another way to calculate reactive power is:

Reaction power:

$$Q = (I_L)^2 X_L - (I_C)^2 X_C$$

or

$$Q = (I_C)^2 X_C - (I_L)^2 X_L$$

Subtract the smaller from the larger:

I_C = capacitive current in amperes

X_C = capacitive reactance in ohms

I_L = inductive current in amperes

X_L = inductive reactance in ohms

Apparent power:

$$s = (I_Z)^2 Z$$

Apparent power is measured in volt - amperes (VA).

I_Z = impedance current in amperes

Z = impedance in ohms

or

$$S = (\text{true power})^2 + (\text{reactive power})^2$$

Power factor ($\cos\Theta$) :

$$\cos\Theta = \frac{\text{true power}}{\text{apparent power}}$$

or

$$\cos\Theta = \frac{(I_R)^2 R}{(I_Z)^2 Z}$$

or in a series circuit :

$$\cos\Theta = \frac{R}{Z}$$

$\cos\Theta$ is represented as a decimal or percentage.

You can find more detailed information about power in NEETS, Module 2, *Introduction to Alternating Current and Transformers*.

Reactance

REACTANCE is the result of the difference between the values of X_C (capacitive reactance) and X_L (inductive reactance). Reactance is represented by the letter X and its basic measurement is in ohms.

The formula for reactance is:

$$X = X_L - X_c \text{ or } X = X_c - X_L$$

If you want more detailed information on reactance, look in NEETS, Module 2, *Introduction to Alternating Current and Transformers*.

Impedance

IMPEDANCE is the combined opposition of current flow by reactance and resistance and is represented by the symbol Z.

Formulas for finding impedance:

$$Z = \sqrt{R^2 + (X_L - X_c)^2}$$

or

$$Z = \sqrt{R^2 + (X_c - X_L)^2}$$

or

$$Z = \sqrt{R^2 + X^2}$$

Resistance

RESISTANCE is the opposition to current flow. It is measured in ohms and is represented by the letter R.

Formulas for resistance:

$$R = \frac{E}{I}$$

$$R = \frac{E^2}{P}$$

$$R = \frac{P}{I^2}$$

Voltage

VOLTAGE exists when a charge exists between two bodies. When a one coulomb charge exists, one unit of electrical potential energy is created. This is called a difference of potential, an electromotive force, or a voltage. It is measured in volts and represented by the letter E.

Formulas for voltage:

$$E = IR$$

$$E = \frac{P}{I}$$

$$E = \sqrt{PR}$$

Formulas for ac circuits:

(Average voltage)

$$(E_{avg} = 0.636 \times E_{max})$$

(Effective voltage)

$$E_{eff} = 0.707 \times E_{max}$$

(Maximum voltage)

$$E_{max} = 1.414 \times E_{eff}$$

Voltage across the primary of a transformer:

$$E_p = \frac{E_s N_p}{N_s}$$

Voltage across the secondary of a transformer:

$$E_S = \frac{E_p N_S}{N_p}$$

Transformers

A **TRANSFORMER** is a device that transfers electrical energy from one circuit to another by electromagnetic induction (transformer action). Voltage induced into the secondary from the primary is determined by the turns ratio.

Turns ratio formula:

$$\frac{E_S}{E_p} = \frac{N_S}{N_p}$$

or

$$E_p N_S = E_S N_p$$

transposing:

$$E_S = \frac{E_p N_S}{N_p}$$

Where:

E_S = voltage induced in the secondary

E_p = voltage applied to the primary

N_S = number of turns in the secondary

N_p = ampere – turns in the secondary winding

Turns and current ratios:

$$I_p N_p = I_S N_S$$

$I_p N_p$ = ampere – turns in the primary winding

$I_S N_S$ = ampere – turns in the secondary winding

By dividing both sides of the equation by $I_p N_s$, you obtain:

$$\frac{N_p}{N_S} = \frac{I_S}{I_p}$$

Since:

$$\frac{E_S}{E_p} = \frac{N_S}{N_p}$$

Then:

$$\frac{E_p}{E_S} = \frac{N_p}{N_S}$$

And:

$$\frac{E_p}{E_S} = \frac{I_S}{I_p}$$

Where:

E_p = voltage applied to the primary in volts

E_S = voltage across the secondary in volts

I_p = current in the primary in amperes

I_S = current in the secondary in amperes

Transformer power:

$$P_S = P_p - P_L$$

P_S = power delivered to the load by the secondary

P_p = power delivered to the primary by the source

P_L = power losses in the transformer

Transformer efficiency:

$$\text{Efficiency in } (\%) = \frac{P_o}{P_i} \times 100$$

Where:

P_o = total output power delivered to the load

P_i = total input power

Impedance matching transformers:

$$\frac{N_p}{N_S} = \sqrt{\frac{Z_p}{Z_S}}$$

WARNING

Transformers are often used to STEP-UP voltage. You may find a low voltage across the primary and a much higher voltage across the secondary. Use extreme caution, especially when working around television and other crt high voltage transformers. They often step voltages up to, or in excess of, 30,000 volts.

BASIC ELECTRONICS FORMULAS

Basic electronics formulas are included to aid you in solving any electronics problem that you may encounter. These formulas are for antennas, resonance, transistors, vacuum tubes, wavelength, and radar. Additional formulas may be found in the appropriate NEETS module.

Antennas

An antenna is a conductor or a group of conductors used either for radiating electromagnetic energy into space or collecting it from space or both.

Antenna gain remains the same for the antenna whether it is transmitting or receiving. Antenna gain (G) can be described as the effectiveness of a directional antenna in a particular direction, compared to a standard or reference antenna. Some antenna formulas are shown below:

Gain formula:

$$G = KD$$

K = radiation efficiency factor ($K \leq 1$)

D = directivity

Effective aperture:

$$A_e = \frac{W}{P}$$

W = power delivered to a matched load

P = power density

Also:

$$A_e = \frac{\lambda 2G}{4\pi}$$

λ = wavelength (covered in depth later in this section)

G = gain

Directivity of an antenna:

$$D = \frac{U_m}{U_o}$$

U_m = maximum radiation intensity

U_o = average radiation intensity

Also:

$$D = \frac{U_m}{W/4\pi} = \frac{4\pi U_m}{W}$$

W = total power radiated

Field strength:

$$E = \frac{5870P}{D}$$

E = field intensity in millivolts

P = transmitter power in watts

D = distance in miles

Antenna length (L):

(Half-wave up to 30 megahertz)

$$L(\text{feet}) = \frac{492 \times 0.95}{f(MH_z)} = \frac{468}{f(MH_z)}$$

(Half-wave above 30 megahertz)

$$L(\text{feet}) = \frac{492 \times .94}{f(MH_z)} = \frac{462}{f(MH_z)}$$

$$L(\text{inches}) = \frac{5540}{f(MH_z)}$$

WARNING

Rf voltages may be induced in ungrounded metal objects such as wire guys, wire cables (hawsers), handrails, or ladders. You could receive a shock or rf burn if you come in contact with these objects. Obtain proper permission prior to going topside or "working aloft."

Rf burns are usually deep, penetrating, and third degree. They must heal from the inside out. If you are burned, seek medical attention. A person in an RF field will usually have a body temperature rise. The eyes and reproductive organs are especially susceptible to RF energy. Read and heed all warning signs!

You can find more information about antennas in NEETS, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas*.

Resonance

RESONANCE is a condition that exists in a circuit when inductance, capacitance, and the applied frequency are such that inductive reactance and capacitive reactance cancel each other.

Formula for resonant frequency (f_r):

$$fr = \frac{1}{2\pi\sqrt{LC}}$$

Where:

fr = resonant frequency in hertz

L = inductance in henrys

C = capacitance in farads

π (pi) = 3.1416

NOTE: The formula for resonance is the same for series or parallel circuits when $X_L = X_C$.

Transistors

Semiconductor devices that have three or more elements are called **TRANSISTORS**. The term is derived from **TRANS**fer and res**ISTOR**. This term describes the operation of the transistor — the transfer of an input signal current from a low-resistance circuit to a high-resistance circuit.

Some transistor formulas are shown below.

Transistor total current:

$$I_E = I_B + I_C$$

Where:

I_E = emitter current

I_B = base current

I_C = collector current

Common emitter gain:

$$\text{Beta } (\beta) \text{ or } h_{fe} = \frac{\Delta I_C}{\Delta I_B}$$

Where:

hfe = h = hybrid

f = forward current ratio

e = common emitter configuration

Δ = delta (indicates a change)

Common base gain:

$$\text{Alpha } (\alpha) = \frac{\Delta I_c}{\Delta I_E}$$

or

When β is known:

$$\alpha = \frac{\beta}{\beta + 1}$$

Alpha is always less than 1 for a common base configuration.

Common collector gain:

$$\text{Gamma or } \gamma = \frac{I_E}{I_B}$$

When beta is known then:

$$\gamma = \beta + 1$$

TRANSISTOR RUGGEDNESS.—Transistors are generally more rugged mechanically than electron tubes. They are susceptible to damage by electrical overloads, heat, humidity, and radiation. Unless you are careful, damage can occur during maintenance.

DAMAGE PREVENTION.—To prevent damage and avoid electrical shock, use the following precautions when working on transistorized equipment:

- Check your test equipment and soldering irons for leakage current from the power source. If leakage current exists, use an isolation transformer to eliminate the current.

- Connect a ground between the test equipment and circuit under test.
- Do not exceed the maximum allowable voltages for circuit components and transistors.
- Ohmmeter ranges that require more than one milliampere should not be used for testing transistors.
- Battery eliminators should not be used to furnish power for transistorized equipment. They have poor voltage regulation.
- The heat applied to a transistor, when soldered connections are required, should be kept to a minimum by the use of low-wattage soldering irons and heat shunts or heat sinks.
- When replacing transistors, never pry them from the printed circuit board.
- Check all circuits for defects before replacing transistors.
- Remove power from the equipment prior to replacing a transistor.
- Use extreme care when using test probes on a transistorized circuit. It is easy to short across adjacent terminals with conventional probes. Try insulating the probe tips and leaving a very short section of the point exposed.

You can find more about transistors in NEETS, Module 7, *Introduction to Solid-State Devices and Power Supplies*.

Vacuum Tubes

The characteristics of a vacuum tube are measured by two factors: **AMPLIFICATION FACTOR**, mu (μ), and **TRANSCONDUCTANCE** (gm).

Formula for amplification factor:

$$\mu = \frac{\Delta E_p}{\Delta E_g}$$

$$E_p = \text{change in plate voltage}$$

$$E_g = \text{change in grid voltage}$$

Formula for transconductance (gm) is:

$$gm = \frac{I_p}{E_g}$$

$$I_p = \text{change in plate current}$$

$$E_g = \text{change in grid voltage}$$

Information on vacuum tubes can be found in NEETS, Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies*.

CAUTION

Because vacuum tubes become hot and most are made of glass, use caution while removing or replacing them. Use vacuum tube pullers or at least wear some type of hand protection.

Wavelength

Wavelength is the distance in space occupied by one cycle of a radio wave at any given instant. If a radio wave could be frozen in time and measured, the distance from the leading edge of one cycle to the leading edge of the next cycle would be the wavelength. Wavelength varies from a few hundredths of an inch at the high frequencies to many miles at extremely low frequencies. Common practice is to express wavelength in meters. The Greek letter lambda (!) is used to signify wavelength. Formulas for wavelength, period, and velocity are shown below.

Wavelength formula:

$$\lambda = \frac{v}{f}$$

Lambda (λ) = wavelength in feet

v = velocity of propagation in feet per second

f = frequency in Hz

Frequency formula:

$$f = \frac{1}{T}$$

T = time of one wave period (cycle) in seconds

f = frequency in Hz

Period formula:

$$T = \frac{1}{f}$$

Velocity formula:

$$v = \lambda f$$

You can find more information on wavelength, frequency, period, and velocity in NEETS, Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas*.

Radar

Some helpful radar information/formulas are shown below.

PW — Pulse Width—The width of the transmitted RF pulse from the radar (the term can also be used regarding other non-RF information).

$$PW = DC \times PRT$$

PRT — Pulse Repetition Time—The duration of the time between radar transmitter pulses (leading edge of pulse to leading edge of the next pulse).

$$PRT = \frac{1}{PRF}$$

PRR or PRF — PRF Pulse Repetition Rate or Pulse Repetition Frequency—the number of pulses that occur during one second.

$$PRF = \frac{1}{PRT}$$

DC — Duty Cycle—The amount of actual transmitter pulse time (PW) divided by the amount of transmitter total time (PRT). For radar applications, the duty cycle will always be less than one.

$$DC = \frac{PW}{PRT} \text{ or } \frac{P_{avg}}{P_{pk}}$$

P_{pk} — Power Peak (normally referenced in kilowatts)—The actual power of the transmitted RF pulse (PW).

$$P_{pk} = \frac{P_{avg}}{DC}$$

P_{avg} — Average Power (normally referenced in watts)—The transmitted power relative to one PRT.

$$P_{avg} = DC \times P_{pk}$$

$$\text{Nautical radar mile} = \frac{\text{elapsed time}}{12.36 \text{ microseconds}}$$

Minimum radar range = (pulse width + *recovery time) × 164 yards

*In most modern radar systems, recovery time is negligible and does not need to be considered when figuring minimum radar range.

$$\text{Radar horizon distance (nautical miles)} =$$
$$1.25\sqrt{\text{antenna height (ft)}}$$

Radar range resolution (in yards) = pulse width × 164 yards per microsecond.

When you use the term decibel (dB), you are referring to a logarithmic comparison between two signals, usually the output and the input. In power measurement applications, however, a reference of 0 dBm equalling 1 milliwatt is usually used. The term dBm is used to represent power levels above, below, or at 1 milliwatt.

The following formulas are used for figuring dB:

As a power ratio:

$$dB = 10 \log_{10} \frac{P_2}{P_1}$$

As a voltage ratio:

$$dB = 20 \log_{10} \frac{E_2}{E_1}$$

As a current ratio:

$$dB = 20 \log_{10} \frac{I_2}{I_1}$$

In circuits where impedances may vary:

$$\text{Voltage dB} = 20 \log_{10} \frac{E_2 R_1}{E_1 R_2}$$

$$\text{Current dB} = 20 \log_{10} \frac{I_2 R_2}{I_1 R_1}$$

Some basic information to remember:

Power

A gain of 1 dB power is equal to 1. 25 × that power

A gain of 3 dB power is equal to 2. 00 × that power

A gain of 10 dB power is equal to 10. 0 × that power

A gain of 1 dB power is equal to 0. 80 × that power

A loss of 3 dB power is equal to 0. 50 × that power

A loss of 10 dB power is equal to 0. 10 × that power

Voltage

A gain of 1 dB is equal to 1. 118 × that voltage

A gain of 6 dB is equal to 2. 000 × that voltage

A gain of 20 dB is equal to 10. 00 × that voltage

A loss of 1 dB is equal to 0. 894 × that voltage

A loss of 6 dB is equal to 0. 500 × that voltage

A loss of 20 dB is equal to 0. 100 × that voltage

POWER CONVERSION

For ease of power conversion, this listing provides rough, basic data:

Log or dB	Gain or mw
11	12.5
10	10
9	8
8	6.25
7	5
6	4
5	3.125
4	2.5
3	2
2	1.6
1	1.25
0	1
-1	0.8
-2	0.625
-3	0.5
-4	0.4
-5	0.312
-6	0.25
-7	0.2
-8	0.16
-9	0.125
-10	0.1
-11	0.08

The figures in the above listing are not precise, but are accurate for most applications. For figures in between the above numbers, logarithm interpolation must be done. Table 1-34 provides a seven-place table of common logarithms.

The following are examples of power conversion:

Example 1:

Convert 56 dBm to watts

5 6 dBm (m = referenced to 1 mw)

6 dBm = 4mw

5 = mantissa or exponent = 10^5

$= 4\text{mW} \times 10^5$

$= 4\ \text{W} \times 10^2$

= 400 watts

Example 2:

Convert -52 dBm to μw (microwatts)

-5 2 dBm

$-2\ \text{dBm} = .625\ \text{mw}$

$-5 = \text{mantissa or exponent} = 10^{-5}$

$= .625\ \text{mw}\ 10^{-5}$

$= .625\ \mu\text{w} \times 10^{-2}$

$= .00625\ \mu\text{w}$

Example 3:

Convert 80 kw to dBm

$$= \frac{8 \times 10^{7}\ mw}{79\ dbm} \quad 8\ mw = 9\ dB$$

Convert 5 µw to dBm

$$= \frac{5 \times 10^{-3}\ mw}{-37\ dBm} \quad 5\ mw = 7\ dBm$$

DATA TABLES

Data tables are provided for reference. Information in the tables are the usually accepted standards. Various military standards have also been used to provide these tables.

Capacitor Identification

Two methods of capacitor identification are used. The first is the typographical method, and the second is the color code method. Typographically marked identification will be discussed first. It is the type marking where a number is printed on the capacitor. You should note that on different physical styles of capacitors, the printed number may be in either microfarads or picofarads. Two styles of capacitors have been selected from Military Standard 198E (MIL-STD-198E) to show how the part number stamped on the capacitor is broken down.

Table 1-1 shows the CB style of capacitor part number breakdown.

Table 1-1.—CB Style Capacitor Part Number Breakdown

CB50 R B 050 K

STYLE - The two-letter symbol "CB" identifies button-style, mica-dielectric, fixed capacitors; the two-digit number identifies the shape, dimensions, and operating temperature range.

TERMINAL ASSEMBLY - The single-letter symbol identifies the terminal assembly as follows:

Symbol	Terminal assembly
P - - - - - - - - - - - -	Single L
R - - - - - - - - - - - -	Double L

CHARACTERISTIC - The single-letter symbol identifies the relative stability of the capacitor with temperature change as follows:

Symbol	Temperature coefficient	Capacitance drift
	(ppm/°C)	
B - - -	Not specified	Not specified
D - - -	-100 to +100	0.5% or 0.5 pF, whichever is greater
E - - -	-20 to +100	±(0.1% +0.1 pF)
F - - -	-50 to +100	±(0.1% +0.1 pF)

CAPACITANCE - The three-digit number identifies the nominal capacitance value, expressed in picofarads (pF); the first two digits represent significant figures and the last digit specifies the number of zeros to follow.

CAPACITANCE TOLERANCE - The single-letter symbol identifies the capacitance tolerance as follows:

Symbol	Capacitance tolerance
	Percent (±)
F - - -	1
G - - -	2
J - - -	5
K - - -	10

Table 1-2 shows how the part number on the CMR style of capacitor is broken down

Table 1-2.—CMR Style Capacitor Part Number Breakdown

CMR05 C 1R0 D O C M

STYLE - The three-letter symbol "CMR" identifies established reliability, mica dielectric, fixed capacitors; the two-digit number identifies the shape and dimensions of the capacitor.

CHARACTERISTIC - The single-letter symbol indicates the relative stability of the capacitor with temperature change as follows:

Symbol	Temperature coefficient (ppm/°C)	Capacitance drift
C - - -	-200 to +200	±(0.5% + 0.1 pF)
E - - -	-20 to +100	±(0.1% + 0.1 pF)
F - - -	0 to +70	±(0.05% + 0.1 pF)

CAPACITANCE - The three-digit number identifies the nominal capacitance value, expressed in picofarads (pF). Where the nominal capacitance is 10 pF or greater, the first two digits represent significant figures and the last digit specifies the number of zeros to follow (for example: 10 pF = 100; 150 pF = 151; 1500 = 152). Where the nominal capacitance is less than 10 pF (a whole number), the letter "R" shall represent the decimal point, and the other digits are significant (for example: 1 pF = 1R0).

CAPACITANCE TOLERANCE - The single-letter symbol identifies the capacitance tolerance as follows:

Symbol	Capacitance tolerance (±)
D - - - - - - - - - - - -	0.5 pF
F - - - - - - - - - - - -	1 percent
G - - - - - - - - - - - -	2 percent
J - - - - - - - - - - - -	5 percent

OPERATING TEMPERATURE RANGE - A single-letter symbol identifies the operating temperature range as follows:

Symbol	Operating temperature range
O - - - - - - - - - - -	-55° to +125°C
P - - - - - - - - - - -	-55° to +150°C

RATED VOLTAGE - The single-letter symbol identifies the rated voltage as follows:

Symbol	Rated voltage (Volts, dc)
Y - - - - - - - - - - -	50
A - - - - - - - - - - -	100
C - - - - - - - - - - -	300
D - - - - - - - - - - -	500

FAILURE RATE LEVEL - The single-letter symbol identifies the failure rate level as follows:

Symbol	Failure rate level (% 1,000 h)
M - - - - - - - - - -	1.0
P - - - - - - - - - -	0.1
R - - - - - - - - - -	0.01
S - - - - - - - - - -	0.001

Table 1-3 is a partial cross reference list of the CYR10 (MIL-C-23269/1) style of capacitor. As an example, if you need a 3.3 pF, 500 VDC capacitor in the CYR10 style, with a failure rate (FR) of 1 percent per 1,000 hours, the part number would be M23269/01-3009.

Table 1-3.—CYR10 Style Capacitor Cross-Reference

STYLE CYR10 (MIL-C-23269/1)

OPERATING TEMPERATURE RANGE -55° TO +125°C -- TEMPERATURE COEFFICIENT 140 ± 25 PPM/°C -- CAPACITANCE DRIFT 0.1% OR 0.1 pF, WHICHEVER IS GREATER

Capacitance value	DC rated voltage	Capacitance tolerance	Dash number M23269/01- FR level in %/1,000 hours			
			M (1.0)	P (0.1)	R (0.01)	S (0.001)
pF	volts, dc					
0.5	500	±0.25 pF	3001	4001	5001	6001
1.0		±0.25 pF	3002	4002	5002	6002
1.5		±0.25 pF	3003	4003	5003	6003
2.2		±0.25 pF	3004	4004	5004	6004
2.7		±0.25 pF	3006	4006	5006	6006
3.3		±0.25 pF	3009	4009	5009	6009
3.6		±0.25 pF	3010	4010	5010	6010
3.9		±0.25 pF	3012	4012	5012	6012
4.7		±0.25 pF	3015	4015	5015	6015
5.6		±0.25 pF	3017	4017	5017	6017
5.6		±5%	3018	4018	5018	6018

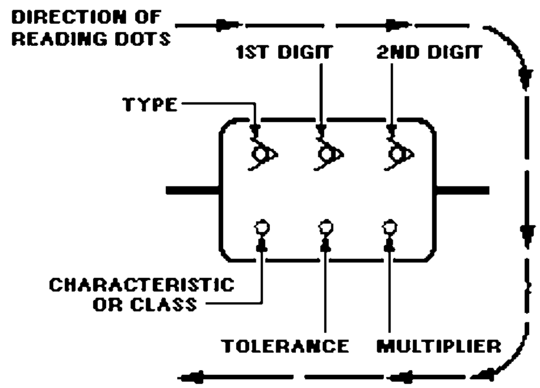
Table 1-3 is not a complete list of the CYR10 style capacitor. The CYR10 is not the only style capacitor listed this way. You should refer to Military Standard 198E (MIL-STD-198E), *Capacitors, Selection and Use of,* for more information.

The color coding identification method is becoming obsolete. This method is included for the technician who is required to work on some older model equipment.



TYPE	COLOR	1ST DIGIT	2ND DIGIT	MULTIPLIER	TOLERANCE (PERCENT)	CHARACTERISTIC OR CLASS

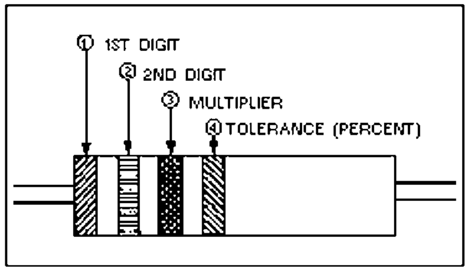
PI = Partially Inactive for design

ER = Extended reliability
NON-ER = Not extended reliability
HI-REL = High reliability

Military Standard 198E (MIL-STD-198E) contains information concerning capacitors and should be helpful in selecting any replacement.

Resistor Identification

This section contains information that will aid you in identifying the specifications indicated on resistors.



COLOR	1ST DIGIT	2ND DIGIT	MULTIPLIER	TOLERANCE (PERCENT)
BLACK	0	0	1	
BROWN	1	1	10	
RED	2	2	100	
ORANGE	3	3	1,000	
YELLOW	4	4	10,000	
GREEN	5	5	100,000	
BLUE	6	6	1,000,000	
VIOLET	7	7	10,000,000	
GRAY	8	8	100,000,000	
WHITE	9	9	1,000,000,000	
GOLD			.1	5
SILVER			.01	10
NO COLOR				20

RESISTORS FOR MILITARY USE MAY HAVE A FIFTH HAND TO INDICATE RELIABILITY IN TERMS OF FAILURE RATE, AS FOLLOWS:

NO COLOR: NO TEST MADE
BROWN : 1.0 PERCENT PER 1000 HOURS
RED : 0.1 PERCENT PER 1000 HOURS
ORANGE : 0.01 PERCENT PER 1000 HOURS
YELLOW : 0.001 PERCENT PER 1000 HOURS

Figure 1-18.—Resistor color code.

Table 1-6 is a resistor selection chart. As an example, let's suppose you need a 1-watt, composition resistor. Look under the "type" heading to find composition. Then look under the "power and max voltage ratings" headings to find 1W/500V. The style you select should be RCR32. This is the first part of the part number. To find the last part of the desired part number, the ohmic value, refer to table 1-7, the resistor type designation part number breakdown.

Tables 1-6 and 1-7 are excerpts from Military Standard 199C(MIL-STD-199C) and are included as examples of the information contained in MIL-STD-199C. If another type of resistor is needed, the complete part number breakdown can be located in MIL-STD-199C.

Table 1-6.—Resistor Selection Chart

Military specification	Type	Styles available in standard	Power and max voltage ratings	Resistance tolerance (+ percent)	Ohmic range
MIL-R-26	Wirewound (Power Type)	RW29	11W	5, 10	.1 to 5.6 K
		RW31	14W		.1 to 6.8 K
		RW33	26W		.1 to 18 K
		RW35	55W		.1 to 43 K
		RW37	113W		.1 to 91 K
		RW38	159V		.1 to.15 M
		RW47	210W		.1 to.18 M
		RW56	14W		.1 to 9.1 K
MIL-R-22684	Film (Insulated)	RL42. . .TX	2W/500V	2, 5	10 to 1.5 M
MIL-R-18546	Wirewound (Power Type, Chassis Mounted)	RE77	75W	1	.05 to 29.4 K
		RE80	120W	1	.1 to 35.7 K
MIL-R-39008	Composition (Insulated), Established Reliability	RCR05	.125W/150V	5, 10	2.7 to 22 M
		RCR07	.25W/250V		2.7 to 22 M
		RCR20	.5W/350V		1.0 to 22 M
		RCR32	1W/500V		1.0 to 22 M
		RCR42	2W/500V		10 to 22 M
MIL-R-55182	Film, Established Reliability	RNR50	.05W/200V .1W/200V	.1, .5, 1	10 to.796 M
		RNR55	.1W/200V .125/200V		10 to 2.0 M
		RNR60	.125W/250V .25W/300V		1.0 to 4.02 M
		RNR65	.25W/300V .5W/350V		1.0 to 8.06 M
		RNR70	.5W/350V .75W/500V		1.0 to 15 M
		RNR75	1W/750V 2W/750V		24.9 to 2 M
		RNC90 .	.3W/300V 6W/300V	.05, .01, .005	4.99 to 100K

1/ M = megohms; K = kilohms.

Table 1-7.—Resistor Type Designation Part Number Breakdown

RCR07 G 470 J M

STYLE: The three-letter symbol "RCR" identifies established reliability, insulated, composition, fixed resistors; the two-digit number identifies the size and power rating.

CHARACTERISTIC: The single-letter symbol "G" identifies the resistance-temperature characteristic as shown in table 301-I.

RESISTANCE: The three-digit number identifies the nominal resistance value, expressed in ohms; the first two digits represent significant figures and the last digit specifies the number of zeros to follow. Where fractional values of an ohm are required, the letter "R" represents the decimal point. (See 3.3 and the following example.)

EXAMPLE:

2R7	2.7 ohms
100	10 ohms
105	1 megohm
226	22 megohm

RESISTANCE TOLERANCE: The single-letter symbol identifies the resistance tolerance as follows:

J	± 5 percent
K	± 10 percent

FAILURE RATE LEVEL: The single-letter symbol identifies the failure rate level as follows:

M	1.0 percent/1,000 hr
P	0.1 percent/1,000 hr
R	0.01 percent/1,000 hr
S	0.001 percent/1,000 hr

Transformer Lead Identification

This area contains color coding identification as it relates to transformers.

Figure 1-19 shows the color codes for power transformers, IF transformers, and interstage-audio transformers.

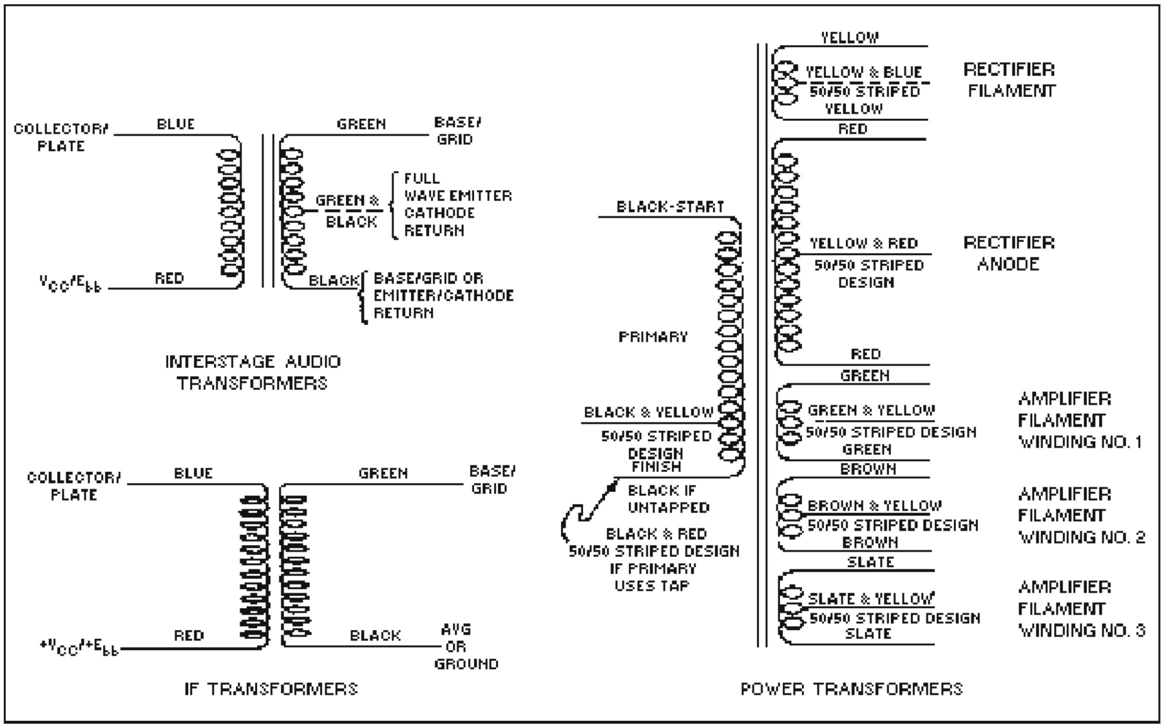

Figure 1-19.—Color code for transformers.

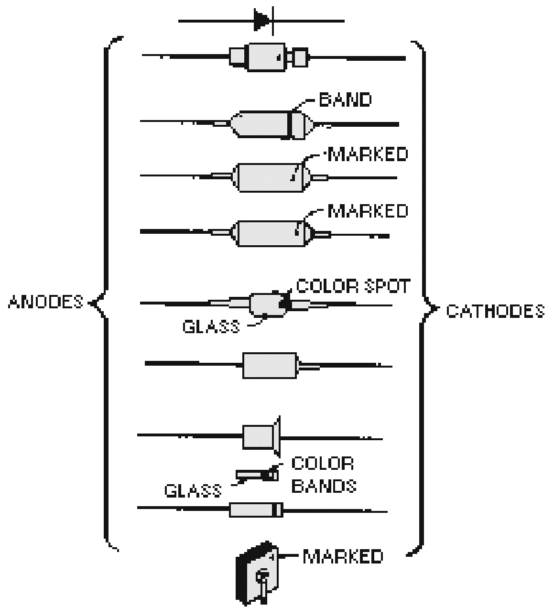
Chassis Wiring Identification

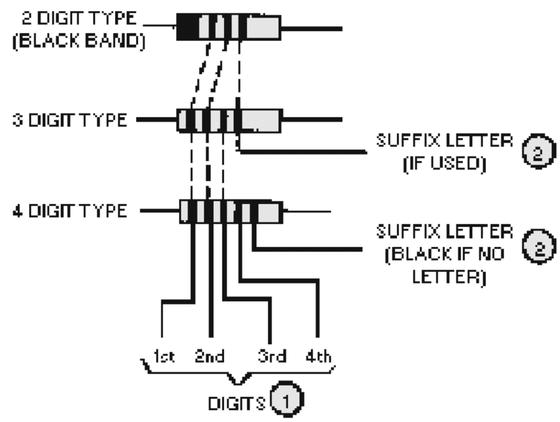
The standard colors used in chassis wiring for the purpose of equipment circuit identification follow:

CIRCUIT	COLOR
GROUNDS, GROUNDED ELEMENTS, AND RETURNS	BLACK
BEATERS OR FILAMENTS, OFF GROUND	BROWN
POWER SUPPLY $+V_{cc}/+E_{bb}$	RED
SCREEN GRIDS	ORANGE
EMITTERS/CATHODES	YELLOW
BASES/CONTROL GRIDS	GREEN
COLLECTORS/PLATES	BLUE
POWER SUPPLY, $-V_{cc}$ /$-E_{bb}$	VIOLET (PURPLE)
AC POWER LINES	GRAY
MISCELLANEOUS, ABOVE OR BELOW GROUND RETURNS, AUTOMATIC VOLUME CONTROL (AVC)	WHITE

Semiconductor Case Outlines, Color Coding, Lead Identification, and Pin Placement

Case outlines, color coding, lead identification, and pin placements of common semiconductor devices are used frequently by the technician and are included in figures 1-20, 1-21, and 1-22.





COLOR	1 DIGIT	2 DIODE SUFFIX LETTER
BLACK	0	-
BROWN	1	A
RED	2	B
ORANGE	3	C
YELLOW	4	D
GREEN	5	E
BLUE	6	F
VIOLET	7	G
GRAY	8	H
WHITE	9	J
SILVER	-	-
GOLD	-	-
NONE	-	-

Figure 1-20.—Semiconductor diode markings and color code system.

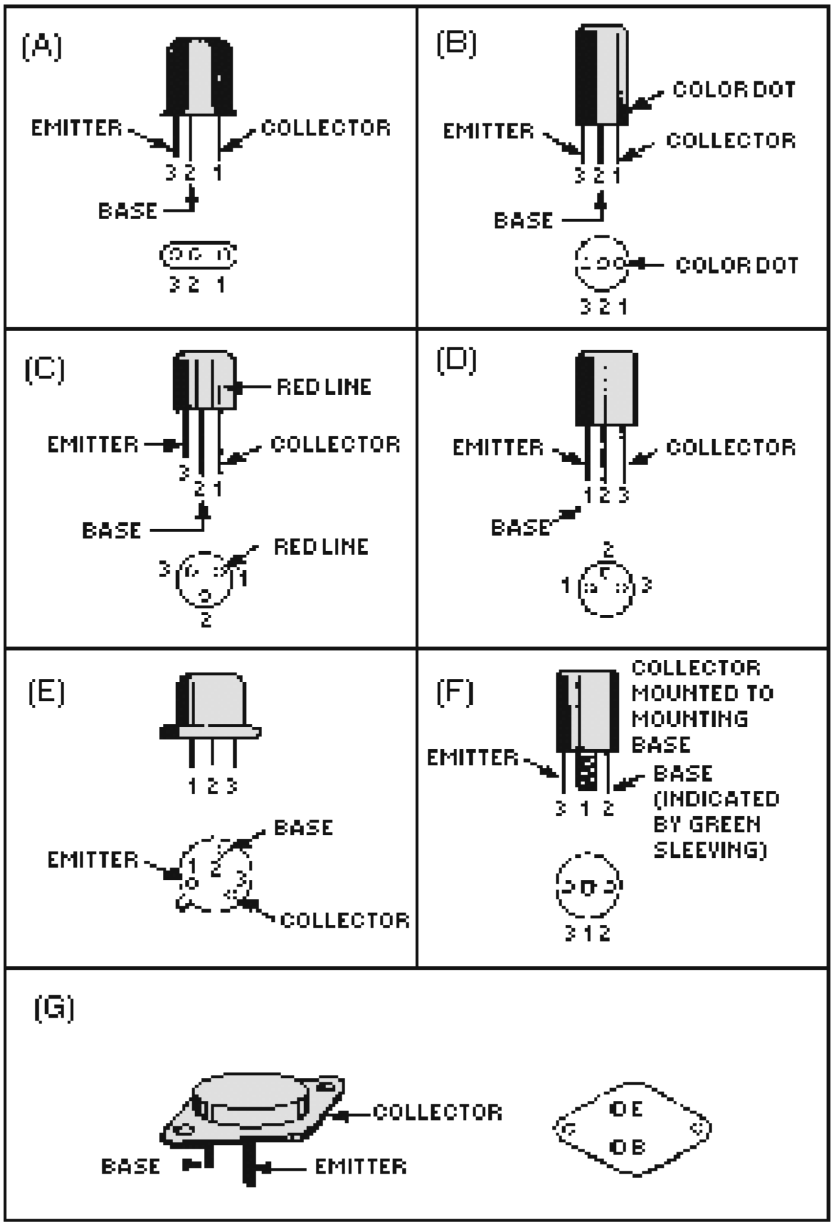


Figure 1-21.—Transistor lead identification and case outline.

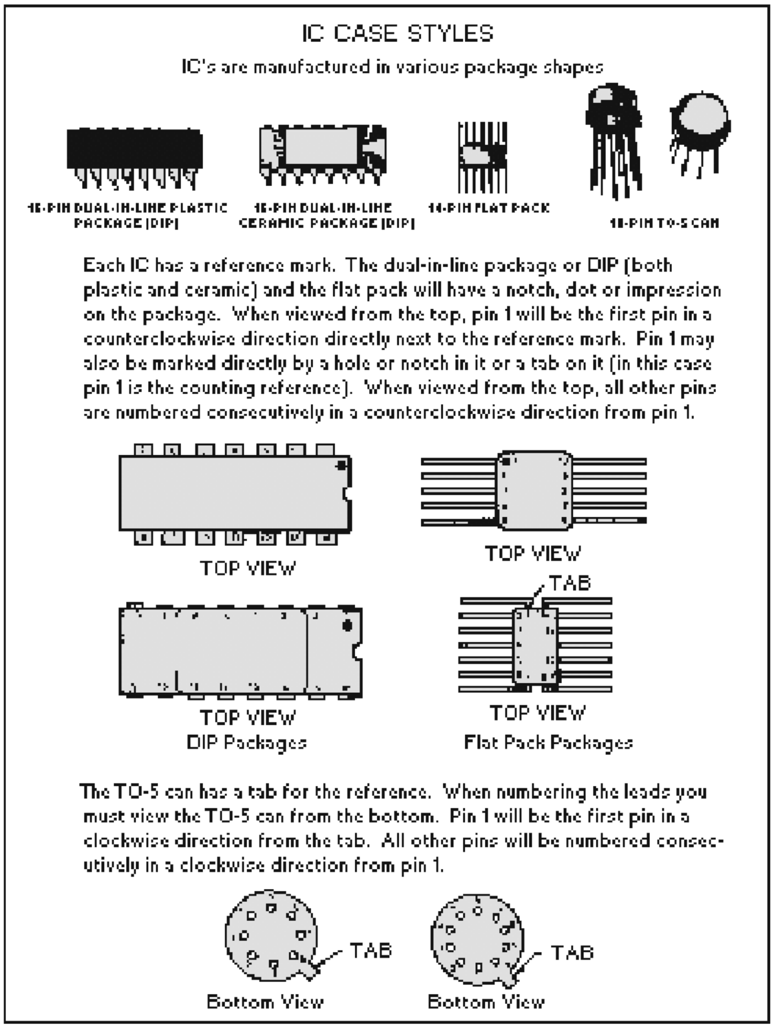

Figure 1-22.—IC identification and pin placement.

Batteries

The two fundamental types of batteries are the **PRIMARY CELL** and **SECONDARY CELL**. Primary cells are those commonly used in flashlights and some portable, hand-held test equipment. Common sizes and part numbers are:

SIZE	PART NUMBER
AA	BA58
C	BA42
D	BA30

Secondary cell batteries are the type used in automobiles. They are rechargeable.

Safety precautions concerning charging, handling, and storage of batteries can be found in the Electronics Installation and Maintenance Book (EIMB), *General*, NAVSEA SE000-00-EIM-100. Stock numbers and part numbers can be found in NAVSUP Publication 4400, the *Afloat Shopping Guide*. The federal supply classification (FSC) number for batteries is 6135. You can also find more information on batteries in NEETS, Module 1, *Introduction to Matter, Energy, and Direct Current*.

Cables

Tables 1-8 and 1-9 contain type, construction, and application data on shipboard cable. These tables contain current, discontinued, and some recently obsolete types of cables and cords.

Table 1-8.—Types and Construction/Description of Shipboard Cable

CVSF	400-Hz aircraft servicing: three synthetic rubber insulated conductors and one uninsulated conductor, overall polychloroprene jacket.
DLT	Divers lifeline and telephone: four rubber insulated conductors cabled around an insulated steel core, reinforced polychloroprene jacket overall.
DSS	Double conductor, shielded: rubber insulation, overall braided shield, polychloroprene or chlorosulfonated polyethylene jacket.
DSWS	Double conductor, shielded: rubber insulation, overall braided shield, polychloroprene jacket.
FSS	Four conductors, shielded: rubber insulated, overall braided shield, polychloroprene or chlorosulfonated polyethylene jacket.
JAS	Jet aircraft servicing: four rubber insulated conductors, two conductors Navy size 250, two conductors Navy size 6, reinforced polychloroprene jacket.
MCSF-4	Multiple conductor, acoustic minesweeping, power: two American Wire Gauge (AWG) 6 and two AWG 1 conductors, rubber insulation, reinforced polychloroprene jacket.
MSP	Multiple conductor: fifty-nine conductors, sixteen AWG 22 having fluorocarbon insulation and a braided copper shield, eighteen AWG 20 having polyvinyl chloride insulation and a braided copper shield (nine singles, one triad and three pairs, each shielded), twenty-five Navy size 3 having polyvinyl insulation (eight pairs and three triads, each shielded), polychloroprene jacket.
MSPW	Multiple conductor: fifty-nine conductors; sixteen AWG 22 having fluorocarbon insulation and a braided copper shield, eighteen AWG 20 having polyvinyl chloride insulation and a braided copper shield (nine singles, one triad and three pairs, each shielded), twenty-five Navy size 3 having polyvinyl insulation (eight pairs and three triads, each shielded), polychloroprene jacket, watertight.
MWF	Multiple conductor: rubber or cross-linked polyethylene insulation, arctic type neoprene jacket.
S2S	Two conductors, shielded: cross-linked polyethylene insulations, braided shield, rubber insulation over shield, outer-braided shield; reinforced rubber, insulated, arctic type polychloroprene jacket.
THOF	Three conductors, heat and oil resistant, flexible: synthetic rubber insulation standard thermoplastic jacket on THOF-42, and polychloroprene jacket on THOF-400 and THOF-500.
TRF	Single conductor, flexible: rubber insulation, polychloroprene jacket.
TPUM-6	Telephone, portable, multiple conductor: copper-clad steel conductors, polypropylene insulation, six pairs cabled, polyurethane jacket applied in two layers.
TRXF	Single conductor: polychloroprene jacket.
TSP	Twisted pairs: polyvinyl chloride insulated, special thermoplastic jacket, watertight, unarmored.
TSPA	Twisted pairs: polyvinyl chloride insulated, special thermoplastic jacket, watertight, armored.

Table 1-8.—Types and Construction/Description of Shipboard Cable—Continued

TSS	Three conductors, special purpose, shielded: rubber insulation, overall braided shield, polychloroprene or chlorosulfonated polyethylene jacket.
1SWF	Singles, shielded: polyethylene insulation, braided shield on each conductor, arctic type polychloroprene jacket.
2SWF	Pairs, shielded, watertight, flexible: polyethylene insulation, braided shield over each pair, arctic type polychloroprene jacket.
5SS	Five conductors, shielded, sonar: rubber insulation, braided shield on one conductor only, and a braided shield over the assembled five conductors, polychloroprene jacket overall.
7SS	Seven conductors, shieled: rubber insulation, overall braided shield, polychloroprene or chlorosulfonated polyethylene jacket.

Table 1-9.—Shipboard Cable Application Data

Application	Cable type 2 Non-flexing service	 Repeated flexing service
Outboard submersible: For hydrophones, transducers, outboard dial telephones, retractable antennae and similar equipment. Types MWF, 1SWF, and 2SWF are for hydrophones, transducers, and telephone lines in the weather. Types 1PR-A20E, 1PR-16, 7PR-16, 3PR-16, 1Q-16, ITR-16, and 7SPR-16S are only for submarine outboard use.	MSPW TSPA 1PR-A20E 1PR-16 7PR-16 2SPR-16 3PR-16 1Q-16 ITR-16 7SPR-16S	MSP, TSP, 5S5, S2S, DSS, FSS, TSS, MWF, DSWS, MCSF, 1SWF, 2SWF, TPUM
Welding electrode circuit		TRF TRXF
Shore-to-ship power		THOF-400 THOF-500
Diver's line and telephone		DLT
400-Hz aircraft servicing		CVSF-4
DC aircraft servicing		JAS-250
1/ The order of listing of cables for general application data has no significant meaning for their usage.		
2/ Many cables are manufactured in variations of armored, unarmored, and unarmored with overall shielding.		

Table 1-10 provides data on the allowable temperature ratings and current-carrying capacities (in amperes) of some single copper conductors in free air at a maximum ambient temperature of 86º F (30º C). With temperatures greater than 86º F, the current-carrying capacity would be less.

Table 1-10.—Current-Carrying Capacities (in Amperes) of Some Single Copper Conductors at 30º C

Size	Moisture Resistant Rubber or Thermoplastic	Varnished Cambric or Heat Resistant Thermoplastic	Silicone Rubber or Fluorinated Ethylene Propylene (FEP)	Polytetra-Fluoroethylene (Teflon)
0000	300	385	510	850
000	260	330	430	725
00	225	285	370	605

10	40	55	75	110
12	25	40	55	80
14	20	30	45	60

More information about electrical cable used aboard ship can be found in NEETS, Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading; Cable Comparison Guide*, NAVSEA 0981-052-8090; and *Design Data Book*, NAVSEA 0902-LP-006-0000, Section DDS-304-1. Cable supply information can be found in NAVSUP Publication 4400, *Afloat Shopping Guide*, under federal supply classification (FSC) 6145. Hook-up or chassis wire is covered in Military Specification 76B (MIL-W-76B). Table 1-11 shows the current-carrying capacity or AMPACITY of equipment hook-up wire.

Table 1-11.—Current-Carrying Capacity of Equipment Hook-up Wire—Continued

Wire Size		Copper Conductor (100°C) Nominal Resistance	Maximum Current in Amperes			
			Copper Wire		Aluminum Wire

Table 1-12 lists the preferred general purpose rf cable selected by the armed services as the most satisfactory types to be used in electronics equipment.

Table 1-12.—Preferred General Purpose RF Cable

Jan Type	Overall Diameter (ins)	Impedance (OHMS)	Operating Voltage (Volts RMS)	Remarks
RG-11A/U	0.412	75.0	5,000	Medium size, flexible video cable
RG-12A/U	0.475	75.0	5,000	Same as RE-11A/U, armored
RG-34B/U	0.630	75.0	6,500	Large size, high power, low attenuation, flexible
RG-35B/U	0.945	75.0	10,000	Large size, high power, low attenuation, video and communications, armored
RG-55B/U	0.206	53.0	1,900	Small size, double braid
RG-58C/U	0.195	50.0	1,900	Small size, flexible
RG-59B/U	0.242	75.0	2,300	Small size, video
RG-84A/U	1.000	75.0	10,000	Same as RG-35B/U, except with lead sheath vice armor for underground installation
RG-85A/U	1.565	75.0	10,000	Same as RG-84A/U except with special armor
RG-164/U	0.870	75.0	10,000	Same as RG-35B/U except no armor
RG-212/U	0.332	50.0	3,000	Wave, formerly RG-5B/U
RG-213/U	0.405	50.0	5,000	Medium size, flexible, formerly RG-8A/U
RG-214/U	0.425	50.0	5,000	Medium size, double braid, flexible, formerly RG-9B/U
RG-215/U	0.475	50.0	15,000	Same as RG-214/U but armored. Formerly RG-10A/U
RG-216/U	0.425	75.0	5,000	Medium size, flexible video and communication, formerly RG-13A/U
RG-217/U	0.545	50.0	7,000	Medium size, power transmission line, formerly RG-14A/U
RG-218/U	0.870	50.0	11,000	Large size, low attenuation, high power transmission line, formerly RG-17A/U
RG-219/U	0.945	50.0	11,000	Same as RG-218/U, but armored, formerly RG-18A/U
RG-220/U	1.120	50.0	14,000	Very large, low attenuation, high power transmission line, formerly RG-19A/U
RG-221/U	1.195	50.0	14,000	Same as RG-220/U but armored, formerly RG-20A/U
RG-223/U	0.216	50.0	1,900	Small size, double braid, formerly RG-55A/U
RG-224/U	0.615	50.0	7,000	Same as RG-217/U but armored.

Specifications on special types of rf cable can be found in the *Military Standardization Handbook* 216 (MIL-HDBK-216).

Connectors

General purpose connectors and rf connectors are covered in this section. We'll cover the general purpose connectors first.

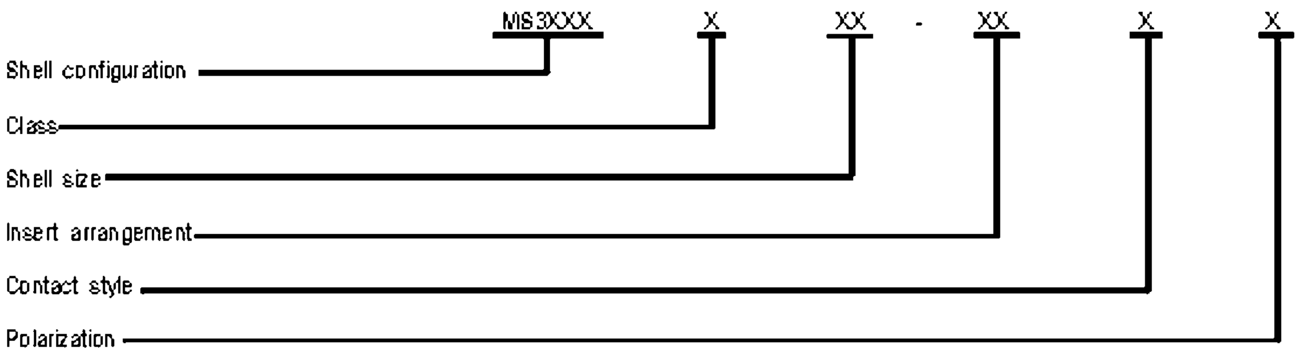
General purpose connectors were formerly designated with the prefix "**AN**." You may find older connectors with this prefix. The superseding connector has the same part number except the "AN" has been replaced by "**MS**." Table 1-13 shows the method used to break down a connector for identification. This breakdown is for MIL-C-5015 connectors. Identification breakdown for other MIL-C connectors can be found in *Naval Shore Electronics Criteria, Installation Standards and Practices*, NAVELEX 0280-LP-900-8000.

Table 1-13.—MS Connector Identification

MIL-STD-1353B
30 August 1983

MIL-C-5015 PART NUMBER SYSTEM

Part No. example: MS3400D22-22S



Shell configuration:	Front release crimp	Rear release crimp
Wall mounting receptacle	MS3400	MS3450
Box mounting receptacle	MS3402	MS3452
Jam nut mounting receptacle	MS3404	MS3454
Straight plug	MS3406	MS3456
Self-locking plug	-	MS3459
Cable connecting receptacle	MS3401	MS3451

Class:

D - Environment resisting - High impact shock MS3400
L - Environment resisting - Fluid resisitant (electroless N) For "space" applications only.
W - Environment resisting - Fluid resistant (Cad OD over suitable underplate)
KS - Firewall, self-locking, stainless steel
KT - Firewall, self-locking, cadmium plated ferrous alloy

(L, W, KS: MS3450)

Shell size: Shell size in 16th of an inch.

Insert arrangements: See MIL-C-STD-1651.

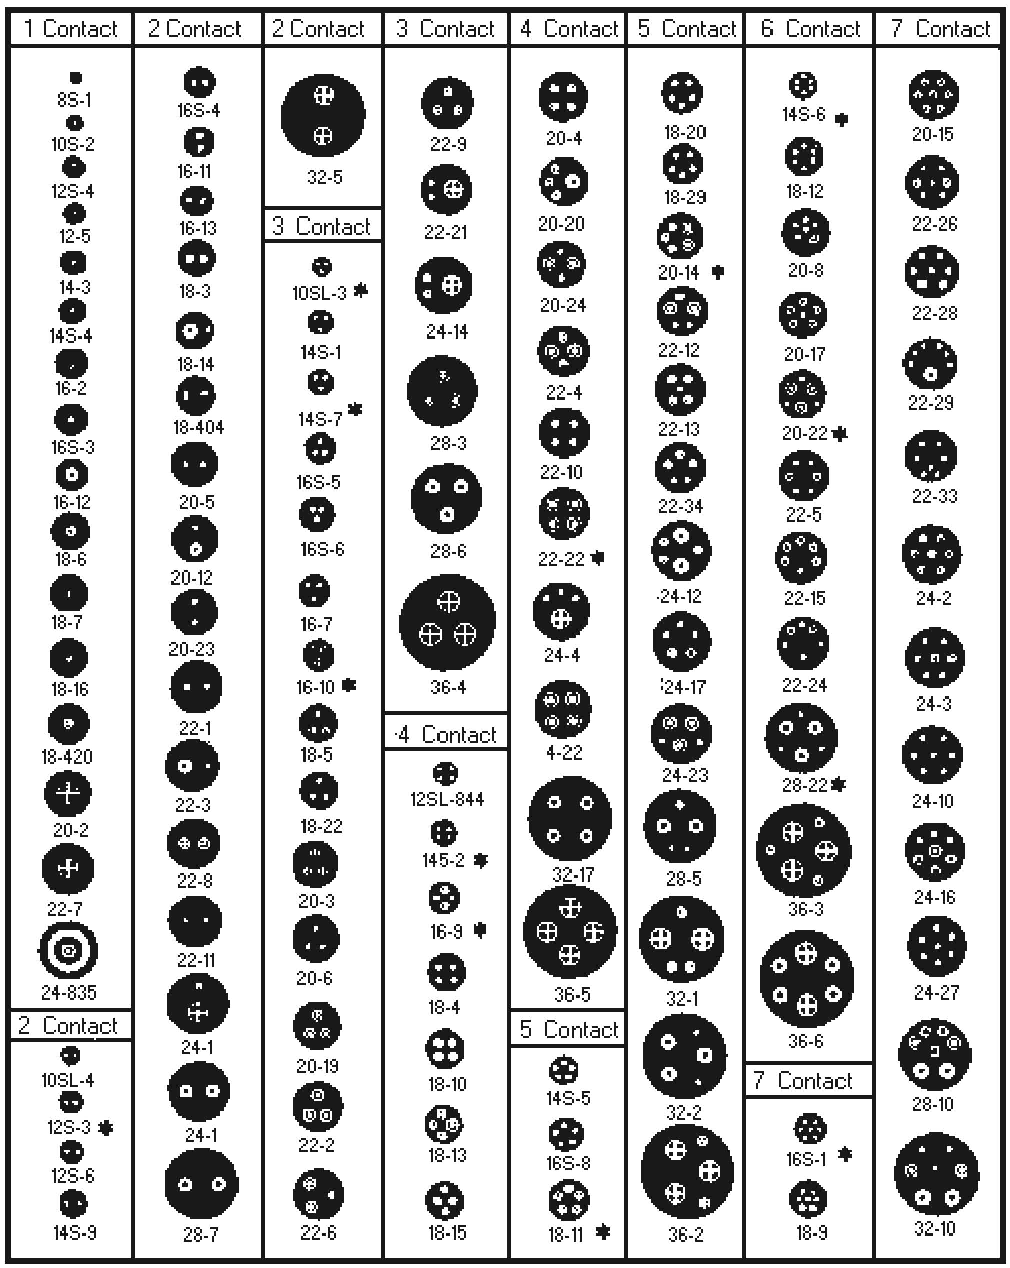
Contact style:

P - Pin contact - MIL-C-39029/29 and /44.
S - Socket contact - MIL-C-39029/30 and /45.

Polarization: Normal polarization is considered preferred; however, alternate polarizations, when required by a system, do not require nonstandard part approval.

Supply information on connectors can be found in NAVSUP Publication 4400, *Afloat Shopping Guide*, under federal supply classification (FSC) 5935.

Insert arrangements for MS type connectors, MIL-C-5015, are shown in figure 1-23. Alternate positions of connector inserts are shown in figure 1-24.



✱ INDICATES AIR STANDARDS COORDINATING COMMITTEE PREFERRED.
NOTE: FACE VIEW OF PIN INSERTS. ALL INSERTS SHOWN IN NORMAL POSITION.

Figure 1-23.—Insert arrangements type connectors, MIL-C-5015.

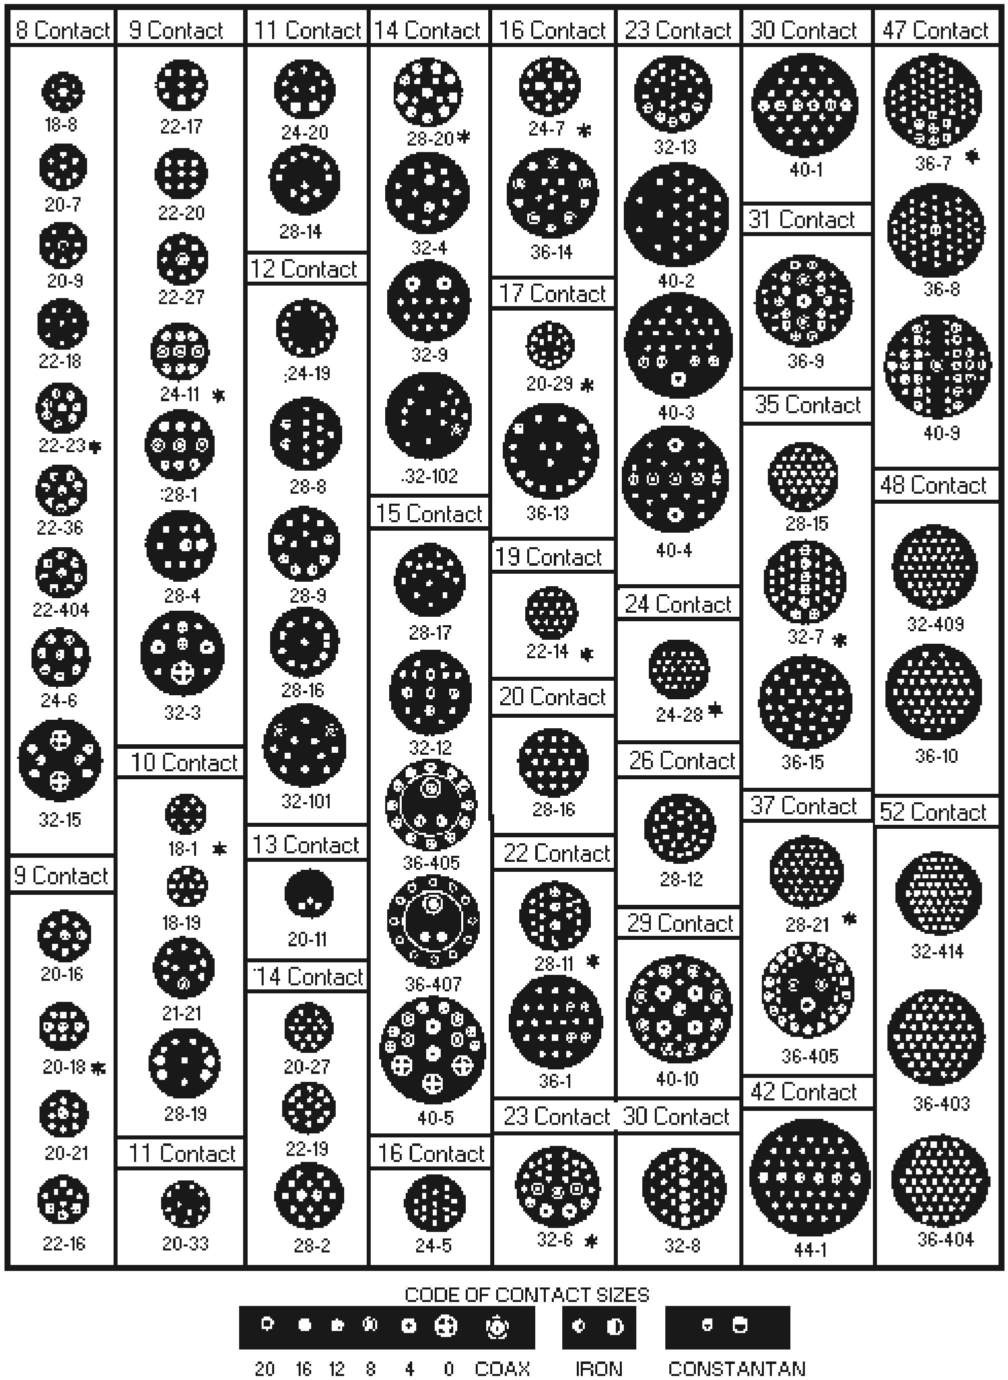


Figure 1-23.—Insert arrangements type connectors, MIL-C-5015. —Continued.

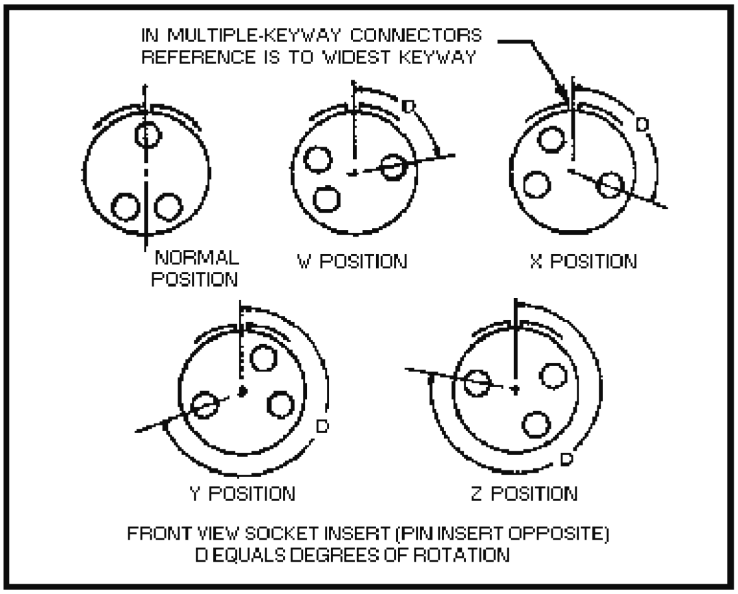

Figure 1-24.—Alternate positions of connector inserts.

MIL-C-5015, MIL-C-26482, and MIL-C-26500 connectors are designated with an MS number such as MS3101. MIL-C-81511, MIL-C-83723, and other later specifications identify the connector by the specification number, a slash, and the connector number. For example: MIL-C-81511/3.

Rf connectors and coaxial cable assemblies are used to carry radio frequency (rf) power from one point to another with a known rate of loss. Rf connectors are available as plugs, jacks, panel jacks, and receptacles. Plugs and jacks are attached to the ends of coaxial cables; panel jacks and receptacles are mounted to panels and chassis.

Baby **N** connector (**BNC**) series connectors are small, lightweight, and feature a quick connect/disconnect, bayonet-lock coupling. The connectors use small rf cables such as **RG-58/U** or **RG-59/U** and operate up to peak voltages of 500 volts. Manufacture is under Military Specification C-3608A (MIL-C-3608A). Figure 1-25 shows three typical **BNC** connectors. Figure 1-26 shows you how to attach **BNC** connectors to coaxial cable. Table 1-14 indicates which **BNC** connector to use with what coaxial cable type.

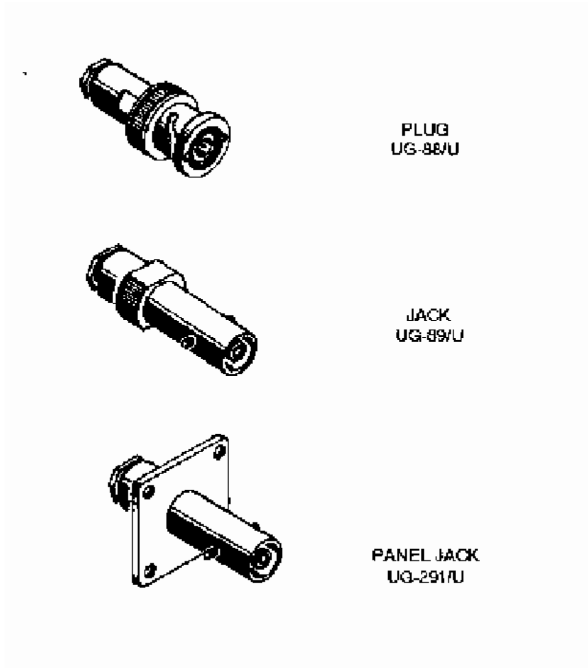

Figure 1-25.—Typical BNC connectors.

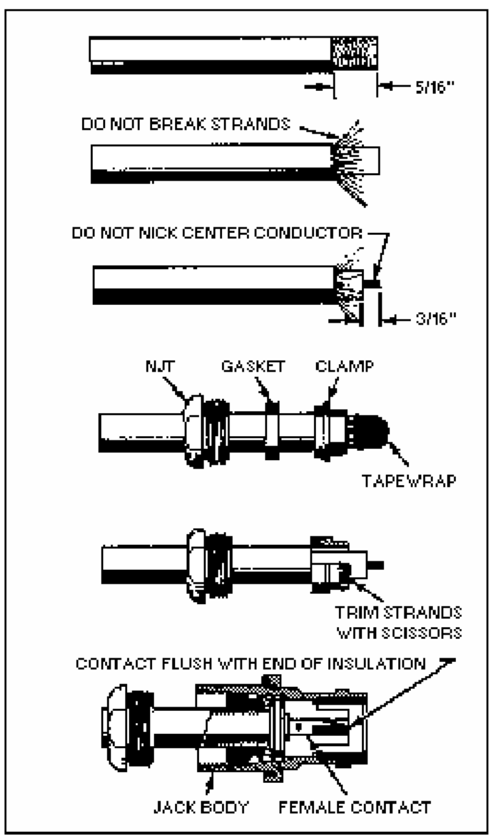

Figure 1-26.—Attaching BNC connectors to coaxial cable.

Table 1-14.—BNC Series Connectors with Associated Cables

Plug	Jack	Panel Jack	For Use With Cable Types
Improved Version:			
UG-88E/U	UG-89C/U	UG-291C/U	RG-55/U, 58/U and 223/U
UG-260D/U	UG-261C/U	UG-262C/U	RG-59/U, 62/U and 71/U
Captivated Contact Version (Amphenol):			
31-301	31-302	31-300	RG-55/U, 58/U, 141/U and 142/U
31-304	31-305	31-303	Rg-59/U, 62/U, 71/U and 140/U

HN series connectors have a 50-ohm impedance and threaded coupling connectors designed for high-voltage applications. These connectors are weatherproof. The frequency range is 0-4 gigahertz. The **HN** series is used with medium size coaxial cable such as **RG-8/U, RG-9/U, RG-87/U, RG-213/U, RG-214/U,** and **RG-225/U**. Figure 1-27 shows three typical **HN** connectors. Figure 1-28 shows how **HN** connectors are attached to coaxial cable. Table 1-15 indicates which HN connector to use with what coaxial cable type.

N series connectors are low-voltage, 50-ohm, threaded coupling connectors designed for use with small and medium size rf cable. They have a 1,000 volts peak rating and are weatherproof. There is a group of **N** series connectors that are 70 ohms and are numbered **UG-98A/U** and **UG-96A/U**. These 70-ohm **N** connectors are designed for cables such as **RG-61C**, **RG-11/U**, and **RG-13/U**. The 70-ohm connectors will not mate with 50-ohm connectors of this series. Figure 1-29 shows three typical **N** series connectors. Figure 1-30 illustrates the method used to attach **N** connectors to coaxial cable. Table 1-16 shows which **N** connector to use with what rf cable type.

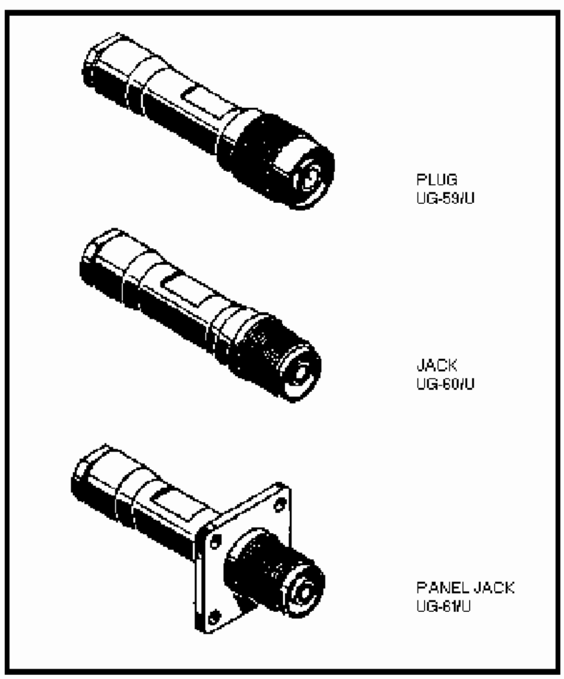

Figure 1-27.—Typical HN connectors.

Improved Version; **Captivated Contact Version			

C series connectors are weatherproof, quick-connect/disconnect, bayonet-locking type connectors. They are used with medium size cables, such as **RG-5/U, RG-8/U**, and **RG-9/U**. They operate up to a peak of 1,000 volts and at frequencies up to 10 gigahertz. Their impedance is 50 ohms. Figure 1-31 shows three typical C series connectors. Figure 1-32 shows you how to attach the C series connectors to a coaxial cable.

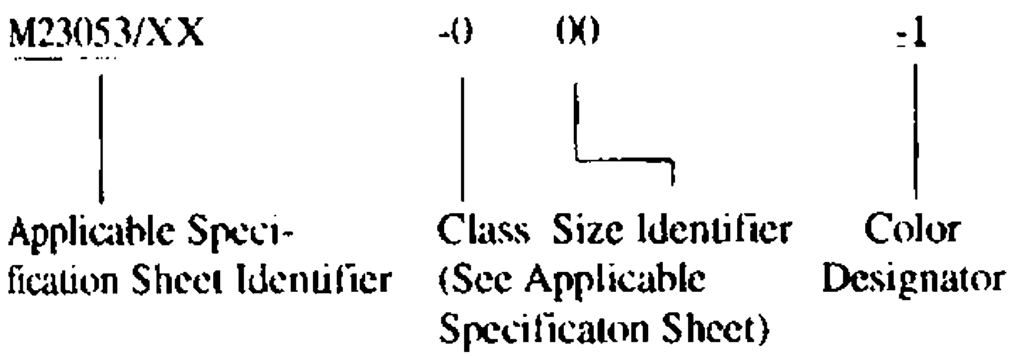
You can find more information on rf connectors in *Military Handbook* 216 (MIL-HDBK-216).

Insulation, Heat Shrinkable Sleeving (Shrink, Tubing), and Cable Straps

Heat shrinkable sleeving is intended for use as a snug-fitting electrical insulator. It is used to insulate wire bundles, splices, bus bars, connectors, terminals, metal, or fibrous tubing. It is also used as extra insulation over hotspot areas and as a cable blast shield in rocket launchings. Heat shrinkable sleeving is found under Military Specification I-23053C (MIL-1-23053C). Part numbers under this military specification are coded as follows:



Color code designations are:

DESIGNATOR	COLOR	DESIGNATOR	COLOR
0	Black	7	Violet (Purple)
1	Brown	8	Gray (Slate)
2	Red	9	White
3	Orange	C	Clear
4	Yellow	P	Pink
5	Green	T	Tan
6	Blue		

The particular uses for heat shrinkable sleeving depend on the specific properties described by the individual specification sheet. Intended uses are indicated below:

Military
Part Number

M23053/1:	Intended for use on heavy duty cables or harness systems such as ground support.
/2 and /3:	Used for light-duty harnessing or wire bundling.
/4:	Used for one-step potting, encapsulation, or moisture sealing and corrosion protection of electrical components or terminations.
/5:	Used for light-duty harness jackets, wire color coding, marking, or identification.
/6:	Used for wire identification, marking, or strain relief.
/7:	Used for light-duty wire identification and component covering.
/8:	Used for wire or termination strain relief at elevated temperatures.
/9:	Canceled.
/10:	Used for high-or low-temperature applications or where resistance to melting in high-blast flame is required.
/11:	Used where strain relief is necessary at high temperatures.
/12:	Used at high temperatures where resistance to flame is important to protect high-temperature cable, components, and terminations.
/13:	Used in elevated-temperature applications or where exposure to elevated-temperature solvents is expected.
/14:	Used as component and electronic lead strain relief where low expansion ratios are satisfactory. Operates over a fairly wide temperature range.
/15:	Used for repair of heavy duty cables and splice covers.
/16	Used on heavy duty cables or harness systems that are subjected to high levels of physical abuse and exposure to fuels and oils coupled with high-and low- temperature extremes.

Tables 1-18 and 1-19 provide part numbers for two types of shrinkable tubing, **M23053/5** and **M23053/4**. These were chosen because of their wide range of sizes **(M23053/5)** and their abilities to provide potting, encapsulating, or moisture sealing of electrical components **(M23053/4)**.

Table 1-18.—Shrinkable Tubing Part Numbers

Military Part Number	As supplied	After unrestricted shrinkage
	I.D. min.	I. D. max.
Class 1	Inches	Inches
M23053/5-101-*	.046	.023
M23053/5-102-*	.063	.031
M23053/5-103-*	.093	.046
M23053/5-104-*	.125	.062
M23053/5-105-*	.187	.093
M23053/5-106-*	.250	.125
M23053/5-107-*	.375	.187
M23053/5-108-*	.500	.250
M23053/5-109-*	.750	.375
M23053/5-110-*	1.000	.500
M23053/5-111-*	1.500	.750
M23053/5-112-*	2.000	1.000
M23053/5-113-*	3.000	1.500
M23053/5-114-*	4.000	2.000

* Asterisk in the part number shall be replaced by color code designations.

Table 1-19.—Shrinkable Tubing Part Numbers

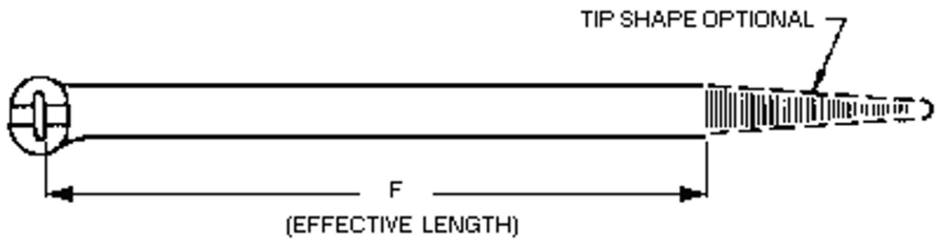
Military Part Number	As supplied		After unrestricted shrinkage	
	I.D. min.		I.D. max.	
Class 1		Inches		Inches
M23053/4-101-*	.125		.023	
M23053/4-102-*	.187		.060	
M23053/4-103-*	.250		.080	
M23053/4-104-*	.375		.135	
M23053/4-105-*	.500		.195	
M23053/4-106-*	.750		.313	
M23053/4-107-*	1.000		.400	
M23053/4-108-*	.300		.050	
Class 2				
M23053/4-201-*	.238		.125	
M23053/4-202-*	.355		.187	
M23053/4-203-*	.475		.250	
M23053/4-204-*	.712		.375	
M23053/4-205-*	.950		.500	
M23053/4-206-*	1.425		.750	
Class 1 = Semi-rigid, flame retardant Class 2 = Flexible, flame retardant * Asterisk in the part number shall be replaced by color code designations.				

When ordering, you should replace the asterisk (*) in the part number with the color code designation.

For example: The part number for **M23053/4**, one-half inch, class 1, black shrinkable tubing would be **M23053/4-105-0**.

Table 1-20 provides data on adjustable nylon cable straps. These straps are adjustable only in one direction. They are not designed to be loosened.

Table 1-20.—Adjustable Nylon Cable Strap Data



Part Number	Bundle diameter Min	Bundle diameter Max	Tensile strength (pounds) (ref)	MS installation tool	MIN F LENGTH
MS3367-1	1/16	1-3/4	50	MS90387-1	6.000 (152.4)
MS3367-2	1/16	4	50	MS90387-1	13.00 (330.20)
MS3367-3	3/16	3-1/2	120	MS90387-2	11.88 (301.75)
MS3367-4	1/16	5/8	18	MS90387-1	2.50 (63.50)
MS3367-5	1/16	1-1/4	30	MS90387-1	4.45 (113.03)
MS3367-6	3/16	8	120	MS90387-2	26.00 (660.40)
MS3367-7	1/16	3	50	MS90387-1	9.950 (252.73)

Color dash no.	Color	Color dash no.	Color
-0(a)	Black	-5	Green
-1	Brown	-6	Blue
-2	Red	-7	Purple
-3	Orange	-8	Gray
-4	Yellow	-9(a)	Natural

(a) ONLY STRAPS IN NATURAL AND BLACK ARE STOCKED BY THE GOVERNMENT.

Fuses and Circuit Breakers

New type military fuse designations can be identified by using table 1-21. Old style military fuse designations can be identified by using table 1-22.

Table 1-21.—New Style Military Fuse Identification

Example: Fuse Part Number = F 02 A 250V 1A S

F -Military designation which stands for fuse

02 -Style - indicates dimensions and construction

A - Characteristic (Time Delay)

A = Standard
B = Delay
C = Fast

250V - Voltage rating. Numerical value of maximum voltage followed by the letter "V".

1A - Current rating - Nominal current in amperes followed by the letter "A".

S - Platings

s = silver
No identification for other platings

Table 1-22.—Old Style Military Fuse Identification

Example: Fuse Part Number F 02 G 1R00 A

F Stands for fuse

02 Style, construction, and dimensions.

G Voltage Rating - Letter value of maximum voltage taken from table.

Voltage Code Letter	Voltage Volts or less
A	32
B	52
C	90
D	125
G	250
H	500
J	1,000
K	2,500
N	5,000
P	10,000

1R00 Current Rating - Nominal current in current in amperes. R = decimal point. Example given is 1 amp

A Characteristic - Time Delay rating

A = Standard
B = Delay
C = Fast

Commercial fuse identification and a fuse cross-reference can be found in NEETS, Module 3, *Introduction to Circuit Protection, Control, and Measurement*; and in Military Standard 1360A (MIL-STD-1360A). These will assist you in selecting or identifying fuses.

Circuit breakers are too numerous to cover in this text. They are used in houses, vehicles, ships, and airplanes. Military Standard 1498 (MIL-STD-1498) contains information to help you select or identify circuit breakers.

Classification of Rf Emissions

The system of designating rf emissions is arranged according to modulation type, mode, and supplementary characteristics. For example: **A3B** indicates amplitude modulation, telephony, two independent sidebands, and a suppressed carrier. Table 1-23 will assist you in breaking down the emission classification code.

Table 1-23.—Emission Types

Emission	Type
Modulation Types	
Amplitude	A
Frequency	F
Pulse	P
Modulation (Transmission Mode)	
None	0
Telegraphy (keyed r-f carrier)	1
Telegraphy (tone)	2
Telephony	3
Facsimile	4
Television	5
Four Channel Diplex Telegraphy	6
Multichannel Voice Frequency Telegraphy Complex Forms	7
Supplemental Characteristics	
Double Sideband	none
Single Sideband	
-reduced carrier	A
-full carrier	H
-suppressed carrier	J
Two Independent Sidebands	
-suppressed carrier	B
Vestigial Sideband Pulse	C
-amplitude modulated	D
-width modulated	E
-phase modulated	F
-code modulated	G

*Capital or lower case letter

**Commercial practice is to reduce carrier 20 dB, to provide sufficient carrier for receiver afc lock-in, where afs receivers are used.

Note: a number preceding the emission designation indicates the bandwidth in kilohertz.

Conversion and Equivalent Tables

Table 1-24 provides the multiplying factors necessary to convert from one unit of measure to another and vice versa.

Table 1-24.—Conversion Chart

To Convert	To	Multiply By	Conversely, Multiply By

Frequency Spectrum Designation

The complete spectrum of communications frequencies is broken down into ranges or bands. The United States practice is to designate a two- or three-letter abbreviation for the name. The practice of the International Telecommunications Union (ITU) is to designate a number. Table 1-25 shows the bands and their designators. Table 1-26 indicates the frequency spectrum broken down as to usage.

Table 1-25.—Frequency Spectrum

FREQUENCY	DESIGNATOR	IUT DESIGNATOR
BELOW 300 Hz	ELF (EXTREMELY LOW FREQUENCY)	--
300 Hz - 3 kHz	ILF (INFRA LOW FREQUENCY) SOMETIMES VF (VOICE FREQUENCY)	--
3 kHz - 30 kHz	VLF (VERY LOW FREQUENCY)	4
30 kHz - 300 kHz	LF (LOW FREQUENCY)	5
300 kHz - 3 MHz	MF (MEDIUM FREQUENCY)	6
3 MHz - 30 MHz	HF (HIGH FREQUENCY)	7
30 MHz - 300 MHz	VHF (VERY HIGH FREQUENCY)	8
300 MHz - 3 GHz	UHF (ULTRAHIGH FREQUENCY)	9
3 GHz - 30 GHz	SHF (SUPERHIGH FREQUENCY)	10
30 GHz - 300 GHz	EHF (EXTREMELY HIGH FREQUENCY)	11
300 GHz – 3 THz	THF (TREMENDOUSLY HIGH FREQUENCY)	12

Table 1-26.—Frequency Spectrum Usage

DIVISION	RANGE	USAGE
ELF	Long	Communication, Navigation, Experimental
ILF	Long	Communication, Navigation, Experimental
VLF	Long	Communication, Navigation
LF	Long Medium	Communication, Broadcasting, Navigation
MF	Medium	Communication, Broadcasting, Navigation
HF	Long	Communication, Broadcasting
VHF		Communication Television, Radar
(Lower) (Upper)	Medium Beyond horizon	
UHF	Beyond line of sight	Communication
	Line of sight	Radar
SHF	Line of sight	Radar, Doppler
EHF	Line of sight	Short-range radar
THF	Line of sight	Experimental

Television Channel Assignments

Table 1-27 lists the VHF and UHF television channel frequencies. The video carrier is 1.25 MHz above the lower channel limit. The sound carrier is .25 MHz below the upper channel limit. For example: Channel 10 sound carrier is 197 MHz, and the video carrier is 193.25 MHz.

Table 1-27.—Television Channel Frequencies

Channel	Band Limits (MHz)	Channel	Band Limits (MHz)
2	54-60	43	644-650
3	60-66	44	650-656
4	66-72	45	656-662
5	76-82	46	662-668

42	638-644	83	884-890

Joint Electronic Type Designation System (JETDS)

This system, formerly known as the Joint Army-Navy (AN) nomenclature system, was designed so that a common designation could be used for all the services' equipment. Figure 1-36 shows you how to identify equipment in the JETDS (AN) System.

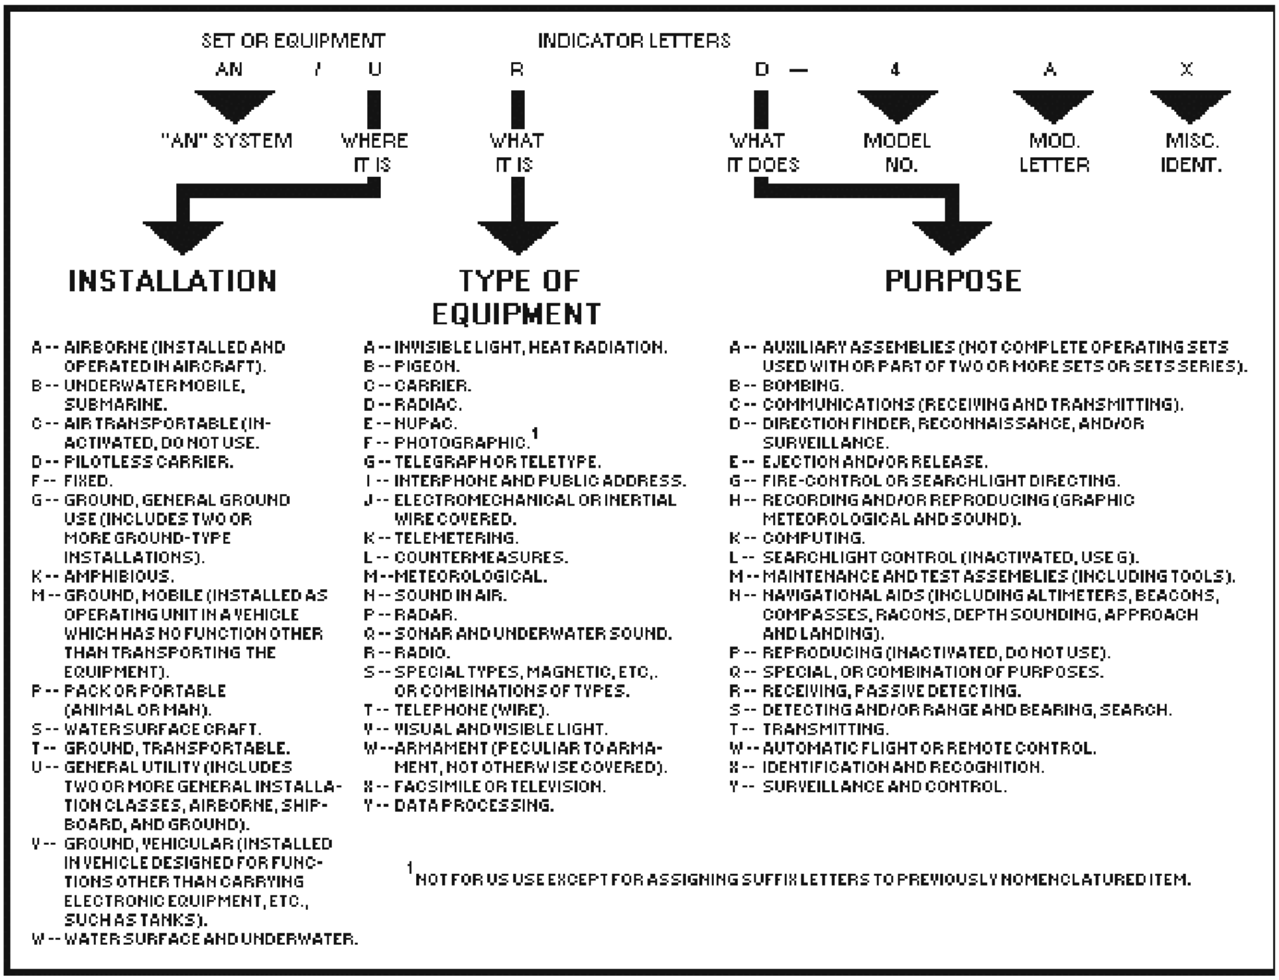

Figure 1-36.—Joint Electronics Type Designation System (AN).

Microcircuit Part Numbers.

The military designator for microcircuits is M38510. Table 1-28 shows by example how the military part number M38510/00104BCB is broken down.

Table 1-28.—Microcircuit Part Number Breakdown

1	2	3	4	5	6
M38510/	001	04	B	C	B

1. Military Specification Designator
2. Detail Specification (Group of devices of similar function)
3. Device Type (Specific part type in group)
4. Device Class:
   Class A - Manual space program
   Class B - Avionics, space satellites
   Class C - Prototype, noncritical ground systems
5. Case outline:
   A--1/4" " 1/4" Flat Pack 14 Pin

You can find more information on microcircuits by referring to Military Specification 38510 (MIL-M-38510), Military Standard 1562D (MIL-STD-1562D), and NEETS, Module 14, *Introduction to Microelectronics*.

Shipboard Announcing System

Table 1-30 is a breakdown list of the shipboard announcing system matched to the circuit designator.

Table 1-30.—Shipboard Announcing System

CIRCUIT	SYSTEM
*1MC	General
*2MC	Propulsion plant
*3MC	Aviators'
4MC	Damage Control
*5MC	Flight Deck
*6MC	Intership
7MC	Submarine Control
8MC	Troop administration and control
*9MC	Underwater troop communication
*10MC	Dock Control (obsolete)
*11-16MC	Turret (obsolescent)
*17MC	Double Purpose Battery (obsolescent)
18MC	Bridge
19MC	Aviation Control
*20MC	Combat Information (obsolescent)
21MC	Captain's Command
22MC	Electronic Control
23MC	Electrical control
24MC	Flag Command
25MC	Ward Room (obsolescent)
26MC	Machinery Control
27MC	Sonar and Radar Control
*28MC	Squadron (obsolescent)
*29MC	Sonar Control and Information
30MC	Special Weapons
31MC	Escape trunk
32MC	Weapons control
33MC	Gunnery Control (obsolescent)
34MC	Lifeboat (obsolescent)
35MC	Launcher Captains'
36MC	Cable Control (obsolete)
37MC	Special Navigation (obsolete)
38MC	Electrical (obsolete)
39MC	Cargo Handling
40MC	Flag Administrative
41MC	Missile Control and Announce (obsolete)
42MC	CIC Coordinating
43MC	Unassigned
44MC	Instrumentation Space
45MC	Research operations
*46MC	Aviation Ordnance and Missile Handling
47MC	Torpedo Control
48MC	Stores conveyor (obsolescent)
49MC	Unassigned
50MC	Integrated operational intelligence center
51MC	Aircraft Maintenance and handling control
52MC	Unassigned

Shipboard Alarm and Warning Systems

Table 1-31 is a breakdown list of the shipboard alarm and warning systems matched to a circuit designator.

Table 1-31.—Shipboard Alarm and Warning System

CIRCUIT	SYSTEM
BZ	Brig cell door alarm and lock operating
BW	Catapult Bridle Arresterman safety Ind.
CX	Bacteriological Lab. & Pharmacy Comb. Refer Failure
DL	Secure communications space door position alarm
DW	Wrong direction alarm
EA	Reactor compartment or fireroom emergency alarm
1EC	Lubricating oil low pressure alarm-propulsion machinery
2EC	Lubricating oil low pressure alarm-auxiliary machinery
1ED	Generator high temperature alarm
2ED	Oxygen-nitrogen generator plant low temperature alarm
EF	Generator bearing high temperature alarm
EG	Propeller pitch control, hydraulic oil system low pressure alarm
EH	Gas turbine exhaust high temperature alarm
EJ	Feed pressure alarm
1EK	Pneumatic control air pressure alarm
3EK	Catapult steam cutoff and alarm
EL	Radar cooling lines temperature and flow alarm
EP	Gas turbine lubricating oil high temperature alarm
1EQ	Desuperheater high temperature alarm
2EQ	Catapult steam trough high temperature alarm
3ES	Reactor fill alarm
ET	Boiler temperature alarm
EV	Toxic vapor detector alarm
1EW	Propulsion engines circulating water high temperature
2EW	Auxiliary machinery circulating water high temperature
EZ	Condenser vacuum alarm
F	High temperature alarm
4F	Combustion gas and smoke detector
9F	High temperature alarm system-ASROC launcher
11F	FBM storage area temperature and humidity alarm
12F	Gyro ovens temperature and power failure alarm
FD	Flooding alarm
FH	Sprinkling alarm
FR	Carbon dioxide release alarm
FS	Flight Deck Readylight Signal system
FZ	Security alarm (CLASSIFIED)
4FZ	Torpedeo alarm (CLASSIFIED)
HF	Air flow indicator and alarm
LB	Steering Emergency Signal system
LS	Submersible steering gear alarm
MG	Gas turbine overspeed alarm
NE	Nuclear facilities air particle detector alarm
NH	Navigation Horn Operating System

Table 1-31.—Shipboard Alarm and Warning System—Continued

CIRCUIT	SYSTEM
QA	Air lock warning
QD	Air filter and flame arrester pressure differential alarm, or gasoline compartment exhaust blower alarm
QX	Oxygen-nitrogen plant ventilation exhaust alarm
RA	Turret emergency alarm
RD	Safety observer warning
RW	Rocket and torpedo warning
4SN	Scavenging air blower high temperature alarm
SP	Shaft position alarm
TD	Liquid level alarm
1TD	Boiler water level alarm
2TD	Deaerating feed tank water level alarm
5TD	Reactor compartment bilge tank alarm
6TD	Primary shield tank, expansion tank level alarm
7TD	Reactor plant fresh water cooling expansion tank level alarm
8TD	Reactor secondary shield tank level alarm
9TD	Lubricating oil sump tank liquid level alarm
11TD	Induction air sump alarm
12TD	Diesel oil sea water compensating system tank liquid level alarm
14TD	Auxiliary fresh water tank low level alarm
16TD	Pure water storage tank low level alarm
17TD	Reserve feed tank alarm
18TD	Effluent tanks and contaminated laundry tank high level alarm
19TD	Sea water expansion tank low level alarm
20TD	Gasoline drain tank high level alarm
21TD	Moisture separator drain cooler high level alarm
24TD	Reactor plant on board discharge tank level alarm
25TD	Crossover drains high level alarm
29TD	Sonar dome fill tank low level alarm
30TD	JP-5 fuel drain tank high level alarm
TW	Train Warning system
W	Whistle Operating System

Sound-Powered Telephone Circuits

Table 1-32 is a breakdown list of the sound-powered telephone circuits matched to circuit designators.

Table 1-32.—Sound-Powered Telephone Circuits

CIRCUIT	PRIMARY CIRCUITS TITLE
JA	Captain's battle circuit
JC	Weapons control circuit
10JC	Missile battery control circuit
JD	Target detectors circuit
JF	Flag officer's circuit
1JG	Aircraft control circuit
2JG	Aircraft information circuit
2JG1	Aircraft strike coordination circuit
2JG2	Aircraft strike requirement and reporting circuit
2JG3	Aircraft information circuit CATTC direct line
3JG	Aircraft service circuit
4JG1	Aviation fuel and vehicular control circuit
4JG2	Aviation fueling circuit forward
4JG3	Aviation fueling circuit aft
5JG1	Aviation ordnance circuit
5JG2	Aviation missile circuit
6JG	Arresting gear and barricade control circuit
9JG	Aircraft handling circuit
10JG	Airborne aircraft information circuit
11JG	Optical landing system control circuit
JH	Switchboard cross connecting circuit
JL	Lookouts circuit
JK	Double purpose fuse circuit
JM	Mine control circuit
JN	Illumination control circuit
JO	Switchboard operators circuit
2JP	Dual purpose battery control circuit
4JP	Heavy machine gun control circuit
5JP	Light machine gun control circuit
6JP	Torpedo control circuit
8JP	ASW weapon control circuit
9JP	Rocket battery control circuit
10JP	Guided missile launcher control circuit
3JV	Engineer's circuit (boiler)
4JV	Engineer's circuit (fuel and stability)
5JV	Engineer's circuit (electrical)
6JV	Ballast control circuit
11JV	Waste control circuit
JW	Ship control bearing circuit
JX	Radio and signals circuit
2JZ	Damage and stability control
3JZ	Main deck repair circuit

Table 1-32.—Sound-Powered Telephone Circuits—Continued

CIRCUIT	PRIMARY CIRCUITS TITLE
4JZ	Forward repair circuit
5JZ	After repair circuit
6JZ	Midships repair circuit
7JZ	Engineer's repair circuit
8JZ	Flight deck repair circuit
9JZ	Magazine sprinkling and ordnance repair circuit forward
10JZ	Magazine sprinkling and ordnance repair circuit aft
11JZ	Gallery deck and island repair circuit

Table 1-32.—Sound-Powered Telephone Circuits

CIRCUIT	PRIMARY CIRCUITS TITLE
	Auxiliary Circuits
XJA	Auxiliary captain's battle circuit
X1JG	Auxiliary aircraft control circuit
X1JV	Auxiliary maneuvering and docking circuit
XJX	Auxiliary radio and signals circuit
X2JZ	Auxiliary damage and stability control circuit
	Supplementary Circuits
X1J	Ship administration circuit
X2J	Leadsman and anchor control circuit
X3J	Engineer watch officer's circuit
X4J	Degaussing control circuit
X5J	Machinery room control circuit
X6J1	Electronic service circuit
X6J7	ECM service circuit
X6J11-14	NTDS service circuits
X7J	Radio-sonde information circuit
10JP1	Starboard launcher circuit
10JP2	Port launcher circuit
11JP	FBM checkout and control circuit
JQ	Double purpose sight setters circuit
JR	Debarkation control circuit
JS	Plotters' transfer switchboard circuit
1JS	CIC information circuit
2JS	NTDS coordinating circuit No. 1
3JS	NTDS coordinating circuit No. 2
20JS1	Evaluated radar information circuit
20JS2	Evaluator's circuit
20JS3	Radar control officer's circuit

Table 1-32.—Sound-Powered Telephone Circuits—Continued

CIRCUIT	PRIMARY CIRCUITS TITLE
	SUPPLEMENTARY CIRCUITS (CONTINUED)
20JS4	Weapons liaison officer's circuit
21JS	Surface search radar circuit
22JS	Long range air search radar circuit
23JS	Medium range air search radar circuit
24JS	Range height finder radar circuit
25JS	AEW radar circuit
26JS	Radar information circuit
31JS	Track analyzer No. 1 air radar information check
32JS	Track analyzer No. 2 air radar information check
33JS	Track analyzer No. 3 air radar information check
34JS	Track analyzer No. 4 air radar information check
35JS	Raid air radar information circuit
36JS	Combat air patrol air radar information circuit
61JS	Sonar information circuit
80JS	ECM plotters' circuit
81JS	ECM information circuit
82JS	Supplementary radio circuit
JT	Target designation control circuit
1JV	Maneuvering and docking circuit
2JV	Engineers' circuit (engines)
X8J	Replenishment-at-sea circuit
X9J	Radar trainer circuit
X10J	Cargo transfer control circuit
X10J1	Cargo transfer circuit-Lower decks
X10J10	Cargo transfer circuit-Upper decks
X11J	Captain's and admiral's cruising circuit
X12J	Capstan control circuits
X13J	Aircraft crane control circuits
X14J	Missile handling and nuclear trunk crane circuit
X15J	SINS information circuit
X16J	Aircraft elevator circuit
X17J	5-inch ammunition hoist circuit
X18J	Machine gun ammunition hoist circuits
X19J	Missile component elevator circuit
X20J	Weapons elevator circuits
X21J	Catapult circuit
X22J	Catapult steam control circuit
X23J	Stores conveyor circuit
X24J	Cargo elevator circuit
X25J	Sonar service circuit
X26J	Jet engine test circuit
X28J	Dumbwaiter circuit

Table 1-32.—Sound-Powered Telephone Circuits—Continued

CIRCUIT	PRIMARY CIRCUITS TITLE
	SUPPLEMENTARY CIRCUITS (CONTINUED)
X29J	Timing and recording circuit
X34J	Alignment cart service circuit
X40J	Casualty communication circuit
X41J	Special weapons shop service circuit
X42J	Missile assembly and handling circuit
X43J	Weapons system service circuit
X44J	ASROC service circuit
X45J	Special weapons security circuit
X50J	Fog foam circuit
X61J	Nuclear support facilities operations and handling circuit

Screw, Drill, and Tap Data

Table 1-33 contains machine screw information, such as threads per inch, drill, and tap information.

Table 1-33.—Screw, Drill, and Tap Data

MACHINE SCREW		THREADS PER INCH		CLEARANCE DRILL		TAP DRILL	
NO.	DIA.	COARSE	FINE	NO.	DIA.	NO.	DIA.
0	0.060		80	52	0.063	56	0.046
1	0.073	64	72	47	0.078	53	0.059
2	0.086	56	64	42	0.093	50	0.079

Julian Date Calendar

Table 1-36 is a Julian date calendar. In leap years you should add one day after 28 February. Leap years occur every four years. The last leap year was 1992; therefore, the next few leap years will be 1996, 2000, and 2004.

Table 1-36.—Julian Date Calendar

Day	Jan	Feb	Mar	Apr	May	June	July	Aug	Sept	Oct	Nov	Dec	Day
1	001	032	060	091	121	152	182	213	244	274	305	335	1
2	002	033	061	092	122	153	183	214	245	275	306	336	2

31	031		090		151		212	243		304		365	31

* In leap year, after February 28, add 1 to the tabulated number.

Windchill Factor

The windchill factor is a computation of the still-air temperature that would have the same cooling effect on exposed human skin as a given combination of temperature and wind speed. You should use table 1-37 as a computation chart to figure windchill factor.

Table 1-37.—Windchill Factors

ESTIMATED WIND SPEED (IN MPH)	ACTUAL THERMOMETER READING (°F)											
	50	40	30	20	10	0	-10	-20	-30	-40	-50	-60
	EQUIVALENT TEMPERATURE (°F)											
CALM	50	40	30	20	10	0	-10	-20	-30	-40	-50	-60
05	48	37	27	16	6	-5	-15	-26	-36	-47	-57	-68
10	40	28	16	4	-9	-24	-33	-46	-58	-70	-83	-95
15	36	22	9	-5	-18	-32	-45	-58	-72	-85	-99	-112
20	32	18	4	-10	-25	-39	-53	-67	-82	-96	-110	-124
25	30	16	0	-15	-29	-44	-59	-74	-88	-104	-118	-133
30	28	13	-2	-18	-33	-48	-63	-79	-94	-109	-125	-140
35	27	11	-4	-20	-35	-51	-67	-82	-98	-113	-129	-145
40	26	10	-6	-21	-37	-53	-69	-85	-100	-116	-132	-148
Wind speeds greater than 40 mph have little added effect.	LITTLE DANGER (for properly clothed person) Maximum danger of false sense of securitly.				INCREASING DANGER Danger from freezing of exposed flesh			GREAT DANGER				

Effects of Heat and Humidity

Humidity combines with heat to create a more uncomfortable apparent temperature. By using table 1-38 you can figure the apparent temperature caused by various combinations of air temperature and humidity. Remember, in heat waves the apparent temperatures may run 15 to 30 degrees higher in more humid areas.

Table 1-38.—Effects of Heat and Humidity

	Air Temperature° 70	75	80	85	90	95	100	105	110	115	120
Relative Humidity	Apparent Temperature°										
0%	64	69	73	78	83	87	91	95	99	103	107
10%	65	70	75	80	85	90	95	100	105	111	116
20%	66	72	77	82	87	93	99	105	112	120	130
30%	67	73	78	84	90	96	104	113	123	135	148
40%	68	74	79	86	93	101	110	123	137	151	
50%	69	75	81	88	96	107	120	135	150		
60%	70	76	82	90	100	114	132	149			
70%	70	77	85	93	106	124	144				
80%	71	78	86	97	113	136					
90%	71	79	88	102	122						
100%	72	80	91	108							°Degrees Fahrenheit

When apparent temperatures are between 90 and 105 degrees, heat cramps, heat exhaustion, and heatstroke are possible after prolonged exposure and physical activity. These become likely when apparent temperatures are between 105 and 130 degrees. Over 130 degrees, heatstroke is imminent. You should note that heatstroke can be fatal if medical care is delayed.

GENERAL MAINTENANCE

The general maintenance section provides you with information on cleaning solvents, lubricants, corrosion control, use of the oscilloscope, troubleshooting, classes of overhaul, and types of equipment modifications. It also provides information such as material identification, names of organizations that provide outside technical assistance, and publications and documents that will assist you in day-to-day maintenance.

Corrosion Control (Cleaning and Lubricating)

A corrosive atmosphere can damage unprotected electric and electronic equipment. You should be aware of the harmful effects of moisture and, in particular, salt spray and salt-impregnated air. To prevent corrosion, you should maintain an effective cleaning and lubricating schedule. Standard preventive maintenance (PMS) procedures provide only minimum protection. Any schedule should include dusting and cleaning, lubrication of moving parts, and the use of approved solvents or wetting agents to remove any dust, dirt, oil film, salt, or other contaminant.

Table 1-39 is a list of standard Navy lubricants and solvents and their uses, as specified in Military Standard 454M (MIL-STD-454M).

Table 1-39.—Standard Navy Lubricants and Solvents

SPECIFICATION NUMBER AND TITLE	UNIT OF ISSUE	GENERAL USE
W-P-236 Petrolatum, Technical	1 lb. can 5 lb. can	For use as a light grade of lubricating grease but not recommended for use as a lubricant in heavily loaded or hot running bearings. It may be used as a constituent in certain types of rust preventive compounds.
P-D-680 Dry Cleaning Solvent	5 gal. pail	For general cleaning of air filters, electronic equipment, and other general purpose cleanup.
MIL-G-23827 Grease, Aircraft and Instrument	1 oz. tube 4 oz. tube 8 oz. Tube 1 lb. can 5 lb. can 35 lb. pail	In ball, roller, needle bearings, gears and sliding and rolling surfaces of such equipment as instruments, cameras, electronic gear and aircraft control systems. Particularly suitable for equipment which must operate at both very low and very high temperatures for short periods. Does not contain extreme pressure or special antiwear additives. It is destructive to paint, natural rubber, and neoprene.
MIL-G-81322 Grease, Aircraft	5 lb. can 35 lb. pail	For lubrication and protection against corrosion of plain ball and roller bearings, and preservation of threads on ammunitions.
MIL-L-17331 Lubricating Oil Steam Turbine	5 gal. 55 gal.	In main turbines and gears, auxiliary turbine installation, certain hydraulic equipment general mechanical lubrication, and air compressors.
MIL-L-2105 Lubrication Oil Gear	5 gal. 1 gal. 55 gal.	For lubrication of automotive gear units, heavy duty industrial-type enclosed gear units, steering gears, and fluid-lubricated universal joints of automotive equipment.
MIL-L-6085 Lubricating Oil Instrument	1 1/2 oz. btl. 4 oz. can 1 qt.	For aircraft instruments, electronic equipment, or where a low evaporation oil is required for both high and low temperature application, and where oxidation and corrosion resistance are desirable. Destructive to paint, neoprene and rubber.
MIL-L-6086 Lubricating Oil Gear	1 gal. can 1 pt. can 1 gal. can 5 gal. drum	For use under extremely low temperature, mild extreme pressure-type oil with load carrying additive. General use in aircraft use in aircraft gear mechanisms, exclusive of engines.
MIL-L-17331 & MIL-L-17672 Lubricating Oil General Purpose	1 pt. 5 gal. 55 gal.	For all applications which require other than special lubricants, and which are subject to normal variation between ambient and operating temperature. Use in lieu of MIL-L-6085 when oil will be in contact with neoprene.

Table 1-42.—Lubricants Used in Electronics Equipment But Not Listed In MIL-STD-454M

SPECIFICATION NUMBER AND TITLE	UNIT OF ISSUE	GENERAL USE
51-F-23 Hydraulic Fluid	5 gal. 55 gal.	Used in connection with the hydraulic transmission of power. For use with Synthetic Seal.
ASTM D-3699 Kerosene	5 gal.	General uses such as a cleaner for machinery or tools.
MIL-L-7870 Lubrication Oil General Purpose	4 oz. 1 qt. 1 gal.	Specially designed for use where an oil of low evaporation, possessing rust-protective properties, is desired.
VV-G-632 General Purpose Grease	35 lb. 100 lb.	Automotive chassis, suitable for lubrication of machinery equipped with pressure grease fitting.
MIL-G-81322.Grease Aircraft	1 lb. 8 oz.	Used in antifriction bearings operating at high speeds and high temperatures.
MIL-C-11090 Cleaning Compound	5 gal. 55 gal.	Used as a solvent for cleaning grease and oils.
MIL-L-17672 Lubrication Oil General Purpose	1 gal. 55 gal.	Used in steam turbines, hydraulic systems, water generators and hydraulic turbine governors.
VV-L-751 Lubrication oil	35 lb.	Cold weather. Warm weather. Hot weather. Used for lubricating chain, wire rope, exposed gears.

Table 1-43 contains a list of common cleaning and preservation materials that were compiled from Naval Air Technical Manual 16-1-540, *Avionic Cleaning and Corrosion Prevention Control*.

Table 1-43.—Cleaning Materials

Non-abrasive cleaning & polishing pad
Isopropyl alcohol TT-I-735
General purpose lubricating oil VV-L-800
Instrument grease MIL-G-8137
General purpose grease MIL-G-81322
Zip-lock plastic bags
Distilled water
Paint brush
Toothbrush
Pipe cleaners
Q tips
Face shield
Goggles
Rubber gloves
Magnifying glass
Vacuum cleaner
Hot air gun
Inspection mirror
Rubber bucket
Plastic spray bottle

Remember to use the proper safety precautions applicable to toxic, volatile solvents and flammable lubricants. You can refer to Naval Ships' Technical Manual (NSTM), Chapter 670, *Stowage, Handling, and Disposal of Hazardous General Use Consumables*, NAVSEA S9086-WK-STM-000.

Using the Oscilloscope

An oscilloscope can be used for more than just studying the shape of a waveform. By looking at lissajous patterns and using an *octopus*, you can compare the phase and frequency relationship of two signals and check electronic components in a circuit.

LISSAJOUS PATTERNS.—The simplest lissajous patterns are produced by two sine waves of the same frequency and amplitude being applied to the horizontal and vertical deflection voltage inputs of an oscilloscope. Figure 1-37 shows patterns for several common phase relationships. These can be used to estimate the approximate phase angle of the two signals being studied.

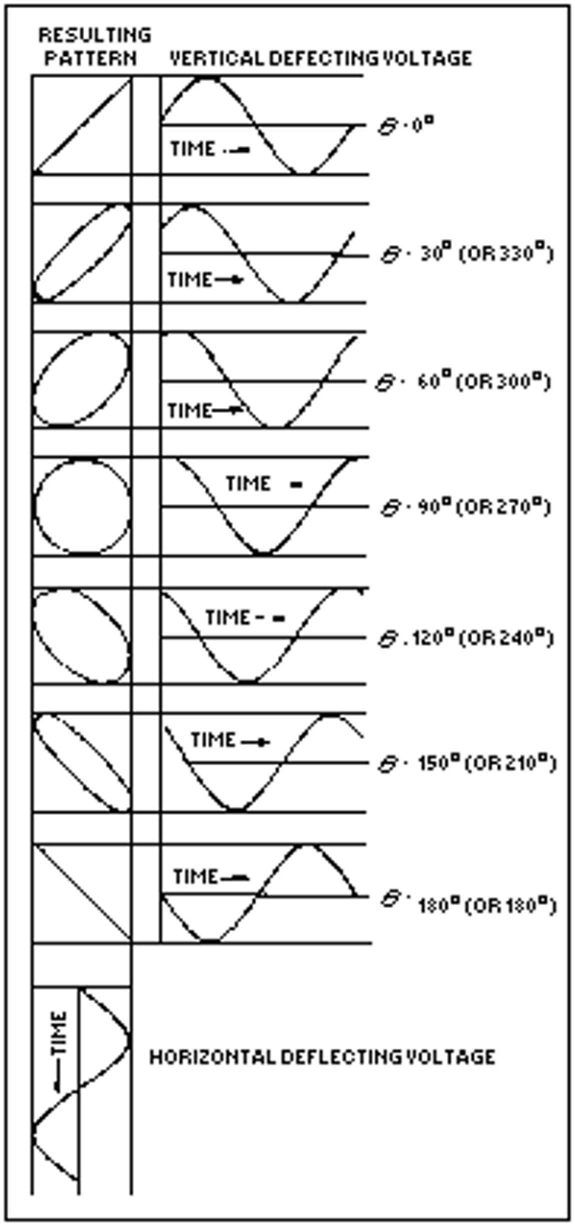

Figure 1-37.—Lissajous patterns, showing the effects of phase relationships.

Figure 1-38 will aid you in computing a phase angle if a more precise calculation is needed. We will use the graticule on the oscilloscope, a ratio formula, and sine (sin) table to compute the angle.

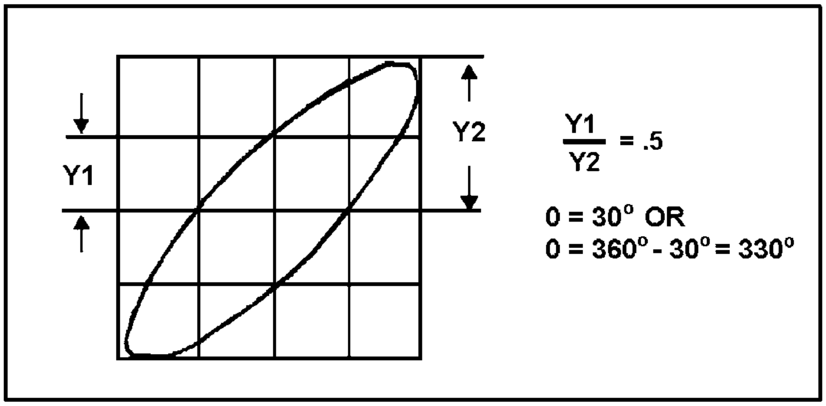

Figure 1-38.—Computation of phase angle.

To find the angle, we should first divide Y1 by Y2. We can then take that number, look it up in the sine portion of table 1-35, and read the angle.

For example, let's let each graticule in figure 1-36 represent 1 centimeter. Then,

$$Y1 = 1$$

$$Y2 = 2$$

$$\frac{Y1}{Y2} = .5$$

If we look for .5 in the sine column of table 1-35, we find that .5 is the value for the sine of 30 degrees.

The frequency ratio between two sine waves can also be determined from lissajous patterns. Figure 1-39 shows various frequency ratios between signals. Figure 1-40 and 1-41, views A, show how phase relationship can affect these patterns. If tangent lines are drawn across the top and down the side of the pattern, the ratio of points (free ends and loops) that touch these lines equals the frequency ratio. Figure 1-41 is an example of this method. Refer back to figure 1-39 and notice the relationship of loops and open ends in each example. You can find more detailed information on lissajous patterns in the Electronics Installation and Maintenance Book (EIMB), *Test Methods and Practices*, NAVSEA 0976-LP-000-0130.

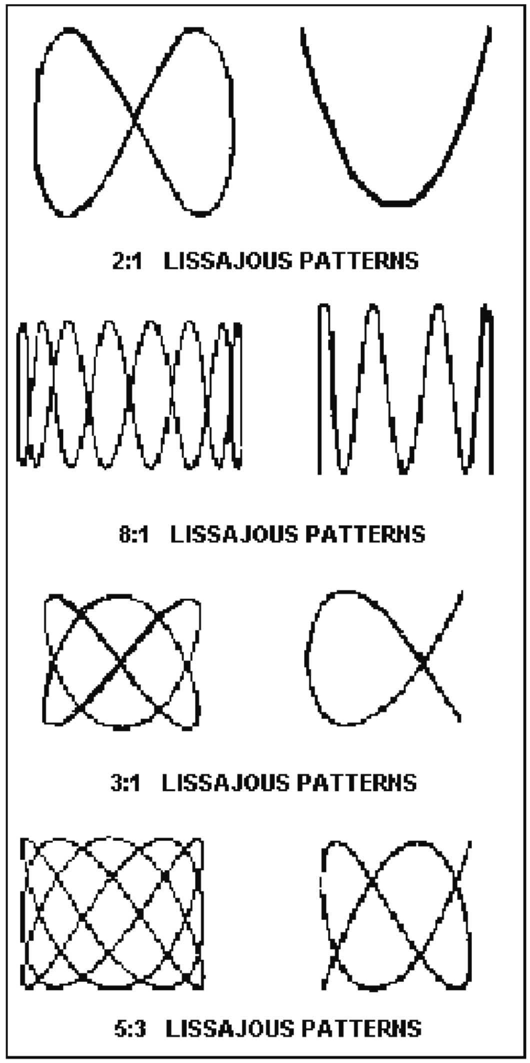

Figure 1-39.—Lissajous patterns of different frequency ratios.

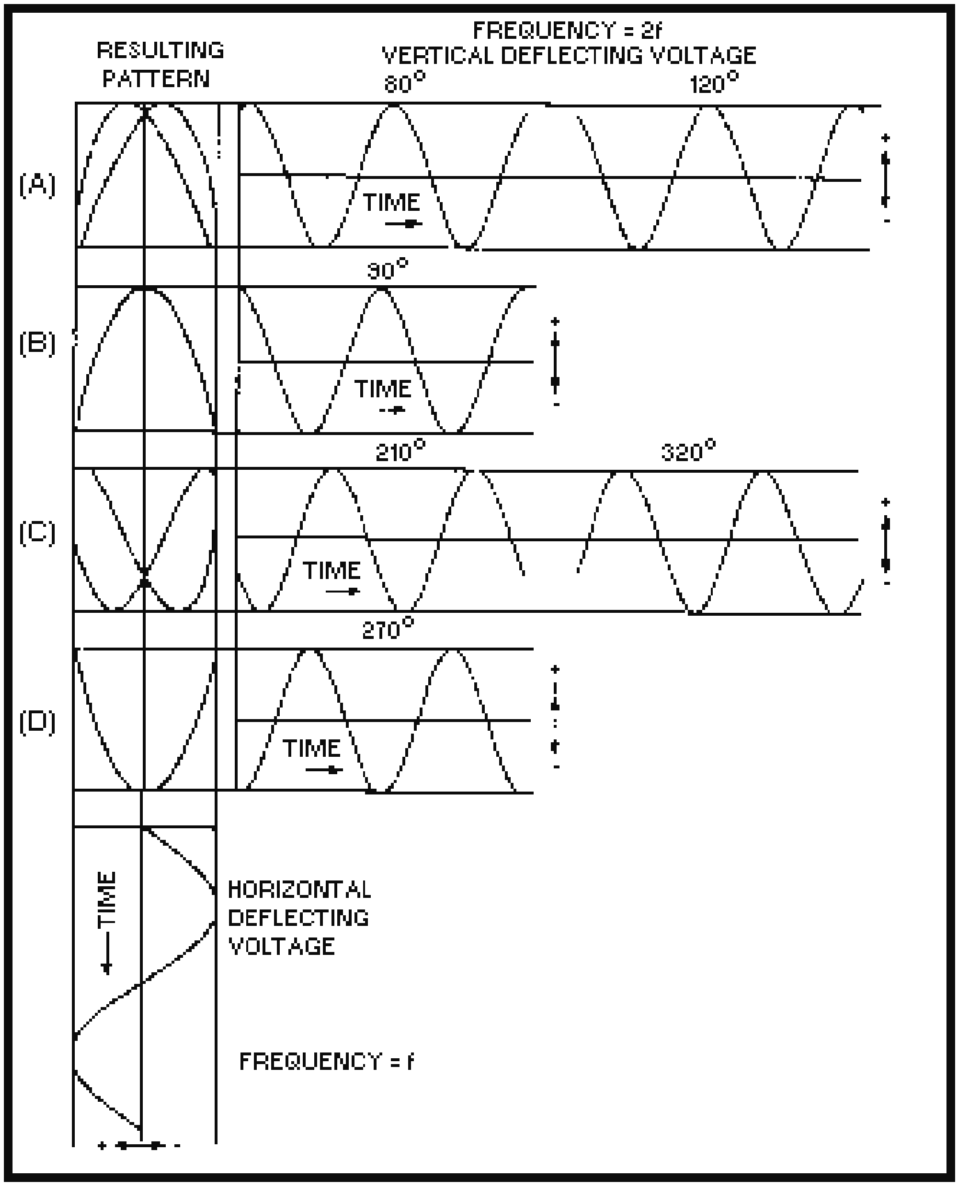

Figure 1-40.—Lissajous patterns for various phase relationships.

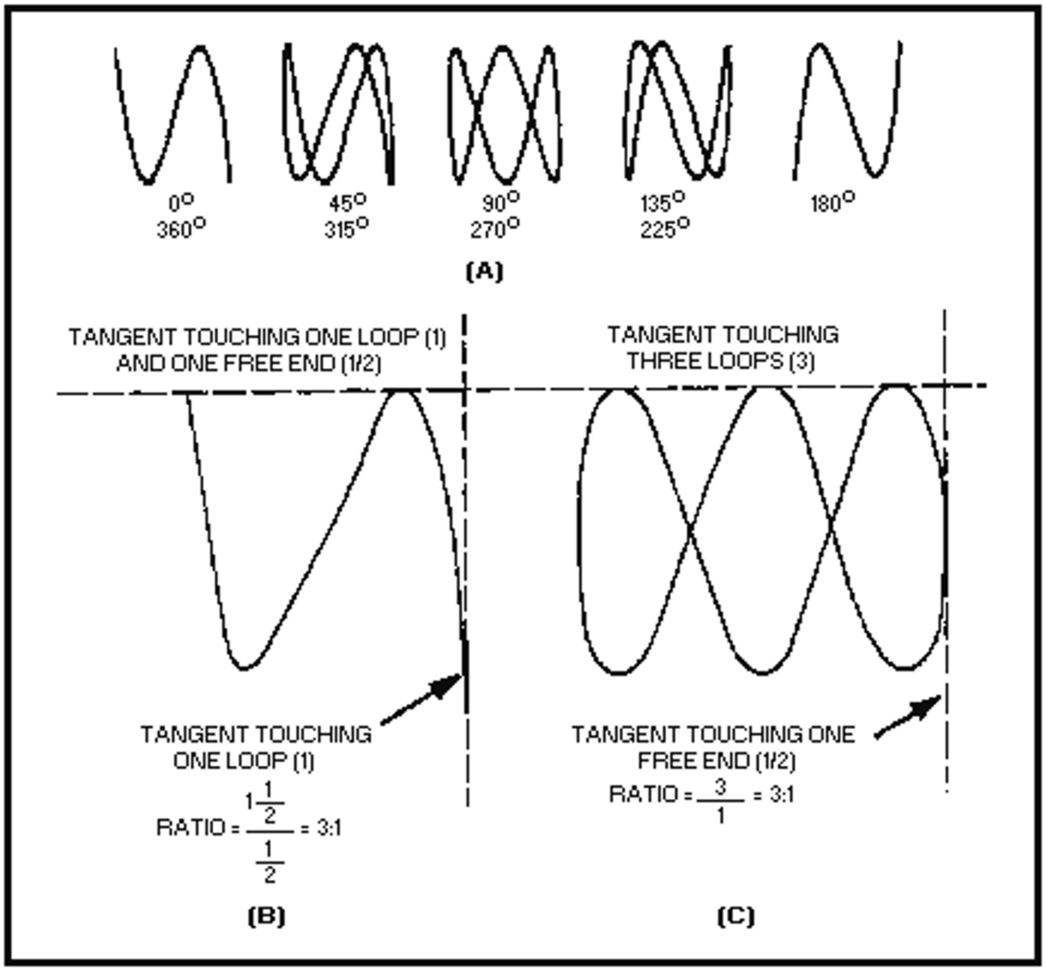

Figure 1-41—3:1 Lissajous patterns and calculation of frequency ratio.

THE OCTOPUS.—The octopus is a small, homemade test set used with an oscilloscope to check electronic components *in circuit*. It can be made easily and cheaply using parts from the supply system. Figure 1-42 is a schematic of an octopus that uses either a 6.3-volt filament transformer or an audio oscillator for input power. The benefits of *in circuit* troubleshooting with an octopus are (1) reduced maintenance time, (2) less chance of damage from soldering-iron heat, and (3) a visual display of the component's condition.

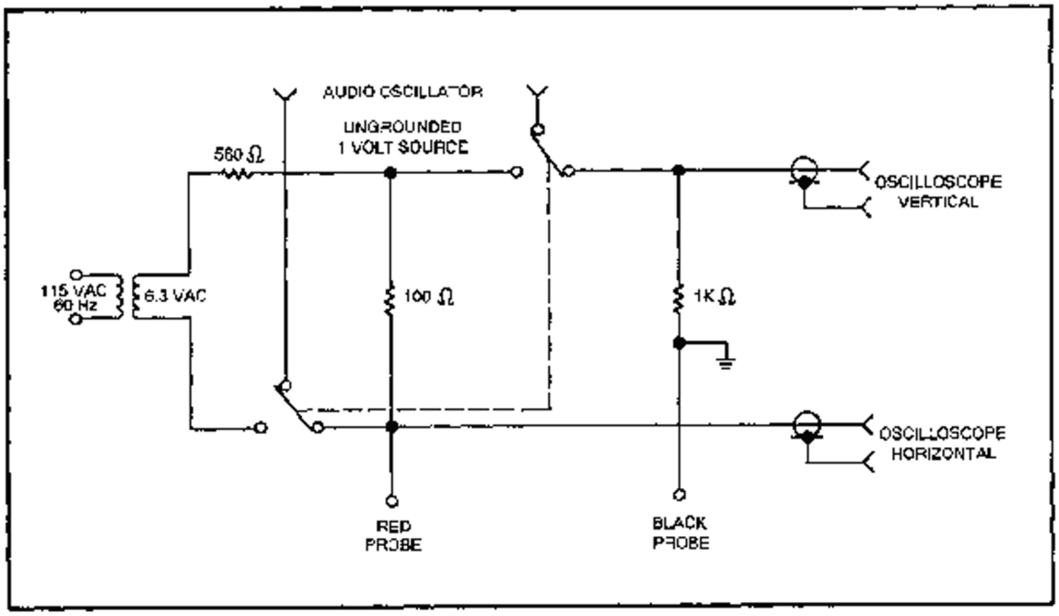

Figure 1-42.—Octopus schematic diagram (typical).

The octopus tests all components for shorts, high resistance, and opens; it checks front-to-back ratios on junction components (transistors and diodes); and it analyzes ICs and reactive components (capacitors and inductors). Figure 1-43 shows some typical oscilloscope displays obtained when the octopus is used. Figures 1-44, 1-45, and 1-46 depict transistor, potentiometer, and combination component displays, respectively. Detailed operating procedures can be found in topic 6 of NEETS, Module 16, *Introduction to Test Equipment*, and in the Electronic Installation and Maintenance Book (EIMB), *Test Methods and Practices*, NAVSEA SE000-00-EIM-130.

Six-Step Troubleshooting Procedure

You may have the job of maintaining or helping to maintain some electrical or electronic unit, subsystem, or system. Some of these jobs may be complex, but even a complex job can be broken down into simple steps. Basically, any repair of electric or electronic equipment should be done in the following order:

1. Symptom recognition. This is the action of recognizing some disorder or malfunction in electronic equipment.

2. Symptom elaboration. Obtaining a more detailed description of the trouble symptom is the purpose of this step.

3. Listing probable faulty functions. This step is applicable to equipment that contains more than one functional area or unit. From the information you have gathered, where could the trouble logically be located?

4. Localizing the faulty function. In this step you determine which of the functional units of the multiunit equipment is actually at fault.

5. Localizing trouble to the circuit. You will do extensive testing in this step to isolate the trouble to a specific circuit.

6. Failure analysis. This step is multipart. Here you determine which part is faulty, repair/replace the part, determine what caused the failure, return the equipment to its proper operating status, and record the necessary information in a recordkeeping book for other maintenance personnel in the future. While not a part of this step, the technician should reorder any parts used in repair of the faulty equipment.

Sometimes you may run into difficulty in finding (or troubleshooting) the problem. Some hints that may help in your efforts are:

- Observe the equipment's operation for any and all faults
- Check for any defective components with your eyes and nose
- Analyze the cause of the failure for a possible underlying problem

Classes of Overhaul Work

There are five classes of equipment overhaul (A, B, C, D, and E). The class defines the type and scope of work to be done on each equipment by the overhauling activity. (Do not confuse equipment overhaul with the term regular overhaul.)

CLASS A OVERHAUL.—A class A overhaul includes overhaul, repair, and/or modification; for example a modification could be an Ordnance Alteration (ORDALT), Special Program Alteration (SPALT), Ship Alteration (SHIPALT), or a field change that will sustain or improve the performance of a system or component to meet its most-recent design and technical specifications. The end product should be like new in appearance and operation.

CLASS B OVERHAUL.—A class B overhaul includes overhaul and repair that will restore the performance of a system or component to its original design and technical specifications. Modifications or alterations are not done unless specified by the customer.

CLASS C OVERHAUL.—A class C overhaul includes only repair work on a system or component specified by a work request or work required to correct malfunctions specified by the customer.

CLASS D OVERHAUL.—A class D overhaul includes work related to the open, inspect and report type of work request. It is intended to be diagnostic in nature and may require various tests. It is normally associated with preoverhaul test and inspection (POT& I).

CLASS E OVERHAUL.—A class E overhaul includes work required to incorporate all alterations and/or modifications specified for a system or component.

Alterations and Modifications to Equipment

Alterations and modifications to shipboard systems and equipment may take several forms. Some of these are Ship Alterations (SHIPALTS), Ordnance Alterations (ORDALTS), Special Program Alterations (SPALTS), and Air Alterations (AIRALTS). These alterations (with the exception of electronic equipment field changes) are categorized as follows:

- A military alteration that changes or improves the operational or military characteristics of a ship.

- A technical alteration that generally concerns personnel safety and equipment effectiveness.

- An alteration-equivalent-to-repair (AER) could be one of three types. One involves substitution, without change in design, of approved, different material, available from standard stock. The second involves replacement of worn or damaged parts, assemblies, or equipment with those of later and more efficient design that have been approved by the responsible systems command. The last type is used for strengthening of parts that need repair or replacement to improve the reliability of the parts, provided no other change in design is involved.

ALTERATION RESPONSIBILITIES.—Ship alterations (SHIPALTS) involve material under the technical control of the Naval Sea Systems Command (NAVSEA). Alterations which affect shipboard systems and equipment under the technical control of other systems commands; for example, air alterations (AIRALTS), ordnance alterations (ORDALTS), and special program alterations (SPALTS), are not SHIPALTS. However, they may require concurrent SHIPALTS if changes affect shipboard system interface.

ELECTRONIC EQUIPMENT FIELD CHANGES.—Field changes are identified by type and class. The type depends on the material included in the change kit or furnished by the installing activity. The class refers to the funding and the installation responsibility.

Details concerning various types of and approval authority for alterations can be found in the Electronics Installation and Maintenance Book (EIMB), *General*, NAVSEA SE000-00-EIM-100.

Material Identification

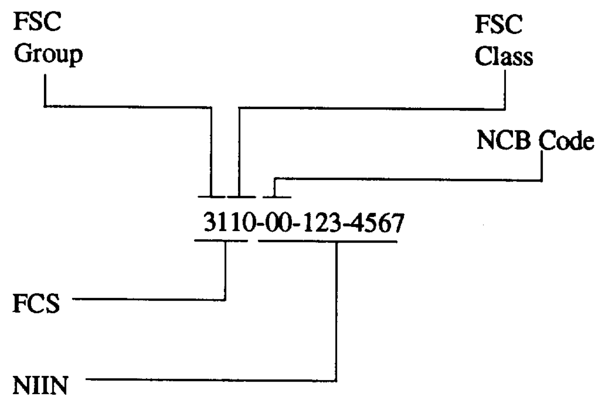
At some time in your work, you will probably have to replace a defective part or component. If you are familiar with national stock numbers (NSNs), Navy item control numbers (NICNs), part numbers (PNs), and the Coordinated Shipboard Allowance List (COSAL), getting the replacement should be a simple chore.

NATIONAL STOCK NUMBERS (NSNs).—An NSN is a 13-digit stock number used to identify an item of material in the Federal Catalog System of the Department of Defense. It consists of a four-digit federal supply classification (FSC) and a nine-digit national item identification number (NIIN). The first two digits of the FSC denote the group or major division of materials and the last two digits denote the class of subdivision of material within a group.

Examples of groups are:

GROUP	TITLE
31	Bearings
48	Valves
59	Electrical and Electronic Systems Components
79	Cleaning supplies

A complete listing of groups is provided in NAVSUP P-485, *Afloat Supply Procedures*. The NIIN consists of a two-digit national codification bureau (NCB) code and seven digits which, in conjunction with the NCB code, uniquely identify each NSN item in the Federal Supply System. For example:



Two NCB codes are assigned for the United States, 00 and 01. Code 00 identifies all FSNs (11-digit federal stock numbers used prior to NSNs) assigned prior to 31 March 1975. Code 01 identifies the numbers assigned after that time. The NCBs must be included and be correct, or the material may be rejected or you may receive the wrong material.

NAVY ITEM CONTROL NUMBERS (NICNs).—Material not included in the Federal Catalog System, but stocked or monitored in the Navy Supply System, are listed by 13-character Navy item control numbers (NICNs). These NICNs are readily identified by a two-position alpha code which signifies the type of NICN. This code and a seven-position alphanumeric uniquely identify each NICN item in the Navy Supply System. NICN codes that are currently used and examples of NICNs follow:

NICN CODE	APPLICATION	EXAMPLE
LE	Poseidon items common to Trident	1220-LE-F00-4016
LF	Stock numbers for forms	1018-LF-504-2201
LK	Aircraft change kit numbers	1234-LK-UA1-2345
LP	Stock numbers for publications	0530-LP-485-0000
LS	Special programs alteration kit numbers	1234-LS-123-4567
LX	ASO local control numbers	1560-LX-NPI-2345
LL	Local control numbers (Temporary)	4820-LL-000-1234
	Local control numbers (Permanent)	7520-LL-CAO-0001

Note: The permanent local control number can always be recognized by a C in the seventh position.

Parts can be ordered by using a NIIN or NICN.

PART NUMBERS (PNs).—A part number (also known as reference number) may be used to identify a material item or to assist you in finding the current NSN. Part numbers include old NSNs, FSNs, electron tube type numbers, and electronic equipment circuit symbol numbers. Two other important sources for reference numbers are manufacturers' part numbers and Navy drawing and piece numbers. They can be easily converted to NSNs by using the *Master Cross-Reference List* (MCRL). Table 1-44 shows excerpts from the MCRL. If the part or reference numbers do not cross to an NSN, the P/N can be used to order the replacement. A good source of part numbers is the parts list in the equipment technical manual.

Table 1-44.—Excerpts from Master Cross-Reference List (MCRL)

PART - 2

(NSN - TO - REFERENCE NUMBER)

COORDINATED SHIPBOARD ALLOWANCE LIST (COSAL).—The COSAL can help you to identify repair or replacement parts. Part IIB of the COSAL is a cross-reference (microfiche only) from circuit symbol number to PN/NIIN/NICN. These parts are normally carried onboard ship for ready issue.

Outside Assistance

Your command may from time to time request assistance from another activity. This outside assistance is usually for the purpose of training, technical assistance on unusual design, planning, installation, or solving maintenance problems. Many of these activities exist throughout the fleet and shore establishments. Their capabilities and areas of responsibility differ just as equipment and systems differ. Several of the more widely known activities are included below.

MOBILE TECHNICAL UNITS (MOTU).—MOTUs provide on-the-job training and technical assistance for shipboard NAVSEA-SYSCOM/NAVELEXSYSCOM systems and equipment. They are staffed by senior military personnel and Contractor Engineering and Technical Services (CETS) representatives. MOTU's and NAUSEA combined about 10 years ago to form FTSCLANT/PAC.

MOTUs are located in the following areas:

FTSCLANT/PAC
Pearl Harbor, Hawaii
Norfolk, Va.
Groton, Conn.
San Diego, Calif.
Naples, Italy
Yokosuka, Japan
Mayport, Fla.
NSB Kings Bay, Ga.
Seattle, Wash.

NAVAL SEA SYSTEMS COMMAND (NAVSEA).— NAVSEA provides technical assistance through the use of direct fleet support technicians (TECHREP). These technicians are not to be used primarily as repairmen. The objective of their services is to promote fleet readiness and maintenance self-sufficiency. NAVSEATECHREP are located at Naval Sea Support Centers (NAVSEACENs) in Portsmouth, Va., and San Diego, Calif. They are also located at Fleet Support Offices (FSOs) in Mayport, Fla., Charleston, S.C., and New London, Conn. Selected equipment may have services provided by NAVSES, Philadelphia, or NAVSHIPWPNSYSENGSTA (NSWSES), Port Hueneme, Calif.

NAVAL ELECTRONIC SYSTEMS COMMAND (NAVELEX).— **NAVELEX** equipment is supported by the Fleet Liaison Program. Training and technical assistance is provided by civilian technicians at six NAVELEX field activities. Five are Naval Electronic Systems Engineering Centers (NESECs) and one is a Naval Electronic Systems Engineering Activity (NESEA). Fleet Liaison Offices are located at NESEC Washington, D.C., NESEC Charleston, S.C., NESEC Portsmouth, Va., NESEC San Diego, Calif., NESEC Vallejo, Calif., and NESEA St. Inigoes, Md.

NAVAL AIR SYSTEMS COMMAND (NAVAIR).— **NAVAIR** established the Navy Engineering and Technical Services (NETS) program to provide a source of technical and training assistance expertise. The program is comprised of military and civilian personnel. These people are qualified to provide advice, instruction, and training to support the installation, operation, and maintenance of Navy weapons, weapon-systems, and equipment. NETS technicians are assigned and administered by the Pacific Missile Test Center, Point Mugu, Calif., and the Naval Aviation Engineering Service Unit (NAESU), Philadelphia, Pa.

The Pacific Missile Test Center provides engineering and technical services on air-launched missile systems, air-launched guided weapons, Navy target systems, conventional ordnance, and associated support equipment. All aircraft equipment and systems not specified above are the responsibility of the Naval Aviation Engineering Service Unit (NAESU).

NAVAL AVIATION ENGINEERING SERVICE UNIT (NAESU).— **NAESU** provides field engineering assistance and instruction in installation, repair, and operation of all types of aviation systems and equipment to naval aviation fleet and shore activities throughout the world. This is accomplished by detachments (NAESU DETs) at the following locations:

Atlanta, Ga.	Miramar, Calif.
Atsugi, Japan	Misawa, Japan
Barbers Point, Hawaii	Moffett Field, Calif.
Beaufort, S.C.	Naples, Italy
Bermuda	New Orleans, La.
Brunswick, Maine	New River, N.C.
Cecil Field, Fla.	Norfolk, Va
Cherry Point, N.C.	Oceana, Va.
China Lake, Calif.	Okinawa, Japan
Corpus Christi, Tex.	Patuxent River, Md.
Cubi Point, Philippines	Pensacola, Fla.
Dallas, Tex.	Point Mugu, Calif.
Detroit, Mich.	Rota, Spain
El Toro, Calif.	San Diego, Calif.
Glenview, Ill.	Sigonella, Sicily
Agana, Guam	South Weymouth, Mass.
Iwakuni, Japan	Washington, D.C.
Jacksonville, Fla.	Whidbey Island, Wash.
Kaneohe Bay, Hawaii	Willow Grove, Pa.
Key West, Fla.	Yuma, Ariz.
Lemoore, Calif	Memphis, Tenn

CARRIER AND FIELD SERVICE UNITS (CAFSUs).— **CAFSUs** furnish technical guidance and assistance to shipyards, ship repair facilities, and shore and fleet personnel concerning the installation, operation, maintenance, and testing of shipboard NAVAIR equipment. This equipment includes catapults, arresting gear, visual landing aids, flight deck lighting, pilot landing aid television (PLAT) systems, Fresnel-lens optical landing systems (FLOLS), and integrated launch and recovery television surveillance (ILARTS) systems.

CAFSUs are under the administrative control of the Naval Air Engineering Center (NAEC), Lakehurst, N.J., and are located at the following activities:

NAS Norfolk, Va.	SRF Subic Bay, Philippines
NAVSTA Mayport, Fla.	NAEC Philadelphia, Pa.
NAF Naples, Italy	SRF Yokosuka, Japan
NAS North Island, Calif.	NAS Alemeda, Calif.

INTERMEDIATE MAINTENANCE ACTIVITIES (IMAs).—Afloat **IMAs** (tenders and repair ships) and shore IMAs (SIMAs) provide maintenance support for repairs beyond the capabilities of ship's force. IMAs also have facilities for test equipment calibration and emergency parts manufacture. Electrical, electronic, and ordnance repair divisions provide repairs on various equipment including gyrocompasses, navigational equipment, film projectors, internal communications, sonar, radar, IFF, radio receivers and transmitters, test antennas, guns and small arms, torpedoes, fire control, and missile systems. Table 1-45 lists the various IMAs and their locations.

Publications and Documents

Various publications, some of which are discussed below, are available for guidance in maintenance work or for reference and study. In general, these publications are available from the Naval Publications and Forms Center through the supply system.

NAVAL SHIPS' TECHNICAL MANUAL (NSTM).—The Naval Ships' Technical Manual (NSTM) is a prime reference for information on NAVSEA equipment. Chapter 400, *Electronics*, is most useful as it provides major policies and instructions pertaining to electronics work and material under NAVSEA and NAVELEX responsibility. Other chapters of interest to electrical and electronics technicians are:

300	Electrical Plant General
302	Electric Motors and Controllers
310	Electric Power Generators and Conversion Equipment
320	Electric Power Distribution Systems
330	Lighting
430	Interior Communication Installations
434	Motion Picture Equipment
491	Electrical Measuring and Test Instruments
510	Ventilating, Heating, Cooling, and Air-Conditioning Systems for Surface Ships
532	Liquid-Cooling Systems for Electronic Equipment
9006	Submarine Antennas and Masts
634	Deck Coverings

ELECTRONICS INSTALLATION AND MAINTENANCE BOOK (EIMB).—The Electronics Installation and Maintenance Book series supplements instructions and data supplied in equipment technical manuals. The EIMB is intended to reduce time-consuming research on electronic equipment and circuit theory. These handbooks fall into two categories: general information and equipment-oriented handbooks. The latter includes general test procedures, adjustments, and general servicing information. All handbooks of the series are listed below.

TITLE	NUMBERS
GENERAL	
General	SE000-00-EIM-100
Installation Standards	0967-LP-000-0110
Electronic Circuits	0967-000-0120
Test Methods & Practices	0967-LP-000-0130
Reference Data	0967-000-0140
EMI Reduction	0967-000-0150
General Maintenance	SE000-00-EIM-160
EQUIPMENT-ORIENTED	
Communications	SE000-00-EIM-010
Radar	SE000-00-EIM-020
Sonar	SE000-00-EIM-030
Test Equipment	SE000-00-EIM-040
Radiac	0967-000-0050
Countermeasures	SE000-00-EIM-07

ENGINEERING INFORMATION BULLETIN (EIB).—The *Engineering Information Bulletin* is published biweekly and distributed to all naval ships and electronics installation and maintenance activities. It is authoritative and is a means of rapid dissemination of advanced hull, mechanical, electronic, electrical, and related equipment information. It includes information concerning approved beneficial suggestions, electronics field changes, mechanical alterations (MECHALTS), installation techniques, maintenance notes and practices, and technical manual availabilities, advance change notices, and distribution.

EQUIPMENT TECHNICAL MANUALS.—Technical manuals carry information essential to the proper operation, maintenance, and repair of specific equipment. These manuals may occasionally contain errors. In those cases, change notices are provided to correct the manuals. Updates because of equipment changes are also provided. These changes must be installed in the technical manuals to maintain accuracy and to prevent the loss of man-hours resulting from the use of obsolete data and/or schematics. The *Guide for User Maintenance of NAVSEA Technical Manuals*, NAVSEA S005-AA-GYD-030/TMMP, provides information on identifying, ordering, deficiency reporting, and updating technical manuals.

NAVSUP PUBLICATION 2002.—**NAVSUP 2002** is the *Navy Stock List of Publication and Forms* and provides NSNs for ordering Navy publications and their changes. Each edition is issued quarterly and supersedes the previous one in its entirety. It is produced in *microfiche* only and contains three sections:

Section 1—Forms

Section 2—Publications

Section 3—NAVAIR Technical Directives

DECKPLATE.—The *deckplate* is a technical periodical published monthly by NAVSEA. It contains information on design, construction, conversion, operation, maintenance, and repair of Navy vessels and their equipment. It also includes articles on personnel safety, service hints, and adopted beneficial suggestions.

NAVAL SAFETY CENTER PUBLICATIONS.—The Naval Safety Center publishes bulletins and several periodicals to keep Navy personnel informed on the subject of accident prevention.

- *Ship Safety Bulletin*—This monthly newsletter contains safety notes and accident data.
- *Fathom*—This quarterly magazine contains a review of surface ship and submarine accident prevention and safety articles.
- *Approach*—This magazine is a monthly review of articles concerning aviation safety and accident prevention.
- *MECH*—MECH is a bimonthly review of aviation maintenance related mishaps, material/personnel hazards, and general aviation ground safety.

TRAINING MANUALS (TRAMANS).—Training manuals are designed to give enlisted personnel background knowledge for the proper performance of their assigned jobs. Electrical and electronic theory and operation and maintenance information on pertinent equipment are presented at different rating levels in the TRAMANs written for the technical rates.

PREFACE

About this course:

This is a self-study course. By studying this course, you can improve your professional/military knowledge, as well as prepare for the Navywide advancement-in-rate examination. It contains subject matter about day-to-day occupational knowledge and skill requirements and includes text, tables, and illustrations to help you understand the information. An additional important feature of this course is its reference to useful information in other publications. The well-prepared Sailor will take the time to look up the additional information.

Training series information:

This is Module 20 of a series.

History of the course:

Sep 1998: *Original edition released. Prepared by FTCM Gilbert J. Coté*
Jan 2004: *Administrative update released. Reviewed by ETC(SW) Jack Weatherford. Technical content was not revised.*

TABLE OF CONTENTS

CHAPTER **PAGE**

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

CHAPTER 1

MASTER GLOSSARY OF TERMS

INTRODUCTION

This module presents the combined glossaries from modules 1 through 18, the primary texts in the NEETS series. Definitions of terms used in NEETS are presented in an alphabetical glossary. Numbers in parenthesis ( ) indicate more than one definition for the same term. Numbers in brackets [ ] indicate the module number in which more information about the term may be found.

ABSORPTION—(1) Dissipation of radio or sound waves as they interact with matter. (2) The absorbing of light waves without reflection or refraction [10].

ABSORPTION, LAW OF—In Boolean algebra, the law which states that the odd term will be absorbed when a term is combined by logical multiplication with the logical sum of that term and another term, or when a term is combined by logical addition with the logical product of one term and another term (for example, $A(A + B) = A + AB = A$) [13].

ABSORPTION WAVEMETER—An instrument used to measure audio frequencies [16].

ACCELERATING ANODE—An electrode charged several thousand volts positive and used to accelerate electrons toward the front of a cathode-ray tube [6].

ACCELERATION SERVOSYSTEM—A servosystem that controls the acceleration (rate of change in velocity) of a load [15].

ACCELEROMETER—A device that measures the acceleration to which it is subjected and develops a signal proportional to it [15].

ACCEPTOR IMPURITY—An impurity which, when added to a semiconductor, accepts one electron from a neighboring atom and creates a hole in the lattice structure of the crystal. Also called TRIVALENT IMPURITY [7].

ACORN TUBE—A very small tube with closely spaced electrodes and no base. The tube is connected to its circuits by short wire pins that are sealed in a glass or ceramic envelope. The acorn tube is used in low-power uhf circuits [6].

ACOUSTICS—The science of sound [10].

ACQUISITION—Operational phase of a fire-control or track radar during which the radar system searches a small volume of space in a prearranged pattern [18].

ACTIVE SATELLITE—A satellite that amplifies the received signal and retransmits it back to earth [17].

ACTUATOR—The part of a switch that is acted upon to cause the switch to change contact connections; for example, toggle, pushbutton, and rocker [3].

AFDS—An abbreviation for the amphibious flagship data system [17].

AIR-CONTROL PANEL—Panel that monitors the dry-air input at each user equipment [18].

AIR-CORE TRANSFORMER—A transformer composed of two or more coils that are wound around a nonmetallic core [2].

ALLOWANCE PARTS LIST (APL)—Repair parts required for units having the equipment/ component listed [14].

ALLOYED JUNCTION—A junction formed by recrystallization of a molten region of P-type material on an N-type substrate, or vice versa [7].

ALPHA—The emitter-to-collector current gain in a common-base circuit [7].

ALTERNATING CURRENT—An electrical current that constantly changes amplitude and changes polarity at regular intervals [2].

ALTITUDE—The vertical distance of an aircraft or object above a given reference, such as ground or sea level [18].

ALUMINUM CREEP—(1) The movement of aluminum wire from a point where pressure is applied. (2) The "retreat" of heated aluminum wire as it cools [4].

AMBIENT TEMPERATURE—The surrounding temperature such as the temperature of air surrounding a conductor in a compartment or within a piece of equipment [4].

AMBIGUOUS RETURNS—Echoes that exceed the prt of a radar and appear at incorrect ranges [18].

AMERICAN WIRE GAUGE (AWG)—The standards adopted in the United States for the measurement of wire sizes [4].

AMMETER—An instrument for measuring the amount of electron flow (in amperes) [1] [3] [6].

AMPERE—The basic unit of electrical current [1].

AMPERE-TURN—The magnetomotive force developed by 1 ampere of current flowing through a coil of one turn [8].

AMPERITE (BALLAST) TUBE—A current-controlling resistance device designed to maintain substantially constant current over a specified range of variation in applied voltage or resistance of a series circuit [6].

AMPLIDYNE—A special dc generator in which a small dc voltage applied to field windings controls a large output voltage from the generator. In effect, an amplidyne is a rotary amplifier that often times produces gain of approximately 10,000 [5].

AMPLIFICATION—(1) The process of enlarging a signal in amplitude (as of voltage or current) [8]. (2) The ratio of output magnitude to input magnitude in a device that is intended to produce an output that is an enlarged reproduction of its input [6] [7].

AMPLIFICATION FACTOR—The voltage gain of an amplifier with no load on the output [6] [7].

AMPLIFIER—The device that provides amplification (the increase in current, voltage, or power of a signal) without appreciably altering the original signal [7] [8].

AMPLITRON—See CROSS-FIELD AMPLIFIER [18].

AMPLITUDE—The size of a signal as measured from a reference line to a maximum value above or below the line. Generally used to describe voltage, current, or power [8] [12].

AMPLITUDE DISTORTION—Distortion that is present in an amplifier when the amplitude of the output signal fails to follow exactly any increase or decrease in the amplitude of the input signal [6] [7].

AMPLITUDE MODULATION—Any method of varying the amplitude of an electromagnetic carrier frequency in accordance with the intelligence to be transmitted [12].

AMPLITUDE STABILITY—Amplitude stability refers to the ability of the oscillator to maintain a constant amplitude in the output waveform [9].

AND CIRCUIT—See AND GATE [13].

AND GATE—(1) An electronic gate whose output is energized only when every input is in its prescribed state. An AND gate performs the function of the logical "AND"; also called an AND circuit. (2) A binary circuit, with two or more inputs and a single output, in which the output is a logic 1 *only* when all inputs are a logic 1 and the output is a logic 0 when *any* one of the inputs is a logic 0 [13].

ANGLE MODULATION—Modulation in which the angle of a sine-wave carrier is varied by a modulating wave [12].

ANGLE OF INCIDENCE—The angle between the incident wave and the normal [10].

ANGLE OF INCLINATION—The angular difference between the equatorial plane of the earth and the plane of orbit of the satellite [17].

ANGLE OF REFLECTION—The angle between the reflected wave and the normal [10].

ANGLE OF REFRACTION—The angle between the normal and the path of a wave through the second medium [10].

ANGSTROM UNIT—The unit used to define the wavelength of light waves [10].

ANISOTROPIC—The property of a radiator that allows it to emit strong radiation in one direction [10].

ANODE—(1) A positive electrode of an electrochemical device (such as a primary or secondary electric cell) toward which the negative ions are drawn [1] [6] [7]. (2) The semiconductor-diode terminal that is positive with respect to the other terminal when the diode is biased in the forward direction [13].

ANTENNA—A conductor or set of conductors used to radiate RF energy into space or to collect RF energy from space or to do both [10].

ANTENNA BEAM WIDTH—Width of a radar beam measured between half-power points [18].

ANTENNA COUPLER—A device used for impedance matching between an antenna and a transmitter or receiver [17].

ANTENNA SYSTEM—Routes RF energy from the transmitter, radiates the energy into space, receives echoes, and routes the echoes to the receiver [18].

ANTIJAMMING CIRCUIT—An electronic circuit used to minimize the effects of enemy countermeasures, thereby permitting radar echoes to be visible on the indicator [18].

ANTISEIZE COMPOUND—A silicon-based, high-temperature lubricant applied to threaded components to aid in their removal after they have been subjected to rapid heating and cooling [4].

ANTITRANSMIT-RECEIVE TUBE (atr)—A tube that isolates the transmitter from the antenna and receiver. Used in conjunction with a tr tube [18].

APERTURE—See SLOT [11].

APOGEE—The point in the orbit of a satellite the greatest distance from the earth [17].

APPARENT DRIFT—The effect of the earth's rotation on a gyro that causes the spinning axis to appear to make one complete rotation in one day. Also called APPARENT PRECESSION or APPARENT ROTATION [15].

APPARENT POWER—That power apparently available for use in an ac circuit containing a reactive element. It is the product of effective voltage times effective current expressed in volt-amperes. It must be multiplied by the power factor to obtain true power available [2].

APPARENT PRECESSION—See APPARENT DRIFT [15].

APPARENT ROTATION—See APPARENT DRIFT [15].

ARC EXTINGUISHER—The part of a circuit breaker that confines and divides the arc which occurs when the contact of the circuit breaker opens [3].

ARMATURE—(1) In a relay, the movable portion of the relay [3]. (2) The windings in which the output voltage is generated in a generator or in which input current creates a magnetic field that interacts with the main field in a motor [5].

ARMATURE LOSSES—Copper losses, eddy current losses, and hysteresis losses that act to decrease the efficiency of armatures [5].

ARMATURE REACTION—The effect in a dc generator of current in the armature creating a magnetic field that distorts the main field and causes a shift in the neutral plane [5].

ARRAY OF ARRAYS—Same as COMBINATION ARRAY [10].

ARTIFICIAL TRANSMISSION LINE—An LC network that is designed to simulate characteristics of a transmission line [18].

ASBESTOS—A noncombustible, nonconductive, fiber-like mineral used as an insulating material [4].

ASBESTOSIS—Fibrosis of the lungs caused by inhalation of asbestos fibers [4].

A-SCOPE—A radar display on which slant range is shown as the distance along a horizontal trace [18].

ASSEMBLY—A number of parts or subassemblies, or any combination thereof, joined together to perform a specific function [17].

ASTABLE MULTIVIBRATOR—A multivibrator that has no stable state. Also called free-running because it alternates between two different output voltage levels during the time it is on. The frequency is determined by the RC time constant of the coupling circuit [9].

ASWTDS—An abbreviation for the antisubmarine warfare tactical data system [17].

ASYMMETRICAL MULTIVIBRATOR—A multivibrator that generates rectangular waves [18].

ASYNCHRONOUS—The teletypewriter operation where the transmitter and receiver do not operate continuously [17].

ASYNCHRONOUS ORBIT—One where the satellite does not rotate or move at the same speed as the earth [17].

ATDS—An abbreviation for the airborne tactical data system [17].

ATTENUATION—The ability of a filter circuit to reduce the amplitude of unwanted frequencies to a level below that of the desired output frequency [9].

ATTRACTION—The force that tends to make two objects approach each other. Attraction exists between two unlike magnetic poles (north and south) or between two unlike static charges [1].

AUDIO AMPLIFIER—An amplifier designed to amplify frequencies between 15 hertz (15 Hz) and 20 kilohertz (20 kHz) [8].

AUDIO-FREQUENCY-TONE SHIFT—A system that uses amplitude modulation to change dc mark and space impulses into audio impulses [17].

AUTOMATIC GAIN CONTROL—A circuit used to vary radar receiver gain for best reception of signals that have widely varying amplitudes [18].

AUTOMATIC TRACKING—Tracking done by equipment that compares the direction of the antenna axis and the direction of the received signal and uses the difference (error) signal to reposition the antenna [17].

AUTOMATIC VOLUME/GAIN CONTROL—A circuit used to limit variations in the output signal strength of a receiver [17].

AVALANCHE EFFECT—A reverse breakdown effect in diodes that occurs at reverse voltages beyond 5 volts. The released electrons are accelerated by the electric field, which results in a release of more electrons in a chain or "avalanche" effect [7].

AVERAGE POWER—(1) The peak power value averaged over the pulse-repetition time [12]. (2) Output power of a transmitter as measured from the start of one pulse to the start of the next pulse [18].

AVERAGE VALUE (OF AC)—The average of all the instantaneous values of one-half cycle of alternating current [2].

AXIS—A straight line, either real or imaginary, passing through a body around which the body revolves [15].

AZIMUTH—Angular measurement in the horizontal plane in a clockwise direction [18].

BACK RESISTANCE—The larger resistance value observed when you are checking the resistance of a semiconductor [16].

BALANCED MIXER—A waveguide arrangement that resembles a T and uses crystals for coupling the output to a balanced transformer [18].

BALANCED PHASE DETECTOR—A circuit that controls the oscillator frequency (afc) [17].

BANDPASS FILTER—A filter that allows a narrow band of frequencies to pass through the circuit. Rejects or attenuates frequencies that are either higher or lower than the desired band of frequencies [9] [16].

BAND-REJECT FILTER—A tuned circuit that does not pass a specified band of frequencies [9] [16].

BANDWIDTH—The difference between the highest usable frequency of a device (upper frequency limit) and the lowest usable frequency of the device (lower frequency limit) - measured at the half-power points [8] [9] [12] [15].

BARRETTER—A type of bolometer characterized by an increase in resistance as the dissipated power rises [16].

BASE—The element in a transistor that controls the flow of current carriers [7].

BASE—(1) A reference value. (2) A number that is multiplied by itself as many times as indicated by an exponent. (3) Same as radix. (4) The region between the emitter and collector of a transistor that receives minority carriers injected from the emitter. It is the element that corresponds to the control grid of an electron tube [13].

BASE-INJECTION MODULATOR—Similar to a control-grid modulator. The gain of a transistor is varied by changing the bias on its base [12].

BATTERY—A device for converting chemical energy into electrical energy [1].

BATTERY CAPACITY—The amount of energy available from a battery. Battery capacity is expressed in ampere-hours [1].

BAUD—A measurement of speed based on the number of code elements or units per second [17].

BAY—Part of an antenna array [10].

BEAM—See LOBE [18].

BEAM-LEAD CHIP—Semiconductor chip with electrodes (leads) extended beyond the wafer [14].

BEAM-POWER TUBE—An electron tube in which the grids are aligned with the control grid. Special beam-forming plates are used to concentrate the electron stream into a beam. Because of this action, the beam-power tube has high power-handling capabilities [6].

BEARING—An angular measurement of the direction of an object from a reference direction, such as true north [11].

BEARING RESOLUTION—Ability of a radar to distinguish between targets that are close together in bearing [18].

BEAT FREQUENCIES—Difference and sum frequencies, which result from the combination of two separate frequencies [18].

BEAT FREQUENCY—The difference between the oscillator frequency and the unknown audio frequency [16].

BEAT-FREQUENCY OSCILLATOR—An additional oscillator used in a receiver when it is receiving a cw signal. It provides an audible tone [17].

BEL—The unit that expresses the logarithmic ratio between the input and output of any given component, circuit, or system [16].

BETA—The ratio of a change in collector current to a corresponding change in base current when the collector voltage is constant in a common-emitter circuit [7].

BEVERAGE ANTENNA—A horizontal, long-wire antenna designed for reception and transmission of low-frequency, vertically polarized ground waves [10].

BIAS—Difference of potential applied to a vacuum tube or transistor to establish a reference operating level [13].

BIAS CURRENT—Current that flows through the base-emitter junction of a transistor and is adjusted to set the operating point of the transistor [13].

BIDIRECTIONAL ARRAY—An array that radiates in opposite directions along the line of maximum radiation [10].

BINARY—(1) A number system that uses a base, or radix, of 2. Two digits (1 and 0) are used in the binary system. (2) Pertaining to a characteristic that involves the selection, choice, or condition in which there are only two possibilities. (3) A bistable multivibrator (flip-flop) is one example of a binary device [13].

BINARY CODE—A method of representing two possible conditions (*on* or *off*, high or low, one or zero, the presence of a signal or absence of a signal). Electronic circuits designed to work in such a way that only two conditions are possible [13].

BINARY-CODED—The state in which conditions are expressed by a series of binary digits (0's and 1's) [13].

BINARY DIGIT—(1) A character that represents one of the two digits in the number system that has a radix of two. (2) Either of the digits 0 or 1 that may be used to represent the binary conditions of *on* or *off* [13].

BINARY NOTATION—See BINARY NUMBER SYSTEM [13].

BINARY NUMBER SYSTEM—A number system using two digits, symbols, or characters (usually 1 and 0) [13].

BINARY POINT—The radix point that separates powers of two and fractional powers of two in a binary number [13].

BISTABLE—A device that is capable of assuming either one of two stable states [13].

BISTABLE MULTIVIBRATOR—A multivibrator that has two stable states. It remains in one of the states until a trigger is applied. It then flips to the other stable state and remains there until another trigger is applied. Also referred to as a FLIP-FLOP [9] [13].

BLACK—The reference color of equipment that passes unclassified information. It normally refers to patch panels [17].

BLEEDER CURRENT—The current through a bleeder resistor. In a voltage divider, bleeder current is usually determined by the 10 percent rule of thumb [1].

BLEEDER RESISTOR—A resistor used to draw a fixed current [1].

BLIP—See PIP [18].

BLOCK DIAGRAM—A diagram in which the major components of an equipment or a system are represented by squares, rectangles, or other geometric figures, and the normal order of progression of a signal or current flow is represented by lines [4].

BLOCKED-GRID KEYING—A method of keying in which the bias is varied to turn plate current on and off [12].

BLOCKING—A condition in an amplifier, caused by overdriving one or more stages, in which the amplifier is insensitive to small signals immediately after reception of a large signal [18].

BOLOMETER—A loading device that undergoes changes in resistance as changes in dissipated power occur [16].

BONDING WIRES—Fine wires connecting the bonding pads of the chip to the external leads of the package [14].

BOOLEAN—(1) Pertaining to the process used in the algebra formulated by George Boole. (2) Pertaining to the operations of formal logic [13].

BOOLEAN ALGEBRA—A system of logic dealing with on-off circuit elements associated by such operators as the AND, OR, NAND, NOR, and NOT functions [13].

BOOLEAN LOGIC—See BOOLEAN ALGEBRA [13].

BOUNDARY CONDITIONS—The two conditions that the E-field and H-field within a waveguide must meet before energy will travel down the waveguide. The E-field must be perpendicular to the walls and the H-field must be in closed loops, parallel to the walls, and perpendicular to the E-field [11].

BRANCH—An individual current path in a parallel circuit [1] [4].

BREAK—In a switch, the number of breaks refers to the number of points at which the switch opens the circuit; for example, single break and double break [3].

BREAKDOWN—The phenomenon occurring in a reverse-biased semiconductor diode. The start of the phenomenon is observed as a transition from a high dynamic resistance to one of substantially lower dynamic resistance. This is done to boost the reverse current [7].

BRIGHTNESS CONTROL—The name given to the potentiometer used to vary the potential applied to the control grid of a CRT [6].

BROADSIDE ARRAY—An array in which the direction of maximum radiation is perpendicular to the plane containing the elements [10] [18].

BRUSHES—Sliding contacts, usually carbon, that make electrical connection to the rotating part of a motor or generator [5].

BUFFER—A voltage amplifier used between the oscillator and power amplifier [12].

BUFFER AMPLIFIER—An amplifier that isolates one circuit from another. It decreases the loading effect on an oscillator by reducing the interaction between the load and the oscillator [9] [18].

BUILT-IN TEST EQUIPMENT (BITE)—A permanently mounted device that is used expressly for testing an equipment or system [14].

BUNCHER CAVITY—The input resonant cavity in a conventional klystron oscillator [11].

BUNCHER GRID—In a velocity-modulated tube, the grid that concentrates the electrons in the electron beam into bunches [11].

BURNISHING TOOL—A tool used to clean and polish contacts on a relay [3].

BUS BAR—A heavy copper strap or bar used to connect several circuits together when a large current-carrying capacity is required [4].

BYPASS CAPACITOR—A capacitor used to transfer unwanted signals out of a circuit; for example, coupling an unwanted signal to ground. Also called a DECOUPLING CAPACITOR [8].

CABLE—Either a stranded conductor (single-conductor cable) or a combination of conductors insulated from one another (multiple conductor cable). Small sizes are commonly referred to as stranded wire or as cords [4].

CABLE HARNESS—A group of wires or ribbons of wiring used to interconnect electronic systems and subsystems [14].

CAPACITANCE—The property of an electrical circuit that opposes changes in voltage [2].

CAPACITIVE REACTANCE—The opposition, expressed in ohms, offered to the flow of an alternating current by capacitance. The symbol for capacitive reactance is X_C [2] [9].

CAPACITOR—An electrical device capable of storing electrical energy in an electrostatic field [2].

CAPACITOR FILTER—This filter is used on extremely high-voltage, low-current power supplies and also where the ripple frequency is not critical [7].

CAPACITOR-START MOTOR—A type of single-phase, ac induction motor in which a starting winding and a capacitor are placed in series to start the motor. The values of X_C and R are such that the main-winding and starting-winding currents are nearly 90 degrees apart and the starting torque is produced as in a two-phase motor [5].

CARBON MICROPHONE—A microphone in which sound waves vary the resistance of a pile of carbon granules. May be single-button or double-button [12].

CARDIOPULMONARY RESUSCITATION—Procedure designed to restore breathing after cardiac arrest. Includes clearing air passages to lungs and heart massage [1].

CARRIER FREQUENCY—The frequency of an unmodulated transmitter output [12] [18].

CARRIER-CONTROLLED APPROACH—A shipboard radar system used to guide aircraft to safe landings in poor visibility conditions [18].

CARRY—(1) One or more digits, produced in connection with an arithmetic operation, that is/are forwarded to another digit place for processing there. (2) The number represented by the digit or digits in (1) above [13].

CATCHER GRID—In a velocity-modulated tube, a grid on which the spaced electron groups induce a signal. The output of the tube is taken from the catcher grid [11].

CATHODE—(1) In an electron tube the electrode that is the source of current flow [6]. (2) The general name for any negative electrode [1]. (3) The negative terminal of a forward-biased semiconductor diode, which is the source of the electrons [7].

CATHODE BIAS—The method of biasing a vacuum tube in which the biasing resistor is placed in the common-cathode return circuit, thereby making the cathode more positive with respect to ground [6].

CATHODE KEYING—A system in which the cathode circuit is interrupted so that neither grid current nor plate current can flow [12].

CATHODE MODULATOR—Voltage on the cathode is varied to produce the modulation envelope [12].

CATHODE-RAY TUBE (CRT)—An electron tube that has an electron gun, a deflection system, and a screen. This tube is used to display visual electronic signals [6].

CATHODE SPUTTERING—A process of producing thin film components [14].

CAVITY RESONATOR—A space totally enclosed by a metallic conductor and supplied with energy in such a way that it becomes a source of electromagnetic oscillations. The size and shape of the enclosure determine the resonant frequency [11].

CAVITY WAVEMETER—An instrument used to measure microwave frequencies [16].

CELL—A single unit that transforms chemical energy into electrical energy. Batteries are made up of cells [1].

CENTER-FEED METHOD—Connecting the center of an antenna to a transmission line which is then connected to the final (output) stage of the transmitter [10].

CENTIMETER CUBE—A unit of volume of large rectangular or square conductors. The cross-sectional area equals 1 square centimeter with a length of 1 centimeter [4].

CHANNEL—A carrier frequency assignment, usually with a fixed bandwidth [12].

CHARACTER—A letter, digit, or other symbol that is used as part of the organization, control, or representation of information [13].

CHARACTERISTIC IMPEDANCE—The ratio of voltage to current at any given point on a transmission line represented by a value of impedance [10].

CHARGE—Represents electrical energy. A material having an excess of electrons is said to have a negative charge. A material having a shortage of electrons is said to have a positive charge [1].

CHARGE CYCLE—The period of time that a capacitor in an electrical circuit is storing a charge [2].

CHOKE—An inductor used to impede the flow of pulsating dc or ac by means of self-inductance [6] [7].

CHOKE JOINT—A joint between two sections of waveguide that provides a good electrical connection without power losses or reflections [11].

CIRCUIT—The complete path of an electric current [1].

CIRCULAR MIL—An area equal to that of a circle with a diameter of 0.001 inch. It is used for measuring the cross-sectional area of wires [1].

CIRCULAR MIL-FOOT—A unit of volume of a conductor having a cross-sectional area of 1 circular mil and a length of 1 foot [4].

CLAMPER—A circuit in which either the upper or lower extremity of a waveform is fixed at a desired value [9].

CLASS A AMPLIFIER OPERATION—The type of operation in which the amplifier is biased so that variations in input signal polarities occur within the limits of cutoff and saturation [7].

CLASS AB AMPLIFIER OPERATION—The type of operation in which the amplifier is biased so that collector current is cut off for a portion of the alternation of the input signal [7].

CLASS B AMPLIFIER OPERATION—The type of operation in which the amplifier is biased so that collector current is cut off for one-half of the input signal [7].

CLASS C AMPLIFIER OPERATION—The type of operation in which the amplifier is biased so that collector current is cut off for more than one-half of the input signal [7] [13].

CLUTTER—Confusing, unwanted echoes that interfere with the observation of desired signals on a radar indicator [18].

COAXIAL CABLE—Cable in which the center conductor is separated from an outer conductor by a dielectric material; used in RF transmission [4].

COAXIAL LINE—A type of transmission line that contains two concentric conductors [10].

CODE—In teletypewriter operation, code is a combination of mark and space conditions representing symbols, figures, or letters [17].

COEFFICIENT OF COUPLING—An expression of the extent to which two inductors are coupled by magnetic lines of force. This is expressed as a decimal or percentage of maximum possible coupling and represented by the letter K [2].

COHERENCE—A definite phase relationship between two energy waves, such as transmitted frequency and reference frequency [18].

COHERENT—Radiation on one frequency [17].

COHERENT OSCILLATOR—In cw radar an oscillator that supplies phase references to provide coherent video from target returns [18].

COIL—An inductive device made by looping turns of wire around a core [2].

COLD-CATHODE TUBE—A gas-filled electron tube that conducts without the use of filaments. Cold-cathode tubes are used as voltage regulators [6].

COLLECTOR—The element in a transistor that collects the current carriers [7].

COLLECTOR-INJECTION MODULATOR—The transistor equivalent of a plate modulator. Modulating voltage is applied to a collector circuit [12].

COLLINEAR ARRAY—An array with all the elements in a straight line. Maximum radiation is perpendicular to the axis of the elements [10].

COMBINATION ARRAY—An array system that uses the characteristics of more than one array [10].

COMBINATION CIRCUIT—A series-parallel circuit [1].

COMBINATION PEAKING—A technique in which a combination of peaking coils in series and parallel (shunt) with the output signal path is used to improve high-frequency response [8].

COMMON BASE—A transistor circuit in which the base electrode is the common element to both input and output circuits [7].

COMMON-BASE DETECTOR—An amplifying detector in which detection occurs in the emitter-base junction and amplification occurs at the output of the collector junction [12].

COMMON COLLECTOR—A transistor circuit configuration in which the collector is the element common to both the input and the output circuits [7].

COMMON EMITTER—A circuit configuration in which the emitter is the element common to both the input and the output circuits [7].

COMMON-EMITTER DETECTOR—Often used in receivers to supply detected and amplified output. The emitter-base junction acts as the detector [12].

COMMON IDENTITIES LAW—In Boolean algebra this law states that anytime the expression $A(A + B) = AB$ or $A + AB = A + B$ appears, it can immediately be simplified to AB without going through the process of using the distributive law, complementary law, or the law of union to simplify [13].

COMMUTATION—The act of a commutator in converting generator output from an ac voltage to a dc voltage [5].

COMMUTATIVE LAW—In Boolean algebra this law states that changing the order of the terms in an equation will not affect the value of the equation. Example: $A + B = B + A$; $A \bullet B = B \bullet A$ [13].

COMMUTATOR—A mechanical device that reverses armature connections in motors and generators at the proper instant so that current continues to flow in only one direction. In effect, the commutator changes ac to dc [5].

COMPARATOR—An equipment that compares incoming signals and selects the strongest to be fed to a teletypewriter through a patch panel. This is used in diversity operation [17].

COMPENSATING WINDINGS—Windings embedded in slots in pole pieces, connected in series with the armature, whose magnetic field opposes the armature field and cancels armature reaction [5].

COMPENSATION—The process of overcoming the problems associated with high frequencies in an amplifier [8].

COMPLEMENT—A number or state that is the opposite of a specified number or state. The negative of a number is often represented by its complement [13].

COMPLEMENTARY (SECONDARY) COLORS OF LIGHT—The colors of light produced when two of the primaries are mixed in overlapping beams of light. The complementary colors of light are magenta, yellow, and cyan [10].

COMPLEMENTARY LAW—In Boolean algebra this law states that the logical addition of a quantity and its complement will result in 1 and the logical multiplication of a quantity and its complement will result in a product of 0 [13].

COMPLEMENT NUMBER—A number that when added to another number gives a sum equal to the base of the number system of operation. For example, in the decimal number system, the complement of 1 is 9 [13].

COMPLEX WAVE—(1) A waveform other than a sine wave [9]. (2) A wave that is produced by combining two or more pure tones at the same time [10] [12].

COMPOUND-WOUND MOTORS AND GENERATORS—Machines that have a series field in addition to a shunt field. Such machines have characteristics of both series- and shunt-wound machines [5].

COMPRESSION WAVES—Longitudinal waves that have been compressed (made more dense) as they move away from the source [10].

COMPUTER—A data processor that can perform substantial computation, including numerous arithmetic or logic operations, without intervention by a human operator during the run [13].

CONCURRENT—Pertaining to the occurrence of two or more events or activities within the same specified interval of time [13].

CONDUCTANCE—The ability of a material to conduct or carry an electric current. It is the reciprocal of the resistance of the material and is expressed in mhos or siemens [1] [4] [10].

CONDUCTION BAND—A partially filled energy band in which electrons can move freely [7].

CONDUCTIVITY—The ease with which a substance transmits electricity [1].

CONDUCTOR—(1) A material with a large number of free electrons. (2) A material that easily permits electric current to flow [1].

CONDUIT—A tubular raceway, usually metal or plastic, for holding wires or cables [4].

CONICAL SCANNING—Scanning in which the movement of the beam describes a cone, the axis of which coincides with that of the reflector [18].

CONNECTED ARRAY—Another term for DRIVEN ARRAY [10].

CONTACT—In radar, an object that reflects RF energy; target [18].

CONTINUITY—An uninterrupted, complete path for current flow [3] [16].

CONTINUOUS-WAVE KEYING—The on-off keying of a carrier [12].

CONTROL DIFFERENTIAL TRANSMITTER (CDX)—A type of synchro that transmits angular information equal to the algebraic sum or difference of the electrical input supplied to its stator, the mechanical input supplied to its stator, and the mechanical input supplied to its rotor. The output is an electrical voltage taken from the rotor windings [15].

CONTROL GRID—The electrode of a vacuum tube, other than a diode, upon which a signal voltage is impressed to regulate the plate current [6].

CONTROL-GRID MODULATOR—Uses a variation of grid bias to vary the instantaneous plate voltage and current. The modulating signal is applied to the control grid [12].

CONTROL SYNCHRO SYSTEMS—Synchro systems that contain control synchros and are used to control large amounts of power with a high degree of accuracy. The electrical outputs of these systems control servosystems, which in turn generate the required power to move heavy loads [15].

CONTROL SYSTEM—A group of components systematically organized to perform a specific control purpose. These systems are categorized as either closed- or open-loop systems. The main difference between the two is that the closed-loop system contains some form of feedback [15].

CONTROL TRANSFORMER (CT)—A type of synchro that compares two signals: the electrical signal applied to its stator and the mechanical signal applied to its rotor. The output is an electrical voltage, which is taken from the rotor winding and is used to control a power-amplifying device. The phase and amplitude of the output voltage depends on the angular position of the rotor with respect to the magnetic field of the stator [15].

CONTROL TRANSMITTER (CX)—A type of synchro that converts a mechanical input, which is the angular position of its rotor, into an electrical output signal. The output is taken from the stator windings and is used to drive either a CDX or CT [15].

CONVERTER—In communications, equipment that changes the audio output of a receiver to dc pulses. These pulses are fed to a tty to indicate marks and spaces [17].

COOKIE-CUTTER TUNER—A mechanical magnetron tuning device that changes the frequency by changing the capacitance of the anode cavities [11].

COPPER LOSS (I^2R LOSS)—The power lost because of the resistance of the conductors. In transformers the power lost because of current flow (I) through the resistance (R) of the windings [2] [10] [11].

CORDWOOD MODULE—A method of increasing the number of discrete components in a given space. Resembles wood stacked for a fireplace [14].

CORE—Any material that affords a path for magnetic flux lines in a coil [2].

CORNER-REFLECTOR ANTENNA—A half-wave antenna with a reflector consisting of two flat metal surfaces meeting at an angle behind the radiator [10] [18].

CORONA—The discharge of electricity from a conductor with a high potential [4].

CORRECTIVE MAINTENANCE—Includes location and repair of equipment failures [16].

CORRESPONDENCE—The term given to the positions of the rotors of a synchro transmitter and a synchro receiver when both rotors are on 0 degree or displaced from 0 degree by the same angle [15].

COULOMB—A measure of the quantity of electricity. One coulomb is equal to 6.28×10^{18} electrons [1].

COULOMB'S LAW—Also called the LAW OF ELECTRIC CHARGES or the LAW OF ELECTROSTATIC ATTRACTION. Coulomb's Law states that charged bodies attract or repel each other with a force that is directly proportional to the product of their individual charges and inversely proportional to the square of the distance between them [1].

COUNTER—A circuit that counts input pulses [9].

COUNTER EMF—The voltage generated within a coil by a moving magnetic field cutting across the coil itself. This voltage is in opposition (counter) to the moving field that created it. Counter emf is present in every motor, generator, transformer, or other inductance winding whenever an alternating current flows [2] [5].

COUNTERPOISE—A network of wire connected to a quarter-wave antenna at one end. The network provides the equivalent of an additional one-fourth wavelength [10].

COUPLING—The process of transferring energy from one point in a circuit to another point, or from one circuit to another [8].

COUPLING CAPACITOR—A capacitor used to couple signals [8].

COUPLING DEVICE—A coupling coil that connects the transmitter to the feeder [10].

COVALENT BOND—A type of linkage between atoms in which the atoms share valence electrons [7].

CPR—Cardiopulmonary Resuscitation [1].

CREST (TOP)—The peak of the positive alternation (maximum value above the line) of a wave [10].

CRITICAL ANGLE—The maximum angle at which radio waves can be transmitted and still be refracted back to earth [10].

CRITICAL FREQUENCY—The maximum frequency at which a radio wave can be transmitted vertically and still be refracted back to earth [10].

CROSSED-FIELD AMPLIFIER—A high-power electron tube that converts dc to microwave power by a combination of crossed electric and magnetic fields [18].

CROSS-SECTIONAL AREA—The area of a "slice" of an object. When applied to electrical conductors it is usually expressed in circular mils [1].

CROWN-OF-THORNS TUNER—See SPROCKET TUNER [11].

CRYSTAL—A natural substance, such as quartz or tourmaline, that is capable of producing a voltage when under physical stress or of producing physical movement when a voltage is applied [9].

CRYSTAL FURNACE—A device for artificially growing cylindrical crystals to be used in the production of semiconductor substrates [14].

CRYSTAL MICROPHONE—A microphone that uses the piezoelectric effect of crystalline matter to generate a voltage from sound waves [12].

CRYSTAL OVEN—A closed oven maintained at a constant temperature in which a crystal and its holder are enclosed to reduce frequency drift [9].

CURRENT—The movement of electrons past a reference point. The passage of electrons through a conductor. Measured in amperes [1].

CURRENT-FEED METHOD—Same as CENTER-FEED METHOD [10].

CURRENT RATING—The safe current-carrying capacity of a wire or cable on a continuous basis [4].

CURRENT REGULATOR—A circuit that provides a constant current output [7].

CURRENT STANDING-WAVE RATIO (ISWR)—The ratio of maximum to minimum current along a transmission line [10].

CUSPS—Sharp phase reversals [12].

CUTOFF—The condition in a tube or transistor whereby the reverse bias prevents current flow [13].

CUTOFF FREQUENCY—The frequency at which the attenuation of a waveguide increases sharply and below which a traveling wave in a given mode cannot be maintained. A frequency with a half-wavelength that is greater than the wide dimension of a waveguide [11].

CW DEMODULATOR—A circuit that detects the presence of RF oscillations and converts them into a useful form [12].

CYCLE—(1) One complete positive and one complete negative alternation of a current or voltage [2] [10]. (2) A 360-degree rotation of a vector generating a sine wave [12].

CYLINDRICAL PARABOLIC REFLECTOR—A parabolically shaped reflector that resembles part of a cylinder [18].

DAMPED WAVE—A sinusoidal wave in which the amplitude steadily decreases with time. Often associated with energy loss [9].

DAMPING—(1) The process of smoothing out oscillations. (2) In a meter, this process is used to keep the pointer of the meter from overshooting the correct reading [3]. (3) A mechanical or electrical technique used in synchro receivers to prevent the rotor from oscillating or spinning. Damping is also used in servosystems to minimize overshoot of the load [15] [16].

D'ARSONVAL METER MOVEMENT—The permanent-magnet moving-coil movement used in most meters [3] [16].

DATA PROCESSING—The execution of a systematic sequence of operations performed upon data. Synonymous with information processing [13].

DATA TRANSMISSION—The transfer of information from one place to another or from one part of a system to another [15].

dBm—An abbreviation used to represent power levels above or below a 1-milliwatt reference [16].

DEAD SHORT—A short circuit having minimum resistance [1].

DECIMAL—Pertaining to the number representation system with a radix of ten [13].

DECIMAL DIGIT—In decimal notation, one of the characters 0 through 9 [13].

DECIMAL NOTATION—A fixed radix notation where the radix is ten [13].

DECIMAL NUMERAL—A decimal representation of a number [13].

DECIMAL POINT—The radix point in decimal representation [13].

DECOUPLING CAPACITOR—A capacitor used to transfer unwanted signals out of a circuit; for example, coupling an unwanted signal to ground. Also called a BYPASS CAPACITOR [8].

DEFLECTION COILS—In a cathode-ray tube, coils used to bend an electron beam a desired amount [18].

DEFLECTION PLATES—Two pairs of parallel electrodes, one pair set forward of the other and at right angles to each other, parallel to the axis of the electron stream within an electrostatic cathode-ray tube [6].

DEGENERATION—The process whereby a part of the output signal of an amplifying device is returned to its input circuit in such a manner that it tends to cancel part of the input [7].

DEGENERATIVE FEEDBACK—Feedback in which the feedback signal is out of phase with the input signal; also called NEGATIVE FEEDBACK [8].

DEGREE-OF-FREEDOM—The number of axes about which a gyro is free to precess [15].

DEIONIZATION POTENTIAL—The potential at which ionization of the gas within a gas-filled tube ceases and conduction stops; also referred to as extinction potential [6].

DEIONIZATION TIME—In a spark gap, the time required for ionized gas to return to its neutral state after the spark is removed [18].

DELTA—A three-phase connection in which windings are connected end-to-end, forming a closed loop that resembles the Greek letter delta. A separate phase wire is then connected to each of the three junctions [5].

DEMODULATION—The removal of intelligence from a transmission medium [12].

DEMODULATOR—A circuit used in servosystems to convert an ac signal to a dc signal. The magnitude of the dc output is determined by the magnitude of the ac input signal, and its polarity is determined by whether the ac input signal is in or out of phase with the ac reference voltage [15].

DeMORGAN'S THEOREM—A theorem which states that the inversion of a series of AND applications is equal to the same series of inverted OR applications, or the inversion of a series of OR applications is equal to the same series of inverted AND applications. In symbols,

$$\overline{A \cdot B \cdot C} = \overline{A} + \overline{B} + \overline{C} \text{ or}$$
$$\overline{A + B + C} = \overline{A} \cdot \overline{B} \cdot \overline{C} \text{ [13].}$$

DENSITY—(1) The compactness of a substance. (2) Mass per unit volume [10].

DEPLETION REGION—The region in a semiconductor where essentially all free electrons and holes have been swept out by the electrostatic field which exists there [7].

DEPOT-LEVEL MAINTENANCE (SM&R CODE D)—Supports SM&R Code I and SM&R Code O activities through extensive shop facilities and equipment and highly skilled personnel [14].

DESIGNATION—Operational phase of a fire-control or track radar during which the radar is directed to the general direction of a desired target [18].

DETECTION—The separation of low-frequency (audio) intelligence from the high-frequency carrier [17].

DETECTOR—A mixer or converter in a superheterodyne receiver [18].

DICE—Uncased chips [14].

DIE BONDING—Process of mounting a chip to a package [14].

DIELECTRIC—An insulator; a term applied to the insulating material between the plates of a capacitor [2].

DIELECTRIC CONSTANT—The ratio of a given dielectric to the dielectric value of air [2] [11].

DIELECTRIC FIELD—The space between and around charged bodies in which their influence is felt. Also called ELECTRIC FIELD OF FORCE or an ELECTROSTATIC FIELD [1].

DIELECTRIC HEATING—The heating of an insulating material by a high-frequency electric field [10].

DIELECTRIC HYSTERESIS LOSS—Power loss of a capacitor because of the changes in orientation of electron orbits in the dielectric; the changes in orientation are caused by rapid reversal in polarity of line voltage. The higher the frequency, the greater the loss [2].

DIELECTRIC LEAKAGE—Power loss of a capacitor because of the leakage of current through the dielectric. Also relates to leakage resistance; the higher the leakage resistance, the lower the dielectric leakage [2].

DIELECTRIC LOSSES—The losses resulting from the heating effect on the dielectric material between conductors [10] [11].

DIELECTRIC STRENGTH—The ability of an insulator to withstand a potential difference without breaking down (usually expressed in terms of voltage) [4].

DIFFERENCE FREQUENCY—See BEAT FREQUENCY [18].

DIFFERENCE OF POTENTIAL—A voltage between two points [6].

DIFFERENTIAL AMPLIFIER—A circuit that amplifies the difference between two input signals [8].

DIFFRACTION—The bending of waves (as light or RF) when the waves are met with some form of obstruction [10].

DIFFUSION—(1) The scattering of reflected light waves from an object, such as white paper [10]. (2) Controlled application of impurity atoms to a semiconductor substrate [14].

DIGIT—A symbol that represents one of the nonnegative integers smaller than the radix. For example, in decimal notation a digit is one of the characters from 0 through 9 [13].

DIGITAL COMPUTER—(1) A computer in which discrete representation of data is used. (2) A computer that operates on discrete data by performing arithmetic and logic processes on these data [13].

DIODE—An electron tube containing two electrodes: a cathode and a plate [6]. (2) A two element, solid-state device made of either germanium or silicon; it is primarily used as a switching device [7] [13].

DIODE DETECTOR—A demodulator that uses one or more diodes to provide a rectified output with an average value that is proportional to the original modulation [12] [18].

DIPOLE—A common type of half-wave antenna made from a straight piece of wire cut in half. Each half operates at a quarter wavelength of the output [10].

DIRECT CURRENT—An electric current that flows in one direction only [1].

DIRECTIONAL ANTENNA—An antenna that radiates most effectively in only one direction [18].

DIRECTIONAL COUPLER—A device that samples the energy traveling in a waveguide in one direction only [11].

DIRECTIVITY—The ability of an antenna to radiate or receive more energy in some directions than in others. The degree of sharpness of the antenna beam [10] [11] [18].

DIRECTLY HEATED CATHODE—A wire, or filament, designed to emit the electrons that flow from cathode to plate. The filament is designed so that a current is passed through it; the current heats the filament to the point where electrons are emitted [6].

DIRECTOR—The parasitic element of an array that reinforces energy coming from the driver element [10].

DIRECT SHORT—Same as SHORT CIRCUIT [3].

DISCRETE COMPONENTS—Individual transistors, diodes, resistors, capacitors, and inductors [14].

DISCRIMINATOR—A circuit in which amplitude variations are derived in response to phase or frequency variations [18].

DISPERSION—The refraction of light waves that causes the different frequencies to bend at slightly different angles [10].

DISPLACEMENT CURRENT—The current that appears to flow through a capacitor [2].

DISTILLED WATER—Water that has been purified through a process of evaporation and condensation [18].

DISTORTION—Any unwanted change between an input signal and output signal [6] [8].

DISTRIBUTED CONSTANTS—The constants of inductance, capacitance, and resistance in a transmission line. They are spread along the entire length of the line and cannot be distinguished separately [10].

DISTRIBUTIVE LAW—In Boolean algebra the law which states that if a group of terms connected by like operators contains the same variable, the variable may be removed from the terms and associated with them by the appropriate sign of operation (for example, $A(B + C) = AB + AC$) [13].

DOMAIN THEORY—A theory of magnetism based upon the electron-spin principle. Spinning electrons have a magnetic field. If more electrons spin in one direction than another, the atom is magnetized [1].

DOMINANT MODE—The easiest mode to produce in a waveguide, and the most efficient mode in terms of energy transfer [11].

DONOR—An impurity that can make a semiconductor material an N-type by donating extra "free" electrons to the conduction band [7].

DONOR IMPURITY—See PENTAVALENT IMPURITY [7].

DOORKNOB TUBE—An electron tube that is similar to the acorn tube but larger. The doorknob tube is designed to operate, at high power, in the uhf frequencies [6].

DOPING—The process of adding impurities to semiconductor crystals to increase the number of free charges that can be moved by an external, applied voltage. Doping produces N-type or P-type material [7] [14].

DOPPLER EFFECT—(1) The apparent change in frequency or pitch when a sound source moves either toward or away from a listener [10]. (2) In radar, the change in frequency of a received signal caused by the relative motion between the radar and the target [18].

DOPPLER FREQUENCY—The difference between transmitted and reflected frequencies; caused by the Doppler effect [18].

DOUBLE-MODING—In a transmitter output tube, the abrupt and random change from one frequency to another [18].

DOUBLE NEGATIVE LAW—In Boolean algebra, the law which states that the complement of a complement is the equivalent of the original term [13].

DOUBLE RECEIVER—A fine and coarse synchro receiver enclosed in a common housing with a two-shaft output (one shaft inside the other) [15].

DOUBLET—Another name for the dipole antenna [10].

DOUBLING UP—This is a type of two-equipment installation where one unit can be substituted for another in the event of failure [17].

DOWN LINK—The frequency used to transmit an amplified signal from a satellite or other craft back to earth [17].

DRIFT SPACE—In an electron, a region free of external fields in which relative electron position depends on velocity [11].

DRIVEN ARRAY—An array in which all of the elements are driven [10].

DRIVEN ELEMENT—The element of an antenna connected directly to the transmission line [10].

DRIVER—The final stage of amplification [8].

DRUM-TYPE ARMATURE—An efficient, popular type of armature designed so that the entire length of the winding is cutting the field at all times. Most wound armatures are of this type [5].

DRY-AIR SYSTEM—Provides dehumidified air for electronic equipment that is moisture critical [18].

DRY CELL—An electrical cell in which the electrolyte is not a liquid. In most dry cells the electrolyte is in the form of a paste [1].

DUAL-GATE MOSFET—A two-gate MOSFET in which either gate can control the conductor independently, a fact which makes this MOSFET very versatile [7].

DUAL IN-LINE PACKAGE (DIP)—IC package having two parallel rows of preformed leads [14].

DUCTILE—Easily drawn out (as to form filaments or wires) [4].

DUCTING—Trapping of an RF wave between two layers of the earth's atmosphere or between an atmospheric layer and the earth [18].

DUMMY ANTENNA—See DUMMY LOAD [16].

DUMMY LOAD—A dissipative but nonradiating device that has the impedance characteristics of an antenna or transmission line. Also called ARTIFICIAL LOAD [11] [16] [17].

DUPLEXER—A radar device that switches the antenna from the transmitter to the receiver and vice versa [18].

DUTY CYCLE—In a transmitter, ratio of time on to time off [12] [18].

DYNAMIC MICROPHONE—A device in which sound waves move a coil of fine wire that is mounted on the back of a diaphragm and located in the magnetic field of a permanent magnet [12].

ECHO—(1) The reflection of the original sound wave as it bounces off a distant surface [10]. (2) The RF signal reflected back from a radar target [18].

ECHO BOX—A resonant cavity device that is used to check the overall performance of a radar system. It receives a portion of the transmitted pulse and retransmits it back to the receiver as a slowly decaying transient [18].

ECLIPSE—A condition in which the satellite is not in view or in direct line of sight with the sun. This happens when the earth is between them [17].

EDDY CURRENT—Induced circulating currents in a conducting material that are caused by a varying magnetic field [2] [5].

EDDY CURRENT LOSS—Losses caused by random current flowing in the core of a transformer. Power is lost in the form of heat [2].

EDISON EFFECT—Also called RICHARDSON EFFECT. The phenomenon wherein electrons emitted from a heated element within a vacuum tube will flow to a second element that is connected to a positive potential [6].

EFFECTIVE VALUE—Same as ROOT-MEAN-SQUARE [2].

EFFICIENCY—The ratio of output-signal power compared to the total input power, generally expressed as a percentage [1] [7].

E-FIELD—Electric field that exists when a difference in electrical potential causes a stress in the dielectric between two points [11].

ELASTICITY—The ability of a substance to return to its original state [10].

ELECTRIC CURRENT—The flow of electrons [1].

ELECTRIC (E) FIELD—The field of force that is produced as a result of a voltage charge on a conductor or antenna [10] [11].

ELECTRICAL CHARGE—Symbol **Q, q**. Electric energy stored on or in an object. The negative charge is caused by an excess of electrons; the positive charge is caused by a deficiency of electrons [1].

ELECTRICAL CHEMICAL—The action of converting chemical energy into electrical energy [1].

ELECTRICAL-LOCK—A synchro zeroing method. This method is used only when the rotors of the synchros to be zeroed are free to turn and their leads are accessible [15].

ELECTRICAL POWER SYSTEM—Provides the necessary input power [18].

ELECTRICAL SYMBOLS—Graphic symbols used to illustrate the various electrical or electronic components of a circuit [4].

ELECTRICAL ZERO—A standard synchro position, with a definite set of stator voltages, that is used as the reference point for alignment of all synchro units [15].

ELECTRODE—The terminal at which electricity passes from one medium into another, such as in an electrical cell where the current leaves or returns to the electrolyte [1].

ELECTRODYNAMIC METER MOVEMENT—A meter movement using fixed field coils and a moving coil; usually used in ammeters and wattmeters [3].

ELECTRODYNAMOMETER—A meter using an electrodynamic movement to measure an electric current [16].

ELECTROLYSIS—The process of changing the chemical composition of a material by passing an electric current through it [4] [11].

ELECTROLYTE—A solution of a substance that is capable of conducting electricity. An electrolyte may be in the form of either a liquid or a paste [1].

ELECTROMAGNET—An electrically excited magnet capable of exerting mechanical force or of performing mechanical work [1].

ELECTROMAGNETIC—The term describing the relationship between electricity and magnetism. A quality that combines both magnetic and electric properties [1].

ELECTROMAGNETIC FIELD—The combination of an electric (E) field and a magnetic (H) field [10].

ELECTROMAGNETIC INDUCTION—The production of a voltage in a coil because of a change in the number of magnetic lines of force (flux linkages) passing through the coil [1] [2].

ELECTROMAGNETIC INTERFERENCE—Man-made or natural interference that degrades the quality of reception of radio waves [10] [17].

ELECTROMAGNETIC RADIATION—The radiation of radio waves into space [10].

ELECTROMAGNETISM—The generation of a magnetic field around a current-carrying conductor [2] [3].

ELECTROMOTIVE FORCE (emf)—The force (voltage) that produces an electric current in a circuit [2].

ELECTRON—The elementary negative charge that revolves around the nucleus of an atom [1].

ELECTRON GUN—An electrode of a CRT that is equivalent to the cathode and control grid of conventional tubes. The electron gun produces a highly concentrated stream of electrons [6].

ELECTRON ORBITAL MOVEMENT—The movement of an electron around the nucleus of an atom [11].

ELECTRON SHELL—A group of electrons which have a common energy level that forms part of the outer structure (shell) of an atom [1].

ELECTRONIC COUNTER-COUNTERMEASURES (ECCM) CIRCUITS—See ANTIJAMMING CIRCUITS [18].

ELECTRONIC-EQUIPMENT DEHYDRATOR—A device that provides an alternate dry-air input in the event of failure of the central dry-air system. It may include a compressor [18].

ELECTRONIC FREQUENCY COUNTER—An instrument that counts the number of cycles (pulses) occurring during a precise time interval [18].

ELECTRONIC SCANNING—Scanning in which the axis of the beam is moved, relative to the antenna axis, in a desired pattern [18].

ELECTRONIC SWITCH—A circuit that causes a start-and-stop switching action by electronic means [13].

ELECTRONICS DRY-AIR BRANCH—A common line for providing dry air to various electronic equipment, such as search radar, fire-control radar, and repeaters [18].

ELECTRONIC TUNING—In a reflex klystron, changing the frequency and output power of the tube by altering the repeller voltage [11].

ELECTRON SPIN—The movement of an electron around its axis [11].

ELECTROSTATIC—Pertaining to electricity at rest, such as charges on an object (static electricity) [1].

ELECTROSTATIC DEFLECTION—The method of deflecting an electron beam by passing it between parallel charged plates mounted inside a cathode-ray tube [6].

ELECTROSTATIC FIELD—The field of influence between two differently charged bodies [2].

ELECTROSTATIC METER MOVEMENT—A meter movement that uses the electrostatic repulsion of two sets of charged plates (one fixed and the other movable). This meter movement reacts to voltage rather than to current and is used to measure high voltage [3].

ELECTROSTATIC STRESS—The force exerted on an insulator by the voltage in a conductor [4].

ELEMENT—(1) A substance, in chemistry, that cannot be divided into simpler substances by any means ordinarily available [1]. (2) A part of an antenna that can be either an active radiator or a parasitic radiator [10].

ELEPHANT TRUNK—Ducting used for ventilation purposes [4].

ELEVATION ANGLE—The angle between the horizontal plane and the line of sight to a target or object [11] [18].

EMERGENCY POWER—Temporary source of limited electrical power used upon the loss of the normal power source [18].

EMF (ELECTROMOTIVE FORCE)—The force that causes electricity to flow between two points with different electrical charges or when there is a difference of potential between the two points. The unit of measurement is volts [1].

EMITTER—The element in a transistor that emits current carriers (electrons or holes) [7] [13].

EMITTER-INJECTION MODULATOR—The transistor equivalent of the cathode modulator. The gain is varied by changing the voltage on the emitter [12].

ENAMEL—A synthetic compound of cellulose acetate (wood pulp and magnesium). Used to insulate wire in meters, relays, and motor windings [4].

ENCAPSULATED—Imbedded in solid material or enclosed in glass or metal [14].

END-FEED METHOD—A method in which one end of an antenna is connected through a capacitor to the final output stage of a transmitter [10].

END-FIRE ARRAY—An array in which the direction of radiation is parallel to the axis of the array [10].

ENERGY—The ability or capacity to do work [1].

EPHEMERIS—A table showing the precalculated position of a satellite at any given time [17].

E_p-I_p CURVE—The characteristic curve of an electron tube used to graphically depict the relationship between plate voltage (E_p) and plate current (I_p) [6].

EPITAXIAL PROCESS—A method of depositing a thin, uniformly doped crystalline region (layer) on a substrate [14].

EQUATORIAL ORBIT—An orbit that occurs when the plane of a satellite coincides with the plane of the earth at the equator [17].

EQUIVALENT RESISTANCE (R_{eq})—A resistance that represents the total ohmic values of a circuit component or group of circuit components. Usually drawn as a single resistor in a simplified circuit [1].

ERECTING (A GYRO)—The positioning of a gyro into a desired position and the maintaining of that position [15].

ERROR DETECTOR—The component in a servosystem that determines when the load has deviated from its ordered position, velocity, and so forth [15].

ERROR REDUCER—The name commonly given to the servomotor in a servosystem. So named because it reduces the error signal by providing feedback to the error detector [15].

ERROR SIGNAL—(1) In servosystems, the signal whose amplitude and polarity or phase are used to correct the alignment between the controlling and the controlled elements. (2) The name given to the electrical output of a control transformer [15].

E-TRANSFORMER—A special form of differential transformer employing an E-shaped core. The secondaries of the transformer are wound on the outer legs of the E, and the primary is wound on the center leg. An output voltage is developed across the secondary coils when its armature is displaced from its neutral position. This device is used as an error detector in servosystems that have limited load movements [15].

E-TYPE T-JUNCTION—A waveguide junction in which the junction arm extends from the main waveguide in the same direction as the E-field in the waveguide [11].

EUTECTIC ALLOY—An alloy that changes directly from a solid to a liquid with no plastic or semiliquid state [14].

EUTECTIC SOLDER—An alloy of 63 percent tin and 37 percent lead. Melts at 361° F [14].

EXCITATION VOLTAGE—The supply voltage required to activate a circuit [15].

EXCITING CURRENT—The current that flows in the primary winding of a transformer when the secondary is open-circuited; it produces a magnetic flux field. Also called magnetizing current [2].

EXCLUSIVE OR—A function whose output is a 1 if one and only one of the input variables is a 1 [13].

EXCLUSIVE-OR GATE—A gate that produces a logic 1 output when the inputs are different, but not when they are the same [13].

EXPONENT—The numeral written in superscript (10^2) which indicates the power to which the base is to be raised [13].

EXPRESSION—A validated series of variables, constants, and functions that can be connected by operating symbols to describe a desired computation [13].

EXTERNALLY EXCITED METER—A term used to describe meters that get their power from the circuit to which they are connected [16].

EXTERNALLY SYNCHRONIZED RADAR—A radar system in which timing pulses are generated by a master oscillator external to the transmitter [18].

EXTREMELY HIGH FREQUENCY—The band of frequencies from 30 gigahertz to 300 gigahertz [17].

EXTREMELY LOW FREQUENCY—The band of frequencies up to 300 hertz [17].

EXTRINSIC—A semiconductor in which impurities have been added to create certain charge carrier concentrations [7].

FACSIMILE—The method for transmitting and receiving still images. These images can be maps, photographs, and handwritten or printed text [17].

FACTOR—Any of the elements, quantities, or symbols that, when multiplied together, form a product [13].

FADING—Variations in signal strength by atmospheric conditions [101 [17].

FARAD—The basic unit of capacitance. A capacitor has a capacitance of 1 farad when a voltage potential of 1 volt across it produces a charge of 1 coulomb [2].

FARADAY ROTATION—The rotation of the plane of polarization of electromagnetic energy when it passes a substance influenced by a magnetic field that has a component in the direction of propagation [11].

FAST-TIME-CONSTANT CIRCUIT—Differentiator circuit in the first video amplifier that allows only the leading edges of target returns, no matter how small or large, to be used [18].

FEEDBACK—The return of a portion of the output of a circuit to its input [8] [18].

FEEDER—A transmission line that carries energy to the antenna [10].

FEEDHORN—A horn radiator used to feed a reflector [18].

FEP—A synthetic type of insulation (fluorinated ethylene propylene) [4].

FERRITE—A powdered and compressed ferric oxide material that has both magnetic properties and light resistance to current flow [11].

FERRITE SWITCH—A ferrite device that blocks the flow of energy through a waveguide by rotating the electric field 90 degrees. The rotated energy is then reflected or absorbed [11].

FERROMAGNETIC MATERIAL—A highly magnetic material, such as iron, cobalt, nickel, or their alloys [1].

FERRULES—The cylindrical metallic ends of a cartridge fuse [3].

FIBER OPTICS—Conductors or optical waveguides that readily pass light [17].

FIBROUS BRAID—An outer covering used to protect a conductor's insulating material. Commonly made from cotton, linen, silk, rayon, or fiberglass [4].

FIDELITY—(1) The faithful reproduction of a signal. (2) The accuracy with which a system reproduces a signal at its output that faithfully maintains the essential characteristics of the input signal [7] [8] [12] [17].

FIELD—The electromagnet which furnishes the magnetic field that interacts with the armature in motors and generators [5].

FIELD-EFFECT TRANSISTOR (FET)—A transistor consisting of a source, a gate, and a drain. Current flow is controlled by the transverse electric field under the gate [7].

FIELD EXCITATION—The creation of a steady magnetic field within the field windings by the application of a dc voltage either from the generator itself or from an external source [5].

FIELD OF FORCE—A term used to describe the total force exerted by an action-at-a-distance phenomenon such as gravity upon matter, electric charges acting upon electric charges, and magnetic forces acting upon other magnets or magnetic materials [1].

FILAMENT—The cathode of a thermionic tube, usually a wire or ribbon, which is heated by current passing through it [6].

FILM ICs—Conductive or nonconductive material deposited on a glass or ceramic substrate. Used for passive circuit components, resistors, and capacitors [14].

FILTER—A selective network of resistors, capacitors, and inductors that offers comparatively little opposition to certain frequencies, while blocking or attenuating other frequencies [6] [9].

FINAL POWER AMPLIFIER (FPA)—The final stage of amplification in a transmitter [12].

FIRST DETECTOR—See MIXER [18].

FIXED BIAS—A constant value of bias voltage [6] [7] [13].

FIXED RESISTOR—A resistor having a definite resistance value that cannot be adjusted [1].

FIXED SPARK GAP—A device used to discharge the pulse-forming network. A trigger pulse ionizes the air between two contacts to initiate the discharge [12].

FLAT LINE—A transmission line that has no standing waves. This line requires no special timing devices to transfer maximum power [10].

FLAT PACK—An IC package [14].

FLEMING VALVE—An earlier name for a diode, or a two-electrode vacuum tube used as a detector [6].

FLEXIBLE COAXIAL LINE—A line made with an inner conductor that consists of flexible wire insulated from the outer conductor by a solid, continuous insulating material [10].

FLIP CHIP—A monolithic IC packaging technique that eliminates the need for bonding wires [14].

FLIP-FLOP—A device having two stable states and two input terminals (or types of input signals), each of which corresponds with one of the two states. The circuit remains in either state until caused to change to the other state by application of a voltage pulse. A similar bistable device with an input that allows it to act as a single-stage binary counter [13].

FLUX—(1) In electrical or electromagnetic devices, a general term used to designate collectively all the electric or magnetic lines of force in a region [1]. (2) A solution that removes surface oxides from metals being soldered [2] [14].

FLUX DENSITY—The number of magnetic lines of force passing through a given area [1].

FLYWHEEL EFFECT—The ability of a resonant circuit to operate continuously because of stored energy or energy pulses [9].

FOCUSING ANODE—An electrode of a CRT that is used to focus the electrons into a tight beam [6].

FOLDED DIPOLE—An ordinary half-wave antenna (dipole) that has one or more additional conductors connected across the ends parallel to each other [10].

FORBIDDEN BAND—The energy band in an atom lying between the conduction band and the valence band. Electrons are never found in the forbidden band but may travel back and forth through it. The forbidden band determines whether a solid material will act as a conductor, a semi-conductor, or an insulator [7].

FORWARD AGC—The type of AGC that causes an amplifier to be driven towards saturation [17].

FORWARD BIAS—An external voltage that is applied to a PN junction in the conducting direction so that the junction offers only minimum resistance to the flow of current. Conduction is accomplished by majority current carriers (holes in P-type material; electrons in N-type material) [7] [13] [14].

FORWARD RESISTANCE—The smaller resistance value observed when you are checking the resistance of a semiconductor [16].

FOSTER-SEELEY DISCRIMINATOR—A circuit that uses a double-tuned RF transformer to convert frequency variations in the received FM signal to amplitude variations. Also known as a phase-shift discriminator [12].

FOUR-ELEMENT ARRAY—An antenna array with three parasitic elements and one driven element [10].

FRAMING—The process of synchronizing a facsimile receiver to a transmitter. This allows proper picture reproduction [17].

FREE CHARGES—Those electrons that can be moved by an externally applied voltage [7].

FREE-SPACE LOSS—The loss of energy of radio waves caused by the spreading of the wavefront as it travels from the transmitter [10].

FREQUENCY (f)—(1) The number of complete cycles per second existing in any form of wave motion, such as the number of cycles per second of an alternating current [2] [10]. (2) The rate at which the vector that generates a sine wave rotates [12].

FREQUENCY COMPENSATION NETWORK—Circuit modification used to improve or broaden the linearity of its frequency response [18].

FREQUENCY CUTOFF—The frequency at which the filter circuit changes from an action of rejecting the unwanted frequencies to an action of passing the desired frequencies. Conversely, the point at which the filter circuit changes from an action in which it passes the desired frequencies to an action in which it rejects the undesired frequencies [9].

FREQUENCY-DETERMINING NETWORK—A circuit that provides the desired response (maximum or minimum impedance) at a specific frequency [8].

FREQUENCY DEVIATION—The amount the frequency varies from the carrier frequency [12].

FREQUENCY DIVERSITY—Transmitting (and receiving) of radio waves on two different frequencies simultaneously [10].

FREQUENCY-DIVISION MULTIPLEXING—Multiplexing that transmits and receives the full 360 degrees of each sine wave [17].

FREQUENCY METER—A meter used to measure the frequency of an ac signal [3] [16].

FREQUENCY MODULATION (fm)—Angle modulation in which the modulating signal causes the carrier frequency to vary. The amplitude of the modulating signal determines how far the frequency changes, and the frequency of the modulating signal determines how fast the frequency changes [12].

FREQUENCY MULTIPLIERS—Special RF power amplifiers that multiply the input frequency [12].

FREQUENCY RESPONSE—The measure of a servo's ability to respond to various input frequencies [15].

FREQUENCY-RESPONSE CURVE—A curve showing the output of an amplifier (or any other device) in terms of voltage or current plotted against frequency with a fixed-amplitude input signal [8].

FREQUENCY SCANNING—Varying the output frequency to achieve electronic scanning [18].

FREQUENCY-SHIFT KEYING (fsk)—Frequency modulation somewhat similar to continuous-wave (cw) keying in AM transmitters. The carrier is shifted between two differing frequencies by opening and closing a key [12].

FREQUENCY SPECTRUM—In a radar, the entire range of frequencies contained in an RF pulse or signal [18].

FREQUENCY STABILITY—Refers to the ability of an oscillator to accurately maintain its operating frequency [9].

FREQUENCY SYNTHESIS—A process that uses hetrodyning and frequency selection to produce a signal [17].

FREQUENCY SYNTHESIZER—(1) A frequency source of high accuracy [17]. (2) A bank of oscillators in which the outputs can be mixed in various combinations to produce a wide range of frequencies [18].

FRONT-TO-BACK RATIO—The ratio of the energy radiated in the principal direction compared to the energy radiated in the opposite direction [10].

FULL-WAVE RECTIFIER—A circuit that uses both positive and negative alternations in an alternating current to produce direct current [6] [7].

FULL-WAVE VOLTAGE DOUBLER—Consists of two half-wave voltage rectifiers and is used to reduce the output ripple amplitude [7].

FUNCTION—A specific purpose of an entity; its characteristic action [13].

FUNDAMENTAL FREQUENCY—The basic frequency or first harmonic frequency [10].

FUSED-ALLOY JUNCTION—See ALLOYED-JUNCTION [7].

GAIN—(1) The ratio between the amount of energy propagated from an antenna that is directional compared to the energy from the same antenna that would be propagated if the antenna were not directional [10]. (2) Any increase in the strength of a signal [18].

GAIN-BANDWIDTH PRODUCT—The number that results when the gain of a circuit is multiplied by the bandwidth of that circuit. For an operational amplifier, the gain-bandwidth product for one configuration will always equal the gain-bandwidth product for any other configuration of the same amplifier [8].

GALENA—A crystalline form of lead sulfide used in early radio receivers [7].

GALVANOMETER—A meter used to measure small values of current by electromagnetic or electrodynamic means [3] [4] [16].

GAMMA (γ)—The emitter-to-base current ratio in a common-collector configuration [7].

GANGED TUNING—The process used to tune two or more circuits with a single control [17].

GAS—One of the three states of matter; it has no fixed form or volume [1].

GATE—As applied to logic circuitry, one of several different types of electronic devices that will provide a particular output when specified input conditions are satisfied. Also, a circuit in which a signal switches another signal on or off [13].

GATED AGC—Circuit that permits automatic gain control to function only during short time intervals [18].

GATED-BEAM DETECTOR—An FM demodulator that uses a special gated-beam tube to limit, detect, and amplify the received FM signal. Also known as a quadrature detector [12].

GATING—The process of selecting those portions of a wave that exist during one or more selected time intervals or that have magnitudes between selected limits. Also, the application of a specific waveform to perform electronic switching [13].

GENERAL PURPOSE ELECTRONIC TEST EQUIPMENT (GPETE)—Test equipment that has the capability, without modification, to generate, modify, or measure a range of electronic functions required to test several equipments or systems of basically different designs [14] [16].

GENERATOR—A machine that converts mechanical energy to electrical energy by applying the principle of magnetic induction. A machine that produces ac or dc voltage, depending on the original design [5].

GENERATOR END—See INPUT END [10].

GERMANIUM—A grayish-white metal having semiconductor properties [7].

GETTER—An alkali metal introduced into a vacuum tube during manufacture. It is fired after the tube has been evacuated to react chemically with (and eliminate) any remaining gases [6].

GIMBAL—A mechanical frame, with two perpendicular intersecting axes of rotation, used to support and furnish a gyro wheel with the necessary freedom to tilt in any direction [15].

GLOW DISCHARGE—Discharge of electricity through a gas in an electron tube [18].

GRAMME-RING ARMATURE—An inefficient type of armature winding in which many of the turns are shielded from the field by its own iron ring [5].

GRAPH—A pictorial presentation of the relation between two or more variable quantities, such as between an applied voltage and the current it produces in a circuit [1].

GRID BIAS—A constant fixed potential applied between the grid and the cathode of a vacuum tube to establish an operating point [6].

GRID CURRENT—The current that flows in the grid-to-cathode circuit of a vacuum tube [6].

GRID-GAP TUNING—A method of changing the center frequency of a resonant cavity by physically changing the distance between the cavity grids [11].

GRID-LEAK BIAS—A self-bias provided by a high resistance connected across the grid capacitor or between the grid and cathode [6].

GROUND—(1) The point in a circuit used as a common reference point for measuring purposes. (2) To connect some point of an electrical circuit or some item of electrical equipment to earth or to the conducting medium used in lieu thereof [13].

GROUND CLUTTER—Unwanted echoes, from surrounding land masses, that appear on a radar indicator [18].

GROUND-CONTROLLED APPROACH—A radar system used to guide aircraft to safe landings in poor visibility conditions [18].

GROUND PLANE—The portion of a ground-plane antenna that acts as ground [10].

GROUND-PLANE ANTENNA—A type of antenna that uses a ground plane as a simulated ground to produce low-angle radiation [10].

GROUND PLANES—Copper planes used to minimize interference between circuits and from external sources [14].

GROUND POTENTIAL—Zero potential with respect to the ground or earth [1].

GROUND RANGE—The distance on the surface of the earth between a radar and its target. Equal to slant range only if both radar and target are at the same altitude [18].

GROUND REFLECTION LOSS—The loss of RF energy each time a radio wave is reflected from the earth's surface [10].

GROUND SCREEN—A series of conductors buried below the surface of the earth and arranged in a radial pattern. Used to reduce losses in the ground [10].

GROUND WAVES—Radio waves which travel near the surface of the earth [10].

GROUP—A collection of units, assemblies, subassemblies, and parts. It is a subdivision of a set or system but is not capable of performing a complete operational function [17].

GROUP VELOCITY—The forward progress velocity of a wave front in a waveguide [11].

GROWN JUNCTION—A method of mixing P-type and N-type impurities into a single crystal while the crystal is being grown [7].

GUIDANCE RADAR—A system which provides information that is used to guide a missile to a target [18].

GYRO—Abbreviation for gyroscope [15].

GYROSCOPE—A mechanical device containing a spinning mass mounted so that it can assume any position in space [15].

HALF-POWER POINT—A point on a waveform or radar beam that corresponds to half the power of the maximum power point [8] [9] [18].

HALF-WAVE DIPOLE ANTENNA—An antenna, consisting of two rods (1/4 wavelength each) in a single line, that radiates electromagnetic energy [10].

HALF-WAVE RECTIFIER—A rectifier using only one-half of each cycle to change ac to pulsating dc [61 [7].

HALF-WAVE VOLTAGE DOUBLER—Two half-wave voltage rectifiers connected to double the input voltage [7].

HAND OVER—The operation where one earth terminal yields control to another as a satellite moves out of its area of coverage [17].

HARD-TUBE MODULATOR—A high-vacuum electron tube modulator that uses a driver for pulse forming [18].

HARMONIC—A frequency that is a whole-number multiple of a smaller base frequency [9] [10] [12] [17].

HEATER—Same as a FILAMENT [6].

HEAT SHUNT—A device (preferably a clip-on type) used to absorb heat and protect heat-sensitive components during soldering [4].

HEIGHT-FINDING RADAR—A radar that provides target altitude, range, and bearing data [18].

HELIX—(1) A spirally wound transmission line used in a traveling-wave tube to delay the forward progress of the input traveling wave [11]. (2) A large coil of wire. It acts as a coil and is used with variable inductors for impedance matching of high-power transmitters [17].

HELIX HOUSE—A building at a transmitter site that contains antenna loading, coupling, and tuning circuits [17].

HENRY (H)—The electromagnetic unit of inductance or mutual inductance. The inductance of a circuit is 1 henry when a current variation of 1 ampere per second induces 1 volt. In electronics, smaller units are used, such as the millihenry (mH), which is one-thousandth of a henry (H), and the microhenry (μH) which is one-millionth of a henry [2].

HERTZ (Hz)—A unit of frequency equal to one cycle per second [2].

HERTZ ANTENNA—A half-wave antenna that is installed some distance above ground and positioned either vertically or horizontally [10].

HETERODYNE DETECTION—The use of an a.f. voltage to distinguish between available signals. The incoming cw signal is mixed with locally generated oscillations to give an a.f. output [12].

HETERODYNING—(1) The process of mixing two frequencies across a nonlinear impedance [12]. (2) The process of mixing the incoming signal with the local oscillator frequency. This produces the two fundamentals and the sum and difference frequencies [17].

HEXADECIMAL—Same as SEXADECIMAL. A number system with a base of sixteen; also pertains to conditions, choices, or selections that have sixteen possible values or states [13].

HEXADECIMAL SYSTEM—Pertaining to the number system with a radix of sixteen. It uses the ten digits of the decimal system and the first six letters of the English alphabet [13].

H-FIELD—Any space or region in which a magnetic force is exerted. The magnetic field may be produced by a current-carrying coil or conductor, by a permanent magnet, or by the earth itself [11].

HIGH FREQUENCY—The band of frequencies from 3 megahertz to 30 megahertz [17].

HIGH-FREQUENCY COMPENSATION—See PEAKING COIL [8].

HIGH-LEVEL MODULATION—Modulation produced in the plate circuit of the last radio stage of the system [12].

HIGH-PASS FILTER—A filter that passes a majority of the high frequencies on to the next circuit and rejects, or attenuates, the lower frequencies. Also called a LOW-FREQUENCY DISCRIMINATOR [9].

HITS PER SCAN—The number of times an RF beam strikes a target per antenna revolution [18].

HOLE FLOW—In the valence band, a process of conduction in which electrons move into holes, thereby creating other holes that appear to move toward a negative potential. (The movement of holes is opposite the movement of electrons.) [7]

HORIZONTAL AXIS—On a graph, the straight line axis that is plotted from left to right [10].

HORIZONTAL-DEFLECTION PLATES—A pair of parallel electrodes that moves the electron beam from side to side in a CRT [6].

HORIZONTALLY POLARIZED—Waves radiated with their E field component parallel to the earth's surface [10].

HORIZONTAL PATTERN—The part of a radiation pattern that is radiated in all directions along the horizontal plane [10].

HORIZONTAL PLANE—An imaginary plane that is tangent (or parallel) to the earth's surface at a given location [11] [18].

HORN—A funnel-shaped section of waveguide used as a termination device and as a radiating antenna [11].

HORN ANTENNA—See HORN RADIATOR [18].

HORN RADIATOR—A tapered, tubular or rectangular microwave antenna that is widest at the open end [18].

HORSEPOWER—The English unit of power equal to work done at the rate of 550 foot-pounds per second; equal to 746 watts of electrical power [1].

HORSESHOE MAGNET—A permanent magnet or electromagnet bent into the shape of a horseshoe or having a U-shape to bring the two poles near each other [1].

HOT CARRIER—A carrier, which may be either a hole or an electron, that has relatively high energy with respect to the carriers normally found in majority-carrier devices [11].

HOT-CARRIER DIODE—A semiconductor diode in which hot carriers are emitted from a semiconductor layer into the metal base. Also called HOT-ELECTRON DIODE. An example is the Schottky barrier diode [11].

HOT-WIRE METER MOVEMENT—A meter movement that uses the expansion of a heated wire to move the pointer of a meter; measures dc or ac [3].

H-TYPE T-JUNCTION—A waveguide junction in which the junction arm is parallel to the magnetic lines of force in the main waveguide [11].

HYBRID CIRCUIT—A circuit where passive components (resistors, capacitors) are deposited onto a substrate made of glass, ceramic, or other insulating material. Then the active components (diodes, transistors) are attached to the substrate and connected to the passive components on the substrate with a very fine wire [7].

HYBRID ICs—Two or more integrated circuit types, or one or more integrated circuit types and discrete components on a single substrate [14].

HYBRID JUNCTION—A waveguide junction that combines two or more basic T-junctions [11].

HYBRID MIXER—See BALANCED MIXER [18].

HYBRID RING—A hybrid-waveguide junction that combines a series of E-type T-junctions in a ring configuration. When properly terminated, energy is transferred from any one branch into any two of the remaining three branches [11] [18].

HYDROMETER—An instrument used to measure specific gravity. In batteries hydrometers are used to indicate the state of charge by the specific gravity of the electrolyte [1].

HYSTERESIS—The time lag of the magnetic flux in a magnetic material behind the magnetizing force producing it. Caused by the molecular friction of the molecules trying to align themselves with the magnetic force applied to the material [2].

HYSTERESIS LOSS—The power loss in an iron-core transformer or other alternating-current device as a result of magnetic hysteresis [2].

IC SYNCHROS—Obsolete synchros with reverse rotation and limited torque capabilities [15].

IDEMPOTENT LAW—In Boolean algebra, combining a quantity with itself either by logical addition or logical multiplication will result in a logical sum or product that is the equivalent of the quantity (for example, A + A = A; A • A = A) [13].

IDENTITY LAW—In Boolean algebra, the law which states that any expression is equal to itself (for example,

$$A = A, \text{ or } A = A \quad [13]$$

IDLER FREQUENCY—In a parametric amplifier, the difference between the input signal and the pump signal frequency. Also called the LOWER-SIDEBAND FREQUENCY [11].

IF AMPLIFIER—Usually a narrow-bandwidth IF amplifier that is tuned to one of the output frequencies produced by the mixer [18].

IGFET—Any field-effect transistor that has an insulated gate [7].

IMAGE FREQUENCY—An undesired frequency capable of producing the desired frequency through heterodyning [17].

IMPEDANCE—The total opposition offered to the flow of an alternating current. It may consist of any combination of resistance, inductive reactance, and capacitive reactance. The symbol for impedance is Z [2] [9].

IMPLOSION—The inward bursting of a CRT because of high vacuum. The opposite of explosion [6].

INCIDENT WAVE—(1) The wave that strikes the surface of a medium. (2) The wave that travels from the sending end to the receiving end of a transmission line [10].

IN-CIRCUIT METER—A meter permanently installed in a circuit; used to monitor circuit operation [3].

INCOHERENT—Refers to radiation on a broad band of frequencies [17].

INDEX OF REFRACTION—The degree of bending of an RF wave when passing from one medium to another [18].

INDICATOR—Equipment in radar that provides a visual presentation of target position information [18].

INDIRECTLY HEATED CATHODE—Same as the directly heated cathode with one exception: The hot filament raises the temperature of the sleeve around the filament; the sleeve then becomes the electron emitter [6].

INDUCED-CHANNEL MOSFET—A MOSFET in which there is no actual channel between the source and the drain. This MOSFET is constructed by making the channel of the same type of material as the substrate [7].

INDUCED CHARGE—An electrostatic charge produced on an object by the electric field that surrounds a nearby object [1].

INDUCED CURRENT—Current caused by the relative motion between a conductor and a magnetic field [1].

INDUCED ELECTROMOTIVE FORCE—The electromotive force induced in a conductor because of the relative motion between the conductor and a magnetic field [1].

INDUCED VOLTAGE—See INDUCED ELECTROMOTIVE FORCE [1].

INDUCTANCE—The property of a circuit that tends to oppose a change in the existing current flow. The symbol for inductance is L [2] [7].

INDUCTANCE BRIDGE—An ac bridge circuit used to measure an unknown value of inductance [16].

INDUCTION—The act or process of producing voltage and current by the relative motion of a magnetic field across a conductor [1].

INDUCTION FIELD—The electromagnetic field that is produced about an antenna when current and voltage are present on the same antenna [10].

INDUCTION LOSSES—The losses that occur when the electromagnetic field around a conductor cuts through nearby metallic objects and induces a current into that object [10].

INDUCTION MOTOR—A simple, rugged, ac motor with desirable characteristics. The rotor is energized by transformer action (induction) from the stator. Induction motors are used more than any other type [5].

INDUCTIVE COUPLING—Coupling of two coils by means of magnetic lines of force. In transformers, coupling applied through magnetic lines of force between the primary and secondary windings [2].

INDUCTIVE REACTANCE—The opposition to the flow of an alternating current caused by the inductance of a circuit, expressed in ohms. Identified by the symbol X_L [2] [9].

INERTIA—The physical tendency of a body in motion to remain in motion and a body at rest to remain at rest unless acted upon by an outside force (Newton's First Law of Motion) [15].

INFINITE—(1) Extending indefinitely, endless. (2) Boundless, having no limits. (3) An incalculable number [1].

INFRALOW FREQUENCY—The band of frequencies from 300 Hz to 3,000 Hz [19].

INFRASONIC (SUBSONIC)—Sounds below 15 Hz [10].

IN PHASE—Applied to the condition that exists when two waves of the same frequency pass through their maximum and minimum values of like polarity at the same instant [2].

INPUT—The current, voltage, power, or driving force applied to a circuit or device [13].

INPUT END—The end of a two-wire transmission line that is connected to a source [10].

INPUT IMPEDANCE—Impedance presented to the transmitter by the transmission line and its load [10].

INPUT/OUTPUT—Pertaining to either input or output or both, especially in data processors [13].

INSTANTANEOUS AMPLITUDE—The amplitude at any given point along a sine wave at a specific instant in time [12].

INSTANTANEOUS AUTOMATIC GAIN CONTROL (IAGC)—A circuit that can vary the gain of the radar receiver with each input pulse to maintain a nearly constant output peak amplitude [18].

INSTANTANEOUS VALUE—The magnitude at any particular instant when a value is continually varying with respect to time [2].

INSULATION—A material used to prevent the leakage of electricity from a conductor and to provide mechanical spacing or support as protection against accidental contact with the conductor [1] [4].

INSULATION RESISTANCE—The resistance offered by an insulating material to current leakage [4].

INSULATOR—(1) Material of such low conductivity that the flow of current through it can usually be neglected. (2) A device having high electrical resistance; used for supporting or separating conductors so as to prevent undesired flow of current from the conductors to other objects [1].

INTEGRATED CIRCUIT (IC)—(1) A circuit in which many elements are fabricated and interconnected by a single process (into a single chip), as opposed to a "nonintegrated" circuit in which the transistors, diodes, resistors, and other components are fabricated separately and then assembled [7]. (2) Elements inseparably associated and formed on or within a single substrate [14].

INTELLIGENCE—In communications any signal that conveys information (voice, teletypewriter, facsimile) [17].

INTENSITY (OF SOUND)—The measurement of the amplitude of sound energy. Generally synonymous with loudness [10].

INTERACTION SPACE—The region in an electron tube where the electrons interact with an alternating electromagnetic field [11].

INTERCEPT—The point where two lines drawn on a graph cross each other [10].

INTERELECTRODE CAPACITANCE—The capacitance between the electrodes of an electron tube [6] [11].

INTERFERENCE—Any disturbance that produces an undesirable response or degrades a signal [10].

INTERMEDIATE FREQUENCY (IF)—A lower frequency to which an RF echo is converted for ease of amplification [18].

INTERMEDIATE-LEVEL MAINTENANCE (SM&R Code I)—Direct support and technical assistance to user organizations. Tenders and shore-based repair facilities [14].

INTERMEDIATE POWER AMPLIFIER—The amplifier between the oscillator and final power amplifier [12].

INTERPOLES—Small auxiliary poles, placed between main field poles, whose magnetic field opposes the armature field and cancels armature reaction. Interpoles accomplish the same thing as compensating windings [5].

INTERSECTION LAW—In Boolean algebra, the law which states that if one input to an AND gate is already TRUE, then the output will depend upon the state of the other inputs only [13].

INVERSELY—Inverted or reversed in position or relationship [1].

INVERT—To change a physical or logical state to its opposite state [13].

INVERTER—A circuit with one input and one output. Its function is to invert or reverse the input. When the input is high, the output is low, and vice versa. The inverter is sometimes called a NOT circuit, since it produces the reverse of the input [13].

ION—An electrically charged atom or group of atoms. Negative ions have an excess of electrons; positive ions have a deficiency of electrons [1].

IONIZATION—(1) The process of producing ions. (2) The electrically charged particles produced by high-energy radiation, such as light or ultraviolet rays, or by the collision of particles during thermal agitation [6] [10].

IONIZATION POINT—The potential required to ionize the gas of a gas-filled tube. Sometimes called firing potential [6].

IONIZE—To make an atom or molecule of an element lose an electron, as by X-ray bombardment, and thus be converted into a positive ion. The free electron may attach itself to a neutral atom or molecule to form a negative ion [1].

IONOSPHERE—The most important region of the atmosphere extending from 31 miles to 250 miles above sea level. Contains four cloud-like layers that affect radio waves [10].

IONOSPHERIC STORMS—Disturbances in the earth's magnetic field that make communications practical only at lower frequencies [10].

IRIS—A metal plate with an opening through which electromagnetic waves may pass. Used as an impedance-matching device in waveguides [11].

I^2R LOSS—See COPPER LOSSES [11].

ISOLATION—The prevention of unwanted interaction or leakage between components [14].

ISOMETRIC DIAGRAM—A diagram showing the outline of a ship, aircraft, or equipment and the location of equipment and cable runs [4].

ISOTROPIC RADIATION—The radiation of energy equally in all directions [10].

JUNCTION—(1) The connection between two or more conductors. (2) The contact between two dissimilar metals or materials, as in a thermocouple [1].

JUNCTION BOX—A box with a cover that serves the purpose of joining different runs of wire or cable and provides space for the connection and branching of the enclosed conductors [4].

JUNCTION DIODE—A two-terminal device containing a single crystal of semiconducting material that ranges from P-type at one terminal to N-type at the other [7].

JUNCTION TRANSISTOR—A bipolar transistor constructed from interacting PN junctions. The term is used to distinguish junction transistors from other types, such as field-effect and point-contact [7].

KEEP-ALIVE CURRENT—See KEEP-ALIVE VOLTAGE [18].

KEEP-ALIVE VOLTAGE—DC voltage applied to a tr gap electrode to produce a glow discharge that allows the tube to ionize faster when the transmitter fires [18].

KEY-CLICK FILTERS—Filters used in keying systems to prevent key-click interference [12].

KEY CLICKS—Interference in the form of "clicks" or "thumps" caused by the sudden application or removal of power [12].

KEYED-OSCILLATOR TRANSMITTER—A transmitter in which one stage is used to produce the RF pulse [18].

KEYER—(1) A device that changes dc pulses to mark and space modulation for teletypewriter transmissions [17]. (2) A synchronizer [18].

KEYING RELAYS—Relays used in radio transmitters where the ordinary hand key cannot accommodate the plate current without excessive arcing [12].

KILO—A prefix meaning one thousand [1].

KINETIC ENERGY—Energy that a body possesses by virtue of its motion [1].

KIRCHHOFF'S LAWS—(1) The algebraic sum of the current flowing toward any point in a circuit and the current flowing away from it is zero. (2) The algebraic sum of the products of the current and resistance in each of the conductors in any closed path in a network is equal to the algebraic sum of the electromotive forces in the path [1].

KLYSTRON POWER AMPLIFIER—A multicavity microwave electron tube that uses velocity modulation [18].

KNEE OF THE CURVE—The point of maximum curvature of a magnetization curve. (Shaped like the knee of a leg that is bent.) [8]

LACING SHUTTLE—A device upon which lacing may be wound to prevent fouling the tape or cord and to aid the lacing process. (Usually made from brass, aluminum, fiber, or plastic) [4].

LAG—The amount one wave is behind another in time; expressed in electrical degrees [2].

LAMINATED CORE—A core built up from thin sheets of metal insulated from each other and used in transformers [2].

LANDS—Conductors or runs on pcbs [14].

LAP WINDING—An armature winding in which opposite ends of each coil are connected to adjoining segments of the commutator so that the windings overlap [5].

LARGE SCALE INTEGRATION (lsi)—An integrated circuit containing 1,000 to 2,000 logic gates or up to 64,000 bits of memory [14].

LASER—An acronym for light amplification by stimulated emission of radiation [17].

LAW OF MAGNETISM—Like poles repel; unlike poles attract [1].

LC CAPACITOR-INPUT FILTER—This is the most common type of filter. It is used in a power supply where output current is low and load current is relatively constant [7].

LC CHOKE-INPUT FILTER—This filter is used in power supplies where voltage regulation is important and where the output current is relatively high and subject to varying load conditions [7].

LEAD—The opposite of lag. Also a WIRE or CONNECTION [2].

LEAD-ACID CELL—A cell in an ordinary storage battery in which electrodes are grids of lead containing an active material consisting of certain lead oxides that change in composition during charging and discharging. The electrodes or plates are immersed in an electrolyte of diluted sulfuric acid [1].

LEAD INDUCTANCE—The inductance of the lead wires connecting the internal components of an electron tube [11].

LEAD SHEATH—A continuous jacket of lead molded around a single conductor or multiple conductor cable. Generally used to ensure conductors are protected from water or extensive moisture [4].

LEAKAGE CURRENT—The small amount of current that flows through the dielectric between the conductors of a transmission line [10].

LEAKAGE FLUX—Magnetic flux lines produced by the primary winding that do not link the turns of the secondary winding [2].

LEAKAGE RESISTANCE—The electrical resistance that opposes the flow of current through the dielectric of a capacitor. The higher the leakage resistance, the slower the capacitor discharges or leaks across the dielectric [2].

LEAST SIGNIFICANT DIGIT (LSD)—The LSD is the digit whose position within a given number expression has the least weighting power [13].

LEFT-HAND RULE FOR GENERATORS—A rule or procedure used to determine the direction of current flow in a generator [2] [5].

LENZ'S LAW—The current induced in a circuit, caused by its motion in a magnetic field or a change in it's magnetic flux, in such a direction as to exert a mechanical force opposing the motion or to oppose the change in flux [2].

LIGHT-EMITTING DIODE (LED)—A PN-junction diode that emits visible light when it is forward biased. Depending on the material used to make the diode, the light may be red, green, or amber [7].

LIGHTHOUSE TUBE—An electron tube shaped like a lighthouse that is designed to handle large amounts of power at uhf frequencies [6].

LIGHT RAYS—Light waves emitting from a source in straight lines [10].

LIMITER—A device that prevents (limits) a waveform from exceeding a specified value [9].

LINEAR—Having an output that varies in direct proportion to the input [6].

LINEAR IMPEDANCE—An impedance in which a change in current through a device changes in direct proportion to the voltage applied to the device [12].

LINE OF FORCE—A line in an electric or magnetic field that shows the direction of the force [1].

LINE OF SIGHT—Straight line from a radar antenna to a target [18].

LINE-PULSING MODULATOR—Circuit that stores energy and forms pulses in the same circuit element, usually the pulse-forming network (pfn) [18].

LIN-LOG AMPLIFIER—An amplifier in which the response is linear for weak signals and logarithmic for large signals [18].

LIQUID—One of the three states of matter. It has a definite volume but no definite form (water is a liquid) [1].

LIQUID-COOLING SYSTEM—Source of cooling for high-heat producing equipments, such as microwave components, radar repeaters, and transmitters [18].

LISSAJOUS PATTERN—A combined, simultaneous display of the amplitude and phase relationships of two input signals on a CRT [17].

LOAD—(1) A device through which an electric current flows and which changes electrical energy into another form. (2) Power consumed by a device or circuit in performing its function [1] [13].

LOAD END—See OUTPUT END [10].

LOADING—See LUMPED-IMPEDANCE TUNING [10].

LOADING EFFECT—The effect of a voltmeter upon the circuit being measured that results in an inaccurate measurement. Loading effect is minimized by using a voltmeter with an internal resistance many times higher than the resistance of the circuit being measured [3].

LOAD ISOLATOR—A passive attenuator in which the loss in one direction is much greater than that in the opposite direction. One example is a ferrite isolator for waveguides that allows energy to travel in only one direction [11].

LOBE—An area of greater signal strength in the transmission pattern of an antenna [10] [18].

LOCAL ACTION—A continuation of current flow within a battery cell when there is no external load. Caused by impurities in the electrode [1].

LOGARITHMIC RECEIVER—Receiver that uses a linear logarithmic amplifier (lin-log) instead of a normal linear amplifier [18].

LOGIC—The basic principles and applications of truth tables, interconnections of off-on circuit elements, and other factors involved in mathematical computation in automatic data processing systems and other devices [13].

LOGIC CIRCUIT—The primary control information processor in digital equipment; made up of electronic gates and so named because their operation is described by simple equations of a specialized logic algebra [13].

LOGIC DIAGRAM—In computers and data processing equipment, a diagram representing the logical elements and their interconnections without necessarily expressing construction or engineering details [13].

LOGIC ELEMENT—The smallest building blocks that can be represented by operators in an appropriate system of symbolic logic. Typical logic elements are the AND-gate and the flip-flop, which can be represented as operators in a suitable symbolic logic. Also a device that performs the logic function [13].

LOGIC INSTRUCTION—Any instruction that executes a logic operation that is defined in symbolic logic, such as AND, OR, NAND, or NOR [13].

LOGIC OPERATION—A nonarithmetical operation in a computer, such as comparing, selecting, making references, matching, sorting, and merging, where the logical YES or NO quantities are involved [13].

LOGIC SWITCH—A diode matrix (See MATRIX) or other switching arrangement that is capable of directing an input signal to one of several outputs [13].

LOGIC SYMBOL—A symbol used to represent a logic element graphically. Also a symbol used to represent a logic operator [13].

LONGITUDINAL WAVES—Those waves in which the disturbance (back and forth motion) takes place in the direction of propagation. Sometimes called compression waves [10].

LONG-WIRE ANTENNA—An antenna that is a wavelength or more long at its operating frequency [10].

LOOP—A curved conductor that connects the ends of a coaxial cable or other transmission line and projects into a waveguide or resonant cavity for the purpose of injecting or extracting energy [10] [11].

LOOSE COUPLING—Inefficient coupling of energy from one circuit to another that is desirable in some applications. Also called weak coupling [11].

LOWER-FREQUENCY CUTOFF—The lowest frequency a circuit will pass [9].

LOWER SIDEBAND—All difference frequencies below that of the carrier [12].

LOWEST USABLE FREQUENCY—The minimum operating frequency that can be used for communications between two points [10].

LOW FREQUENCY—The band of frequencies from 30 kHz to 300 kHz [17].

LOW-LEVEL MODULATION—Modulation produced in an earlier stage than the final [12].

LOW-NOISE AMPLIFIER—See PREAMPLIFIER [18].

LOW-PASS FILTER—A filter that passes a majority of the low frequencies on to the next circuit and rejects, or attenuates, the higher frequencies. Also called a high-frequency discriminator [9] [12].

LSD—See LEAST SIGNIFICANT DIGIT [13].

LUMPED CONSTANTS—The properties of inductance, capacitance, and resistance in a transmission line [10].

LUMPED IMPEDANCE TUNING—The insertion of an inductor or capacitor in series with an antenna to electrically lengthen or shorten the antenna [10].

MACHINE KEYING—A method of cw keying using punched tape or other mechanical means to key a transmitter [12].

MAGIC T—See BALANCED MIXER [18].

MAGIC-T JUNCTION—A combination of H-type and E-type T-junctions [11].

MAGNET WIRE—Wire coated with an enamel insulation and used in coils, relays, transformers, motor windings, and so forth [4].

MAGNETIC AMPLIFIER—An electromagnetic device that uses one or more saturable reactors to obtain a large power gain. This device is used in servosystems requiring large amounts of power to move heavy loads [8] [15].

MAGNETIC FIELD—(1) The region in which the magnetic forces created by a permanent magnet or by a current-carrying conductor or coil can be detected [1] [2]. (2) The field that is produced when current flows through a conductor or antenna [10] [11].

MAGNETIC INDUCTION—Generating a voltage in a circuit by the creation of relative motion between a magnetic field and the circuit. The relative motion can be the result of physical movement or the rise and fall of a magnetic field created by a changing current [5].

MAGNETIC LINES OF FORCE—Imaginary lines used for convenience to designate the direction in which magnetic forces are acting as a result of magnetomotive force [2].

MAGNETIC MICROPHONE—A microphone in which the sound waves vibrate a moving armature. The armature consists of a coil wound on the armature and located between the pole pieces of a permanent magnet. The armature is mechanically linked to the diaphragm [12].

MAGNETIC POLES—The section of a magnet where the flux lines are concentrated; also where they enter and leave the magnet [1].

MAGNETIC TRIP ELEMENT—A circuit breaker trip element that uses the increasing magnetic attraction of a coil with increased current to open the circuit [3].

MAGNETISM—The property possessed by certain materials by which these materials can exert mechanical force on neighboring masses of magnetic materials and can cause currents to be induced in conducting bodies moving relative to the magnetized bodies [1].

MAGNETRON OSCILLATOR—An electron tube that provides a high power output. Theory of operation is based on interaction of electrons with the crossed electric and magnetic fields in a resonant cavity [18].

MAINTENANCE—Work done to correct, reduce, or counteract wear, failure, and damage to equipment [16].

MAJOR LOBE—The lobe in which the greatest amount of radiation occurs [10].

MAJORITY CARRIERS—The mobile charge carriers (hole or electron) which are predominate in a semiconductor material; for example, electrons in an N-type region [7].

MARCONI ANTENNA—A quarter-wave antenna that is operated with one end grounded and is positioned perpendicular to the earth [10].

MARK—An interval during which a signal is present. Also the presence of an RF signal in cw keying. The key-closed condition (presence of data) in communications systems [12].

MARKING—The state where a circuit is closed and current flows in teletypewriter operation [17].

MASK—A device used to deposit materials on a substrate in the desired pattern [14].

MASTER OSCILLATOR—In a transmitter, the oscillator that establishes the carrier frequency of the output [18].

MASTER OSCILLATOR POWER AMPLIFIER (MOPA)—A transmitter in which the oscillator is isolated from the antenna by a power amplifier [12].

MATRIX—In computers, a logic network in the form of an array of input leads and output leads with logic elements connected at some of their intersections [13].

MATTER—Any physical entity that possesses mass [1].

MAXIMUM USABLE FREQUENCY—Maximum frequency that can be used for communications between two locations for a given time of day and a given angle of incidence [10].

MEASURE (METROLOGY AUTOMATED SYSTEM FOR UNIFORM RECALL AND REPORTING)—The Navy data processing system designed to provide a standardized system for the recall, scheduling, and documenting of test equipment into calibration facilities [16].

MECHANICAL-ROTATION FREQUENCY—The speed in revolutions per minute of armatures in electric motors and engine-driven generators; blade speed in turbines [16].

MECHANICAL SCANNING—The reflector, its feed source, or the entire antenna is moved in a desired pattern [18].

MECHANIZATION—Using electric or electro-mechanical switches to represent logic circuits (AND, OR, NOT, NOR, NAND) [13].

MEDIUM—The vehicle through which a wave travels from one point to the next. Air, water, and wood are examples [10].

MEDIUM ALTITUDE ORBIT—An orbit from 2,000 to 12,000 miles above the earth. The rotation rate of the earth and satellite are quite different, and the satellite moves quickly across the sky [17].

MEDIUM FREQUENCY—The band of frequencies from 300 kHz to 3 MHz [17].

MEGA—A prefix meaning one million; also MEG [1].

MEGGER—Common name for a megohmmeter [3] [16].

MEGOHMMETER—A meter that measures very large values of resistance; usually used to check for insulation breakdown in wires [3].

METALLIC ARMOR—A protective covering for wires or cables. Made as a woven wire braid, metal tape, or interlocking metal cover. Made from steel, copper, bronze, or aluminum [4].

METALLIC, INSULATOR—A shorted quarter-wave section of transmission line [11].

METALLIC RECTIFIER—Also known as a DRY-DISC RECTIFIER. A metal-to-semiconductor, large-area, contact device in which a semiconductor is sandwiched between two metal plates. This asymmetrical construction permits current to flow more readily in one direction than the other [7].

METAL-OXIDE SEMICONDUCTOR FIELD-EFFECT TRANSISTOR—See MOSFET [7].

METER—A device used to measure a specific quantity, such as current, voltage, or frequency [3].

METER MOVEMENT—The part of the meter that moves to indicate some value [3] [16].

METER SHUNT—A resistor placed in parallel with the meter terminals; used to provide increased range capability [16].

MHO—Unit of conductance; the reciprocal of the ohm [1].

MICRO—A prefix meaning one-millionth [1].

MICROCIRCUIT—A small circuit having high equivalent-circuit-element density, which is considered as a single part composed of interconnected elements on or within a single substrate to perform an electronic-circuit function [14].

MICROCIRCUIT MODULE—An assembly of microcircuits or a combination of microcircuits and discrete components that perform one or more distinct functions [14].

MICROELECTRONICS—The solid-state concept of electronics in which compact semiconductor materials are designed to function as an entire circuit or subassembly rather than as circuit components [7] [14].

MICROPHONE—An energy converter that changes sound energy into electrical energy [12].

MICROWAVE REGION—The portion of the electromagnetic spectrum from 1,000 MHz to 100,000 MHz [11].

MIL—The diameter of a conductor equal to 1/1000 (.001) inch [4].

MIL FOOT—A unit of measurement for conductors (diameter of 1 mil, 1 foot in length.) [4].

MILITARY SPECIFICATIONS (MIL-SPEC)—Technical requirements and standards adopted by the Department of Defense that must be met by vendors selling materials to DOD [4].

MILITARY STANDARDS (MILSTD)—Standards of performance for components or equipment that must be met to be acceptable for military systems [14].

MILLI—A prefix meaning one-thousandth [1].

MINIATURE ELECTRONICS—Modules, packages, pcbs, and so forth, composed exclusively of discrete components [14].

MINIMUM DISCERNIBLE SIGNAL (MDS)—The weakest input signal that produces a usable signal at the output of a receiver. The weaker the input signal, the more sensitive the receiver [18].

MINORITY CARRIERS—Either electrons or holes, whichever is the less dominant carrier in a semiconductor device. In P-type semiconductors, electrons are the minority carriers; in N-type semiconductors, the holes are the minority carriers [7].

MINORITY CURRENT—A very small current that passes through the base-to-collector junction when this junction is reverse biased [7].

MINOR LOBE—The lobe in which the radiation intensity is less than that of a major lobe [10].

MIXER—In radar, a circuit that combines the received RF signal with a local-oscillator signal to effectively convert the received signal to a lower IF frequency signal [18].

MODE SHIFTING—In a magnetron, the inadvertent shifting from one mode to another during a pulse [18].

MODE SKIPPING—Operation in which the magnetron fires randomly, rather than firing on each successive pulse as desired [18].

MODIFIED TRANSISTOR OUTLINE (TO)—An IC package resembling a transistor [14].

MODULAR CIRCUITRY—A technique where printed circuit boards are stacked and connected together to form a module [7].

MODULAR PACKAGING—Circuit assemblies or subassemblies packaged to be easily removed for maintenance or repair [14].

MODULATED WAVE—A complex wave consisting of a carrier and a modulating wave that is transmitted through space [12].

MODULATING WAVE—An information wave representing intelligence [12].

MODULATION—The process of impressing intelligence upon a transmission medium, such as radio waves [12].

MODULATION FACTOR (M)—An indication of relative magnitudes of the RF carrier and the modulating signal [12].

MODULATION INDEX—The ratio of frequency deviation to the frequency of the modulating signal [12].

MODULATOR—(1) A device that produces modulation; that is, a device that varies the amplitude, frequency, or phase of an ac signal [11] [12]. (2) A circuit used in servosystems to convert a dc signal to an ac signal. The output ac signal is a sine wave at the frequency of the ac reference voltage. The amplitude of the output is directly related to the amplitude of the dc input. The circuit's function is opposite to that of a DEMODULATOR [15]. (3) In radar, it produces a high-voltage pulse that turns the transmitter on and off [18].

MODULATOR SWITCHING DEVICE—Controls the on (discharge) and off (charge) time of the modulator [18].

MODULE—A circuit or portion of a circuit packaged as a removable unit. A separable unit in a packaging scheme displaying regularity of dimensions [14].

MOISTURE LAPSE—Abnormal variation of moisture content at different altitudes because of high moisture located just above large bodies of water [18].

MONOLITHIC CIRCUIT—A circuit where all elements (resistors, transistors, and so forth) associated with the circuit are fabricated inseparably within a continuous piece of material (called the substrate), usually silicon [7].

MONOLITHIC IC—ICs that are formed completely within a semiconductor substrate. Silicon chips [14].

MONOPULSE (SIMULTANEOUS) LOBING—A radar receiving method using two or more (usually four) partially overlapping lobes. Sum and difference locate the target with aspect to the axis of the antenna [18].

MONOPULSE RADAR—A radar that gets the range, bearing, and elevation position data of a target from a single pulse [18].

MONOPULSE RECEIVER—See MONOPULSE RADAR [18].

MONOSTABLE MULTIVIBRATOR—A multivibrator that has one steady state. A signal (trigger) must be applied to cause change of states [9].

MOSFET—A semiconductor device that contains diffused source and drain regions on either side of a P- or N-channel area. Also contains a gate insulated from the channel area by silicon-oxide. Operates in either the depletion or the enhancement mode [7].

MOST SIGNIFICANT DIGIT (MSD)—The MSD is the digit whose position within a given number expression has the greatest weighting power [13].

MOTOR—A machine that converts electrical energy to mechanical energy. It is activated by ac or dc voltage, depending on the design [5].

MOTOR LOAD—Any device driven by a motor. Typical loads are drills, saws, water pumps, rotating antennas, generators, and so forth. The speed and power capabilities of a motor must be matched to the speed and power capabilities of the motor load [5].

MOTOR REACTION—The force created by generator armature current that tends to oppose the normal rotation of the armature [5].

MOTOR STARTERS—Large resistive devices placed in series with dc motor armatures to prevent the armature from drawing excessive current until armature speed develops counter emf. The resistance is gradually removed from the circuit either automatically or manually as motor speed increases [5].

MOVING-IRON METER MOVEMENT—Same as MOVING-VANE METER MOVEMENT [3].

MOVING TARGET INDICATOR—A device that limits the display of radar information to moving targets [18].

MOVING-VANE METER MOVEMENT—A meter movement that uses the magnetic repulsion of the like poles created in two iron vanes by current through a coil of wire; most commonly used movement for ac meters [3].

MSD—See MOST SIGNIFICANT DIGIT [13].

MTDS—An abbreviation for the marine tactical data system [17].

MU—Symbol for amplification factor [6] [7].

MULTICONDUCTOR—More than one conductor, as in a cable [4].

MULTICOUPLERS—Couplers that patch receivers or transmitters to antennas. They also filter out harmonics and spurious responses and impedance-match the equipment [17].

MULTIELECTRODE TUBE—An electron tube normally classified according to its number of electrodes (the multielectrode tube contains more than three electrodes) [6].

MULTIELEMENT ARRAY—An array that consists of one or more arrays and is classified as to directivity [10].

MULTIELEMENT PARASITIC ARRAY—An array that contains two or more parasitic elements and a driven element [10].

MULTILOOP SERVOSYSTEM—A servosystem that contains more than one servo loop; each loop is designed to perform its own function [15].

MULTIMETER—A single meter combining the functions of an ammeter, a voltmeter, and an ohmmeter [3].

MULTIPATH—The multiple paths a radio wave may follow between transmitter and receiver [10].

MULTIPHASE—See POLYPHASE [5].

MULTIPLICATION FACTOR—The number of times an input frequency is multiplied [12].

MULTIPLEXING—A method for simultaneous transmission of two or more signals over a common carrier wave [17].

MULTISPEED SYNCHRO SYSTEMS—Systems that transmit data at different transmission speeds; for example, dual-speed and tri-speed synchro systems [15].

MULTIUNIT TUBE—An electron tube containing two or more units within the same envelope. The multiunit tube is capable of operating as a single-unit tube, or each unit can operate as a separate tube [6].

MULTIVIBRATOR—A form of relaxation oscillator which comprises two stages that are coupled so that the input of one is derived from the output of the other [9] [13].

MULTIVIBRATOR MODULATOR—An astable multivibrator used to provide frequency modulation. The modulating af voltage is inserted in series with the base return of the multivibrator transistors to produce the frequency modulation [12].

MUTUAL FLUX—The total flux in the core of a transformer that is common to both the primary and secondary windings. The flux links both windings [2].

MUTUAL INDUCTANCE—A circuit property existing when the relative position of two inductors causes the magnetic lines of force from one to link with the turns of the other. The symbol for mutual inductance is M [2].

NAND—A logic function of A and B that is true if either A or B is false [13].

NAND CIRCUIT—A combination of a NOT function and an AND function in a binary circuit that has two or more inputs and one output. The output is logic 0 only if ALL inputs are logic 1; it is logic 1 if ANY input is logic 0 [13].

NATURAL FREQUENCY—See RESONANT FREQUENCY [9].

NATURAL HORIZON—The line-of-sight horizon [10].

NAUTICAL MILE—The length of a minute of arc of a great circle of the earth (6,076 ft) [18].

NAUTICAL RADAR MILE—See RADAR MILE [18].

NEAR SYNCHRONOUS ORBIT—An orbit in which the satellite rotates close to but not exactly at the same speed as the earth [17].

NEGATION—The process of inverting the value of a function or variable [13].

NEGATIVE ALTERNATION—That part of a sine wave that is below the reference level [2] [10] [12].

NEGATIVE CLAMPER—A circuit that clamps the upper extremity of the output waveshape to a dc potential of 0 volts [9].

NEGATIVE ELECTRODE—A terminal or electrode having more electrons than normal. Electrons flow out of the negative terminal of a voltage source [1].

NEGATIVE FEEDBACK—Feedback in which the feedback signal is out of phase with the input signal. Also called DEGENERATIVE FEEDBACK [8].

NEGATIVE LOGIC—The form of logic in which the more positive voltage level represents a logic 0, FALSE, or LOW and the more negative voltage represents a logic 1, TRUE, or HIGH [13].

NEGATIVE-RESISTANCE ELEMENT—A component having an operating region in which an increase in the applied voltage increases the resistance and produces a proportional decrease in current. Examples include tunnel diodes and silicon unijunction transistors [11].

NEGATIVE TEMPERATURE COEFFICIENT—A characteristic of a semiconductor material, such as silver sulfide, in which resistance to electrical current flow decreases as temperature increases [1] [4] [7].

NETWORK—A combination of electrical components. In a parallel circuit it is composed of two or more branches [1].

NEUTRAL—(1) In a normal condition, hence neither positive nor negative. A neutral object has a normal number of electrons (the same number as protons) [1]. (2) The teletypewriter operation where current flow represents a mark and no flow represents a space [17].

NEUTRALIZATION—The process of counteracting or "neutralizing" the effects of interelectrode capacitance [8].

NEWTON'S SECOND LAW OF MOTION—If an unbalanced outside force acts on a body, the resulting acceleration is directly proportional to the magnitude of the force, is in the direction of the force, and is inversely proportional to the mass of the body [15].

NODE—The fixed minimum points of voltage or current on a standing wave or antenna [10].

NOISE—(1) In reference to sound, an unwanted disturbance caused by spurious waves that originate from man-made or natural sources [10]. (2) In radar, erratic or random deflection or intensity of the indicator sweep that tends to mask small echo signals [18].

NOISE FIGURE—The ratio of output noise to input noise in a receiver [18].

NOISE LIMITER—Circuit that clips the peaks of the noise spikes in a receiver [17].

NOISE SILENCER—See NOISE LIMITER [17].

NOISE SUPPRESSOR—See NOISE LIMITER [17].

NO-LOAD CONDITION—The condition that exists when an electrical source or secondary of a transformer is operated without an electrical load [2].

NONDEGENERATIVE PARAMETRIC AMPLIFIER—A parametric amplifier that uses a pump signal frequency that is higher than twice the frequency of the input signal [11].

NONDIRECTIONAL—See OMNIDIRECTIONAL [10].

NONLINEAR DEVICE—A device in which the output does not rise and fall in direct proportion to the input [6] [7] [12].

NONLINEAR IMPEDANCE—An impedance in which the resulting current through the device is not proportional to the applied voltage [12].

NONLUMINOUS BODIES—Objects that either reflect or diffuse light that falls upon them [10].

NONRESONANT LINE—A transmission fine that has no standing waves of current or voltage [10].

NONTRIP-FREE CIRCUIT BREAKER—A circuit breaker that can be held in the ON position during an overcurrent condition [3].

NOR—A logic function of A and B that is true if both A and B are false [13].

NOR GATE—An OR gate that is followed by an inverter to form a binary circuit in which the output is a logic 0 if ANY of the inputs is a logic 1 and the output is a logic 1 only if ALL the inputs are a logic 0 [13].

NORMAL—The imaginary line perpendicular to the point at which the incident wave strikes the reflecting surface. Also called the perpendicular [10].

NOT CIRCUIT—A binary circuit with a single output that is always the opposite of the input. Also called an INVERTER CIRCUIT [13].

NPN—An NPN transistor is formed by introducing a thin region of P-type material between two regions of N-type material [7].

NULL—On a polar-coordinate graph, the area that represents minimum or 0 radiation [10].

NUMBER—(1) A mathematical entity that may indicate quantity or amount of units. (2) Loosely, a numeral. An abstract mathematical symbol for expressing a quantity. In this sense, the manner of representing the number is immaterial. Take 26, for example; this is its decimal form - but it could be expressed as a binary (base 2), octal (base 8), or hexadecimal (base 16) number [13].

NUMBER REPRESENTATION—The representation of numbers by agreed sets of symbols according to agreed rules [13].

NUMBER SYSTEM—Loosely, a number representation system. Any system for the representation of numbers (see POSITIONAL NOTATION) [13].

NUMERAL—(1) A discrete representation of a number. For example, twelve, 12, XII, 1100_2 are four different numerals that represent the same number. (2) A numeric word that represents a number [13].

NUTATING—Moving an antenna feed point in a conical pattern so that the polarization of the beam does not change [18].

OCTAL NUMBER SYSTEM—A number system based on powers of eight. This system is used extensively in computer work [13].

OFF-LINE TEST EQUIPMENT—Equipment that tests and isolates faults in modules or assemblies removed from systems [14].

OHM—The unit of electrical resistance. That value of electrical resistance through which a constant potential difference of 1 volt across the resistance will maintain a current flow of 1 ampere through the resistance [1].

OHMIC VALUE—Resistance in ohms [1].

OHMMETER—A meter used to measure resistance [3] [16].

OHM'S LAW—The current in an electrical circuit is directly proportional to the electromotive force in the circuit. The most common form of the law is $E = IR$, where E is the electromotive force or voltage across the circuit, I is the current flowing in the circuit, and R is the resistance of the circuit [1].

OHMS PER SQUARE—The resistance of any square area of thin film resistive material as measured between two parallel sides [14].

OILCAN TUBE—A type of planar tube, similar to the lighthouse tube, which has cooling fins. The oilcan tube is designed to handle large amounts of power at uhf frequencies [6].

OMNIDIRECTIONAL ANTENNA—An antenna that radiates and receives equally in all directions (nondirectional) [10] [18].

ON-LINE TEST EQUIPMENT—Continuously monitors the performance of electronic systems [14].

OPAQUE—Those substances that do not transmit (pass) any light rays; that is, the light rays are either absorbed or reflected [10].

OPEN CIRCUIT—(1) The condition of an electrical circuit caused by the breaking of continuity of one or more conductors of the circuit; usually an undesired condition. (2) A circuit that does not provide a complete path for the flow of current [1].

OPEN-ENDED LINE—A transmission fine that has a terminating impedance that is infinitely large [10].

OPERATIONAL AMPLIFIER (OP AMP)—An amplifier designed to perform computing or transfer operations and that has the following characteristics: (1) very high gain, (2) very high input impedance, and (3) very low output impedance [8].

OPTICAL COUPLER—A coupler composed of an LED and a photodiode and contained in a light-conducting medium. Suitable for frequencies in the low-megahertz range [7].

OPTIMUM WORKING FREQUENCY—The most practical operating frequency that can be used with the least amount of problems and is roughly 85 percent of the maximum usable frequency [10].

OPTOELECTRONIC DEVICES—Devices that either produce or use light in their operation [7].

ORDER-WIRE CIRCUIT—A circuit between operators used for operations control and coordination [17].

ORGANIZATIONAL-LEVEL MAINTENANCE (SM & R CODE O)—Responsibility of the user organization [14].

OR GATE—A gate that performs the logic OR function. It produces an output 1 whenever any or all of its inputs is/are 1 [13].

ORIGIN—The point on a graph where the vertical and horizontal axes cross each other [10].

OSCILLATOR—An oscillator is a nonrotating device that produces alternating current. The frequency is determined by the characteristics of the device [9].

OUT-OF-CIRCUIT METER—A meter that is not permanently installed in a circuit. Usually portable and self-contained, these meters are used to check the operation of a circuit or to isolate troubles within a circuit [3].

OUTPUT END—The end of a transmission line that is opposite the source; receiving end [10].

OUTPUT IMPEDANCE—The impedance that is presented to the load by the transmission line and its source [10].

OVERDRIVEN—When the input signal amplitude is increased to the point that the transistor goes into saturation and cutoff [7].

OVERMODULATION—A condition that exists when the peaks of the modulating signal are limited [12].

PACKAGING LEVELS—A system developed to assist maintenance personnel in determining the repairability of components, printed circuit boards, modules, and so forth [14].

PAGE PRINTER—A high-speed printer that prints teletypewriter characters one at a time in a full-page format [17].

PARABOLIC REFLECTOR—An antenna reflector in the shape of a parabola. It converts spherical wavefronts from the radiating element into plane wavefronts [18].

PARALLAX ERROR—The error in meter readings that results when you look at a meter from some position other than directly in line with the pointer and meter face. A mirror mounted on the meter face aids in eliminating parallax error [3].

PARALLEL CIRCUIT—Two or more electrical devices connected to the same pair of terminals so separate currents flow through each; electrons have more than one path to travel from the negative to the positive terminal [1].

PARALLEL-CONNECTED DUPLEXER—Configuration in which the tr spark gap is connected across the two legs of the transmission line one-quarter wavelength from the T-junction [18].

PARALLEL LIMITER—A resistor and diode, connected in series with the input signal, in which the output is taken across (parallel to) the diode [9].

PARALLEL-NEGATIVE LIMITER—A resistor and diode, connected in series with the input signal, in which the output is taken across the diode and the negative alternation is eliminated [9]

PARALLEL-POSITIVE LIMITER—A resistor and diode connected in series with the input signal, in which the output is taken across the diode and the positive alternation is eliminated [9].

PARALLEL-RESONANT CIRCUIT—A resonant circuit in which the source voltage is connected across a parallel circuit (formed by a capacitor and an inductor) to furnish a high impedance to the frequency at which the circuit is resonant. Often referred to as a tank circuit [9] [10].

PARALLEL-WIRE—A type of transmission line consisting of two parallel wires [10].

PARASITIC ARRAY—An antenna array containing one or more elements not connected to the transmission line [10] [18].

PARASITIC ELEMENT—The passive element of an antenna array that is connected to neither the transmission line nor the driven element [10].

PART—A part is one component or two or more components joined together. It is not normally subject to disassembly without destruction [17].

PASSIVE SATELLITE—A satellite that reflects radio signals back to earth [17].

PATCH PANEL—A panel used to tie a receiver or transmitter to its associated equipment [17].

PEAK AMPLITUDE—The maximum value above or below the reference line [12].

PEAK CURRENT—The maximum current that flows during a complete cycle [6].

PEAK DETECTION—Detection that uses the amplitude of pam or the duration of pdm to charge a holding capacitor and restore the original waveform [12].

PEAKING COIL—An inductor used in an amplifier to provide high-frequency compensation, which extends the high-frequency response of the amplifier [8].

PEAK POWER—The maximum value of the transmitted pulse [12].

PEAK-REVERSE VOLTAGE—The peak ac voltage that a rectifier tube will withstand in the reverse direction [6].

PEAK-TO-PEAK—The measure of absolute magnitude of an ac waveform, measured from the greatest positive alternation to the greatest negative alternation [2].

PEAK VALUE—The maximum instantaneous value of a varying current, voltage, or power. It is equal to 1.414 times the effective value of a sine wave [2].

PEAK VOLTAGE—The maximum value present in a varying or alternating voltage. This value may be positive or negative [6].

PENTAVALENT IMPURITY—A type of impurity that contains five valence electrons and donates one electron to the doped material. Also called DONOR IMPURITY [7].

PENTODE TUBE—A five-electrode electron tube containing a plate, a cathode, a control grid, and two grids [6].

PERCENT OF MODULATION—The degree of modulation defined in terms of the maximum permissible amount of modulation [12].

PERFORATOR—A device that stores a teletypewriter message on a paper tape [17].

PERIGEE—The point in the orbit of a satellite closest to the earth [17].

PERIOD TIME—The time required to complete one cycle of a waveform [2] [10] [12].

PERIODIC WAVE—A waveform that undergoes a pattern of changes, returns to its original pattern, and then repeats the same pattern of changes. Examples are square waves, rectangular waves, and sawtooth waves [9].

PERMANENT MAGNET SPEAKER—A speaker with a permanent magnet mounted on soft iron pole pieces [17].

PERMEABILITY—The measure of the ability of a material to act as a path for magnetic lines of force [1] [8].

PERSISTENCE—The length of time a phosphor dot glows on a CRT before disappearing [6] [18].

PHANTASTRON—A variable-length sawtooth generator often used to produce a sweep on an A-scope [18].

PHASE—The angular relationship between two alternating currents or voltages when the voltage or current is plotted as a function of time. When the two are in phase, the angle is zero; both reach their peak simultaneously. When out of phase, one will lead or lag the other; that is, at the instant when one is at its peak, the other will not be at peak value and (depending on the phase angle) may differ in polarity as well as magnitude [2].

PHASE ANGLE—The number of electrical degrees of lead or lag between the voltage and current waveforms in an ac circuit [2] [12].

PHASE MODULATION (pm)—Angle modulation in which the phase of the carrier is controlled by the modulating waveform. The amplitude of the modulating wave determines the amount of phase shift, and the frequency of the modulation determines how often the phase shifts [12].

PHASE-SHIFT DISCRIMINATOR—See FOSTER-SEELEY DISCRIMINATOR [12].

PHASE SHIFTER—A device used to change the phase relationship between two ac signals [11].

PHASE-SHIFT KEYING—Similar to ON-OFF cw keying in AM systems and frequency-shift keying in FM systems. Each time a mark is received, the phase is reversed. No phase reversal takes place when a space is received [12].

PHASE SPLITTER—A device that provides two output signals from a single input signal. The two output signals differ from each other in phase (usually by 180 degrees) [8].

PHOSPHOR—The material used to convert the energy of electrons into visible light [6].

PHOTOCELL—A light-controlled variable resistor which has a light-to-dark resistance ratio of 1:1000. Used in various types of control and timing circuits [7].

PHOTODIODE—A light-controlled PN junction. Current flow increases when the PN junction is exposed to an external light source [7].

PHOTOELECTRIC VOLTAGE—A voltage produced by light [1].

PHOTOETCHING—Chemical process of removing unwanted material in producing printed circuit boards [14].

PHOTOTRANSISTOR—An optoelectronic device that conducts current when exposed to light. Produces more current and is much more sensitive to light than the photodiode [7].

PHOTOVOLTAIC CELL (SOLAR CELL)—A device that acts much like a battery when exposed to light and converts light energy into electrical energy [7].

PICO—A prefix adopted by the National Bureau of Standards meaning 10^{-12} [1].

PICTORIAL DIAGRAM—A diagram showing actual pictorial sketches of the various parts of an equipment and the electrical connections between the parts [4].

PIEZOELECTRIC EFFECT—The effect of producing a voltage by placing a stress, either by compression, expansion, or twisting, on a crystal and, conversely, producing a stress in a crystal by applying a voltage to it [1].

PIP (BLIP)—On a CRT display, a spot of light or a baseline irregularity representing the radar echo [18].

PITCH—A term used to describe the frequency of a sound heard by the human ear [10].

PLANAR TUBE—An electron tube, constructed with parallel electrodes and a ceramic envelope, that is used at uhf frequencies. It is commonly referred to as a lighthouse tube [6].

PLANE OF POLARIZATION—The plane (vertical or horizontal), with respect to the earth, in which the E field propagates [10].

PLANE WAVEFRONTS—Waves of energy that are flat, parallel planes and are perpendicular to the direction of propagation [18].

PLANNED-POSITION INDICATOR—A radar display in which range is indicated by the distance of a bright spot or pip from the center of the screen and the bearing is indicated by the radial angle of the spot [18].

PLATE—(1) One of the electrodes in a storage battery [1]. (2) One of the electrodes in a capacitor [2]. (3) The principal electrode to which the electron stream is attracted in an electron tube [6].

PLATE DISSIPATION—The amount of power lost as heat in the plate of a vacuum tube [6].

PLATE KEYING—A keying system in which the plate supply is interrupted [12].

PLATE MODULATOR—An electron-tube modulator in which the modulating voltage is applied to the plate circuit of the tube [12].

PLATE RESISTANCE—The plate voltage change divided by the resultant plate current change in a vacuum tube, all other conditions being fixed [6].

POINT BENDER—A tool used to adjust the contact spacing on a relay [3].

POINT-CONTACT DIODE—A diode in which the end of a fine wire is pressed against a semiconductor. Used as a detector or mixer over the microwave region [7].

POINT OF ZERO DISPLACEMENT—See REFERENCE LINE [10].

POINT-TO-POINT WIRING—Individual wires run from terminal to terminal to complete a circuit [14].

POLAR—The teletypewriter operation in which current flow of one polarity represents a mark, and current of the opposite polarity represents a space [17].

POLAR-COORDINATE GRAPH—A graph with a pair of axes. One consists of a series of circles with a common center, and the other consists of a rotating radius extending from the center of the concentric circles [10].

POLARITY—(1) The condition in an electrical circuit by which the direction of the flow of current can be determined. Usually applied to batteries and other direct voltage sources. (2) Two opposite charges, one positive and one negative. (3) A quality of having two opposite magnetic poles, one north and the other south [1] [13].

POLARIZATION—(1) The effect of hydrogen surrounding the anode of a cell, which increases the internal resistance of the cell [1]. (2) The magnetic orientation of molecules in a magnetizable material in a magnetic field, whereby tiny internal magnets tend to line up in the field [2].

POLAR ORBIT—An orbit that has an angle of inclination of or near 90 degrees [17].

POLE—(1) The number of points at which current can enter a switch; for example, single pole, double pole, and three pole [3]. (2) The sections of a field magnet where the flux lines are concentrated; also where they enter and leave the magnet [5].

POLE PIECE—(1) A piece of ferromagnetic material used to control the distribution of magnetic lines of force; that is, it concentrates the lines of force in a particular place or evenly distributes the lines of force over a wide area [3]. (2) The shaped magnetic material upon which the stator windings of motors and generators are mounted or wound [5].

POLYMER FUME FEVER—A flu-like condition caused by a person breathing the vapors of fluorocarbons when they are heated. Sometimes called FOUNDRYMAN'S FEVER [4].

POLYPHASE—A term that describes systems or units of a system that are activated by or which generate separate out-of-phase voltages. Typical polyphase systems are 2-phase and 3-phase; their voltages are 90- and 120-degrees out of phase, respectively. This term means the same as MULTIPHASE [5].

POSITIONAL NOTATION—A numbering system in which a number is represented by means of a stated set of symbols or digits, such that the value contributed by each symbol or digit depends upon its position as well as upon its value [13].

POSITIONAL WEIGHTING—The value given a digit based on the digit's position within a given number [13].

POSITION SENSOR—A component in a servosystem that measures position and converts the measurement into a form convenient for transmission as a feedback signal [15].

POSITION SERVOSYSTEM—A servosystem whose end function is to control the position of the load it is driving [15].

POSITIVE ALTERNATION—The part of a sine wave that is above the reference line [2] [10] [12].

POSITIVE CLAMPER—A circuit that clamps the lower extremity of the output waveshape to a dc potential of 0 volts [9].

POSITIVE FEEDBACK—Feedback in which the feedback signal is in phase with the input signal. Also called REGENERATIVE FEEDBACK [8].

POSITIVE LOGIC—The form of logic in which the more positive logic level represents 1 and the more negative level represents 0 [13].

POSITIVE TEMPERATURE COEFFICIENT—The characteristic of a conductor in which the resistance increases as temperature increases [7].

POTENTIAL ENERGY—Energy caused by the position of one body with respect to another body or to the relative parts of the same body [1].

POTENTIOMETER—A variable resistor, used as a position sensor in servosystems, having a terminal connected to each end of a resistive element and a third terminal connected to a wiper contact. The output is a voltage that is variable depending upon the position of the wiper contact. The potentiometer is commonly referred to as a variable voltage divider. It, in effect, converts mechanical information into an electrical signal [1] [15].

POWER—The rate of doing work or the rate of expending energy. The unit of electrical power is the watt [1].

POWER AMPLIFIER—An amplifier in which the output-signal power is greater than the input-signal power [8].

POWER-AMPLIFIER (CHAIN) TRANSMITTER—Transmitter that uses a series of power amplifiers to create a high level of power [18].

POWER FACTOR—The ratio of the actual power of an alternating or pulsating current, as measured by a wattmeter, to the apparent power, as indicated by ammeter and voltmeter readings. The power factor of an inductor, capacitor, or insulator is an expression of their losses [2] [16].

POWER GAIN—In an antenna, the ratio of its radiated power to that of a reference [11] [18].

POWER LOSS—(1) The electrical power, supplied to a circuit, that does no work and is usually dissipated as heat [2] [4]. (2) The heat loss in a conductor as current flows through it [10].

POWER PENTODE—A special purpose tube used to provide high-current gain or power amplification. Each grid wire is directly in line with the one before and after it, a fact which allows more electrons to reach the plate [6].

POWER RATIO—See POWER GAIN [11].

POWER STANDING-WAVE RATIO (PSWR)—The ratio of the square of the maximum and minimum voltages of a transmission line [10].

POWER SUPPLY—A unit that supplies electrical power to another unit. It changes ac to dc and maintains a constant voltage output within limits [6] [7].

PREAMPLIFIER (PREAMP)—An amplifier that raises the output of a low-level source for further processing without appreciable degradation of the signal-to-noise ratio [18].

PRECESSION—The rotation of the spin axis of a gyro in response to an applied force. The direction of precession is always perpendicular to the direction of applied force [15].

PRECESSION VECTOR—In a gyro, a vector representing the angular change of the spin axis when torque is applied. The precession vector represents the axis about which precession occurs [15].

PRESTANDARD NAVY SYNCHROS—Synchros that are designed to meet Navy, rather than servicewide, specifications [15].

PREVENTIVE MAINTENANCE—Visual, mechanical, electrical, and electronic checks that are made to determine whether or not equipment is functioning properly [16].

PRIMARIES (OF LIGHT)—The three primary colors of light from which all other colors can be derived. The colors are red, green, and blue [10].

PRIMARY CELL—An electrochemical cell in which the chemical action eats away one of the electrodes, usually the negative electrode [1].

PRIMARY LOOP—In a cooling system, the primary source of cooling for the distilled water [18].

PRIMARY WINDING—The winding of a transformer connected to the electrical source [2].

PRIME MOVER—The source of the turning force applied to the rotor of a generator. This may be an electric motor, a gasoline engine, a steam turbine, and so forth [5].

PRINTED CIRCUIT BOARD—A flat, insulating surface upon which printed wiring and miniaturized components are connected in a predetermined design and attached to a common base [7] [14].

PRISM—A triangular-shaped glass that refracts and disperses light waves into component wavelengths [10].

PROBE COUPLER—A resonant conductor placed in a waveguide or cavity to insert or extract energy [18].

PROGRAMMED TRACKING—The method that uses known satellite orbital parameters to generate antenna pointing angles [17].

PROPAGATION—Waves traveling through a medium [10].

PULSE—Signal characterized by a steep rise from and decay toward an initial level [9] [12].

PULSE-AMPLITUDE MODULATION (PAM)—Pulse modulation in which the amplitude of the pulses is varied by the modulating signal [12].

PULSE-CODE MODULATION (PCM)—A modulation system in which the standard values of a quantized wave are indicated by a series of coded pulses [12].

PULSE DURATION (PD)—The period of time during which a pulse is present [12].

PULSE-DURATION MODULATION (PDM)—Pulse modulation in which the time duration of the pulses is changed by the modulating signal [12].

PULSE-FORMING NETWORK (PFN)—An lc network that alternately stores and releases energy in an approximately rectangular wave [12] [18].

PULSE-FREQUENCY MODULATION (PFM)—Pulse modulation in which the modulating voltage varies the repetition rate of a pulse train [12].

PULSE MODULATION—A form of modulation in which one of the characteristics of a pulse train is varied [12].

PULSE OSCILLATOR—A sine-wave oscillator that is turned on and off at specific times. Also known as a ringing oscillator [9].

PULSE-POSITION MODULATION (PPM)—Pulse modulation in which the position of the pulses is varied by the modulating voltage [12].

PULSE-REPETITION FREQUENCY (PRF)—The rate, in pulses per second, at which the pulses occur [9] [12] [18].

PULSE-REPETITION RATE (PRR)—Same as PULSE-REPETITION FREQUENCY (PRF) [9] [12] [18].

PULSE-REPETITION TIME (PRT)—Interval between the start of one pulse and the start of the next pulse; reciprocal of pulse-repetition frequency [18].

PULSE-TIME MODULATION (PTM)—Pulse modulation that varies one of the time characteristics of a pulse train (pwm, pdm, ppm, or pfm) [12].

PULSE WIDTH—Duration of time between the leading and trailing edges of a pulse [12] [18].

PULSE-WIDTH MODULATION (PWM)—Pulse modulation in which the duration of the pulses is varied by the modulating voltage [12].

PULSING—Allowing oscillations to occur for a specific period of time only during selected intervals [12].

PUMP—Electrical source of the energy required to vary the capacitance of a parametric amplifier [11].

PUSH-PULL AMPLIFIER—An amplifier that uses two transistors (or electron tubes) whose output signals are in phase opposition [8].

Q—(1) Figure of merit of efficiency of a circuit or coil. (2) Ratio of inductive reactance to resistance in servos. (3) Relationship between stored energy (capacitance) and rate of dissipation in certain types of electric elements, structures, or materials [2] [9].

QUALITY (OF SOUND)—The factor that distinguishes tones of pitch and loudness [10].

QUANTIZED WAVE—A wave created by the arbitrary division of the entire range of amplitude (or frequency, or phase) values of an analog wave into a series of standard values. Each sample takes the standard value nearest its actual value when modulated [12].

QUANTIZING NOISE—A distortion introduced by quantizing the signal [12].

QUANTUM-MECHANICAL TUNNELING—The action of an electron crossing a PN junction because of tunnel effect [7].

QUARTER-WAVE ANTENNA—Same as the MARCONI ANTENNA [10].

QUIESCENCE—(1) The state of an amplifier with no signal applied. (2) The operating conditions that exist in a circuit when no input signal is applied to the circuit [6] [71 [13].

QUIESCENT STATE—The period during which a transistor, tube, or other circuit element is not performing an active function in the circuit [9] [13].

RADAR—An acronym for **RA**dio **D**etecting **A**nd **R**anging [18].

RADAR ALTIMETER—Airborne radar that measures the distance of the aircraft above the ground [18].

RADAR BEAM—The space in front of a radar antenna where a target can be effectively detected or tracked. Defined by areas that contain half or more of the maximum power transmitted [18].

RADAR DETECTOR—A detector that, in its simplest form, only needs to be capable of producing an output when RF energy (reflected from a target) is present at its input [12].

RADAR DISTRIBUTION SWITCHBOARD—An electrical switching panel used to connect inputs from any of several radars to repeaters (indicators) [18].

RADAR MILE—Time interval (12.36 microseconds) for RF energy to travel out from a radar to a target and back to the radar; radar nautical mile [18].

RADAR TEST SET—A combination of several test circuits and equipment used to test various characteristics of a radar [18].

RADIATION FIELD—The electromagnetic field that radiates from an antenna and travels through space [10].

RADIATION LOSSES—The losses that occur when magnetic lines of force about a conductor are projected into space as radiation and are not returned to the conductor as the cycle alternates [10].

RADIATION PATTERN—A plot of the radiated energy from an antenna [10].

RADIATION RESISTANCE—The resistance that if inserted in place of the antenna would consume the same amount of power as that radiated by the antenna [10].

RADIO COMMUNICATIONS—The term describing teletypewriter, voice, telegraphic, and facsimile communications. [17].

RADIO FREQUENCY (RF)—(1) Any frequency of electromagnetic energy capable of propagation into space [2]. (2) The frequencies that fall between 3 kilohertz and 300 gigahertz used for radio communications [10].

RADIO FREQUENCY CARRIER SHIFT—The system that uses a keyer to shift a radio frequency signal above or below an assigned frequency. These shifts correspond to marks and spaces [17].

RADIO HORIZON—The boundary beyond the natural horizon in which radio waves cannot be propagated over the earth's surface [10].

RADIO SET CONTROL UNIT—Equipment used to remotely control certain transmitter and receiver functions [17].

RADIO WAVES—(1) A form of radiant energy that can neither be seen nor felt. (2) An electromagnetic wave that is generated by a transmitter [10].

RADIX—Also called the base. The number of distinct symbols used in a number system. For example, since the decimal number system uses ten symbols (0, 1, 2, 3, 4, 5, 6, 7, 8, 9), the radix is 10. In the binary number system, the radix is 2 because it uses only two symbols (0, 1) [13].

RADIX POINT—Also called BINARY POINT, OCTAL POINT, DECIMAL POINT, and so forth, depending on the number system [13].

RANGE—The length of a straight line between a radar set and a target [11] [18].

RANGE-GATE—A movable gate used to select radar echoes from a very short range interval [18].

RANGE-HEIGHT INDICATOR—A radar display on which slant range is shown along the X axis and height along the Y axis [18].

RANGE MARKER—A movable vertical pulse on an A-scope or a ring on a PPI scope used to measure the range of an echo or to calibrate the range scale [18].

RANGE RESOLUTION—Ability of a radar to distinguish between targets that are close together [18].

RANGES—The several upper limits a meter will measure as selectable by a switch or by jacks; for example, a voltmeter may have ranges of 1 volt, 2.5 volts, 10 volts, 25 volts, and 100 volts [3].

RANGE STEP—On an A-scope sweep, a vertical displacement used to measure the range of an echo [18].

RAREFIED WAVE—A longitudinal wave that has been expanded or rarefied (made less dense) as it moves away from the source [10].

RATE GYRO—A gyro used to detect and measure angular rates of change [15].

RATIO—The value obtained when one number is divided by another. This value indicates the relative proportions of the two numbers [2].

RATIO DETECTOR—A detector that uses a double-tuned transformer to convert the instantaneous frequency variations of the FM input signal to instantaneous amplitude variations [12].

RATIO OF TRANSMITTED POWERS—The power ratio (FSK versus AM) that expresses the overall improvement of FSK transmission when compared to AM under rapid-fading and high-noise conditions [12].

RC CONSTANT—Time constant of a resistor-capacitor circuit; equal in seconds to the resistance value in ohms multiplied by the capacitance value in farads [2] [9].

RC DIFFERENTIATOR—An RC circuit in which the output is taken from the resistor [9].

RC FILTER—A filter used in applications where load current is low and constant, and voltage regulation is not necessary [7].

RC INTEGRATOR—An RC circuit in which the output is taken from the capacitor [9].

RC NETWORK—A circuit containing resistance and capacitance arranged in a particular manner to perform a specific function [9].

RC OSCILLATOR—An oscillator in which the frequency is determined by resistive and capacitive elements [9].

REACTANCE—The opposition offered to the flow of an alternating current by the inductance, capacitance, or both, in any circuit [2].

REACTANCE AMPLIFIER—A low-noise amplifier that uses a nonlinear variable reactance as the active element instead of a variable resistance. Also called a parametric amplifier [11].

REACTANCE TUBE—A tube connected in parallel with the tank circuit of an oscillator. Provides a signal that will either lag or lead the signal produced by the tank [12].

REACTANCE-TUBE MODULATOR—An FM modulator that uses a reactance tube in parallel with the oscillator tank circuit [12].

RECEIVER—(1) The object that responds to the wave or disturbance. Same as DETECTOR [10]. (2) Equipment that converts electromagnetic energy into a visible or an audible form [17]. (3) In radar, a unit that converts RF echoes to video and/or audio signals [18].

RECEIVER SENSITIVITY—(1) The degree to which a receiver can usefully detect a weak signal. (2) The lower limit of useful signal input to the receiver [18].

RECEIVER TRANSFER SWITCHBOARD—Equipment used to transfer receiver audio outputs to remote control station audio circuits [17].

RECEIVING ANTENNA—The device used to pick up the RF signal from space [10].

RECEIVING END—See OUTPUT END [10].

RECEPTION—The instant when an electromagnetic wave passes through a receiver antenna and induces a voltage in that antenna [17].

RECIPROCAL (OF A QUANTITY)—The value obtained by dividing the number 1 by that quantity [1].

RECIPROCITY—The property of interchangeability of the same antenna for transmitting and receiving [10] [11].

RECOVERY TIME—In a radar, the time interval between the end of the transmitted pulse and the time when echo signals are no longer attenuated by the tr gap [18].

RECTIFIER—A device used to convert ac to pulsating dc [3] [6] [7].

RECTANGULAR-COORDINATE GRAPH—A graph in which straight-line axes (horizontal and vertical) are perpendicular [10].

RED—The reference color of equipment that passes classified information. It normally refers to patch panels [17].

REFERENCE LINE—The position of zero displacement in a wave [10].

REFERENCE POINT—A point in a circuit to which all other points in the circuit are compared [1].

REFLECTED WAVE—(1) The wave that reflects back from a medium. (2) The wave moving back to the source from the termination of a transmission line after reflection has occurred [10].

REFLECTING OBJECT—In radar a air or surface contact that provides an echo [18].

REFLECTION WAVES—Waves that are neither transmitted nor absorbed, but are reflected from the surface of the medium they encounter [10].

REFLECTOR—The parasitic element of an array that causes maximum energy radiation in a direction toward the driven element [10].

REFLEX KLYSTRON—A klystron with a reflector (repeller) electrode in the place of a second resonant cavity used to redirect the velocity-modulated electrons back through the cavity that produced the modulation [11]. (2) A microwave oscillator that is tuned by changing the repealer voltage [18].

REFRACTION—The changing of direction of a wave as it leaves one medium and enters another medium of a different density [10] [18].

REFRACTIVE INDEX—In a wave-transmission medium, the ratio between the phase velocity in free space and in the medium [11] [18].

REGENERATION—See FEEDBACK [18].

REGENERATIVE DETECTOR—A detector circuit that produces its own oscillations, heterodynes them with an incoming signal, and deflects them [12].

REGENERATIVE FEEDBACK—The process by which a portion of the output signal of an amplifying device is fed back in phase to reinforce the input. Also called POSITIVE FEEDBACK [8] [9].

REGULATOR—The section in a basic power supply that maintains the output of the power supply at a constant level in spite of large changes in load current or input line voltage [6] [7].

RELATIVE BEARING—Bearing of a target measured in a clockwise direction from "dead ahead" of a ship or plane [18].

RELAY—An electromagnetic device with one or more sets of contacts that change position by the magnetic attraction of a coil to an armature [3].

RELUCTANCE—A measure of the opposition that a material offers to magnetic lines of force [1].

REMOTE-CUTOFF TUBE—An electron tube in which the control grid wires are farther apart at the centers than at the ends. This arrangement allows the tube to amplify large signals without being driven into cutoff. This tube is also called a VARIABLE-MU TUBE [6].

REPEATER—(1) Another name for an active satellite [17]. (2) Also, a common name for remote radar indicators.

REPELLER—Sometimes called a REFLECTOR. An electrode in a reflex klystron with the primary purpose of reversing the direction of the electron beam [11].

REPERFORATOR—Equipment that converts the incoming TTY signal and stores it on paper tape [17].

REPRODUCTION—The process of converting electrical signals to sound waves. This sound is speech, music, and so on [17].

REPULSION—The mechanical force tending to separate bodies having like electrical charges or like magnetic polarity [1].

RERADIATION—The reception and retransmission of radio waves that is caused by turbulence in the troposphere [10].

RESIDUAL MAGNETISM—Magnetism remaining in a substance after removal of the magnetizing force [1].

RESISTANCE—(1) The opposition a device or material offers to the flow of current. The effect of resistance is to raise the temperature of the material or device carrying the current. (2) A circuit element designed to offer a predetermined resistance to current flow. A resistance of 1 ohm will allow a current of 1 ampere to flow through it when a potential of 1 volt is applied. [1].

RESISTIVITY—See SPECIFIC RESISTANCE. The reciprocal of conductivity [4].

RESISTOR—The electrical component that offers resistance to the flow of current. It may be a coil of fine wire or a composition rod [1].

RESOLVER—A rotary, electromechanical device used to perform trigonometric computations by varying the magnetic couplings between its primary and secondary windings. It is generally used in circuits that solve vector problems, such as analog computers and conversion equipment. The resolver solves three different type problems: (1) Resolution - separating a vector into two mutually perpendicular components; (2) Composition - combining two components of a vector to produce a vector sum; and (3) Combination - the process of resolution and composition taking place simultaneously [15].

RESONANCE—The condition in a circuit containing inductance and capacitance in which the inductive reactance is equal and opposite to the capacitive reactance. This condition occurs at only one frequency and the circuit in that condition is said to be in resonance [2] [9] [10].

RESONANCE CHAMBER—See ECHO BOX [18].

RESONANT CIRCUIT—A circuit that contains both inductance and capacitance and is resonant at one frequency ($X_L = X_C$) [9].

RESONANT FREQUENCY—That frequency in a given resonant circuit at which the inductive and capacitive reactance values are equal and cancel each other [9].

RESONANT LINE—A transmission line that has standing waves of current and voltage [10].

REST FREQUENCY—The carrier frequency during the constant-amplitude portions of a phase modulation signal [12].

REST POSITION—See REFERENCE LINE [10].

REST TIME (RT)—The time when there is no pulse; nonpulse time [12].

RESULTANT MAGNETIC FIELD—The magnetic field produced in a synchro by the combined effects of the three stator magnetic fields [15].

RETENTIVITY—The ability of a material to retain its magnetism [1].

RETURN—The RF signal reflected back from a radar target; echo [18].

REVERBERATION—The multiple reflections of sound waves [10].

REVERSE AGC—The type of AGC that causes an amplifier to be driven toward cut-off [17].

REVERSE BIAS—An external voltage applied to a diode or semiconductor junction to reduce the flow of electrons across the junction. Also called BACK BIAS [7] [13].

RF RADIATION HAZARD—A health hazard caused by exposure to electromagnetic radiation or high-energy particles (ions). Abbreviated RADHAZ [18].

RF (RADIO FREQUENCY) AMPLIFIER—An amplifier designed to amplify signals with frequencies between 10 kilohertz (10 kHz) and 100,000 megahertz (100,000 MHz) [8].

RF (RADIO FREQUENCY) TRANSFORMER—A transformer specially designed for use with RF (radio frequencies). An RF transformer is wound onto a tube of nonmagnetic material and has a core of either powdered iron or air [8].

RGK—The symbol used to express the resistance between the grid and the cathode of an electron tube [6].

RHEOSTAT—A variable resistor used for the purpose of adjusting the current in a circuit [1] [4].

RHO—Greek letter "rho" (ρ). Used in the field of electricity and electronics to represent the specific resistance of a substance [4].

RHOMBIC ANTENNA—A diamond-shaped antenna used widely for long-distance, high-frequency transmission and reception [10].

RIGID COAXIAL LINE—A coaxial line consisting of a central insulated wire (inner conductor) mounted inside of a tubular outer conductor [10].

RIGIDITY—The tendency of the spin axis of a gyro wheel to remain in a fixed direction in space if no force is applied to it [15].

RINGING—RF oscillations caused by shock excitation of a resonant circuit or cavity [18].

RING TIME—In radar, the time during which the output of an echo box remains above a specified level [18].

RIPPLE FREQUENCY—The frequency of the ripple current. In a full-wave rectifier it is twice the input-line frequency [6].

RIPPLE VOLTAGE—The alternating component of unidirectional voltage. (This component is small compared to the direct component.) [6]

RLC CIRCUIT—An electrical circuit that has the properties of resistance, inductance, and capacitance [2].

RL DIFFERENTIATOR—An RL circuit in which the output is taken from the inductor [9].

RL INTEGRATOR—An RL circuit in which the output is taken from the resistor [9].

RMS—Abbreviation of root mean square [2].

ROOT MEAN SQUARE (RMS)—The equivalent heating value of an alternating current or voltage, as compared to a direct current or voltage. It is 0.707 times the peak value of a sine wave [2].

ROTARY CAP—A spark gap, similar to a mechanically driven rotary switch, used to discharge a pulse-forming network [12].

ROTARY SWITCH—A multicontact switch with contacts arranged in a circular or semicircular manner [3].

ROTATING FIELD—The magnetic field in a multiphase ac motor that is the result of field windings being energized by out-of-phase currents. In effect, the magnetic field is made to rotate electrically rather than mechanically [5].

ROTATING JOINT—A joint that permits one section of a transmission line or waveguide to rotate continuously with respect to another while passing energy through the joint. Also called a rotary coupler [11].

ROTOR—(1) The revolving part of a rotating electrical machine. The rotor may be either the field or the armature, depending on the design of the machine [5]. (2) The rotating member of a synchro that consists of one or more coils of wire wound on a laminated core. Depending on the type of synchro, the rotor functions similarly to the primary or secondary winding of a transformer [15].

RPK—The symbol used to represent the resistance between the cathode and plate of a tube [6].

RUNNING OPEN—The teletypewriter condition where the type hammer constantly strikes the type box but does not print or move across the page [17].

SATELLITE ECLIPSE—An eclipse where the rays of the sun do not reach the satellite. This prevents recharging of the solar cells of the satellite and decreases the power to the transmitter [17].

SATELLITE-SUN CONJUNCTION—A period when the satellite and sun are close together and the noise from the sun prevents or hampers communications [17].

SATURABLE-CORE REACTOR—A coil in which the reactance is controlled by changing the permeability of the core [8].

SATURATION—(1) The condition existing in any circuit in which an increase in the input signal produces no further change in the output [13]. (2) The operating point of a vacuum tube or transistor at which a further increase in grid or base current no longer produces an increase in plate or collector current [6] [7]. (3) In a magnetic core, the condition in which a magnetic material has reached a maximum flux density and the permeability has decreased to a value of (approximately) 1 [8].

SCALING FACTOR—The term used to describe the use of unequal resistors in a servo's summing network to compensate for differences between input and output signal levels [15].

SCANNING—(1) The process of subdividing a picture in an orderly manner into segments. This is used in facsimile transmission [17]. (2) Systematic movement of a radar beam to cover a definite pattern or area in space [18].

SCAT CODE—A four-digit subcategory code used to identify the functional measurement parameters that can be satisfied by any one of many pieces of test equipment [16].

SCATTER ANGLE—The angle at which the receiving antenna must be aimed to capture the scattered energy of tropospheric scatter [10].

SCHEMATIC—A diagram which shows, by means of graphic symbols, the electrical connections and functions of a specific circuit arrangement [1] [4].

SCHEMATIC SYMBOLS—A letter, abbreviation, or design used to represent specific characteristics or components on a schematic diagram [1].

SCINTILLATION—Apparent change in target reflectivity. Motion of the target causes successive radar pulses to bounce off different parts of the target, such as fuselage and wingtip [18].

SCREEN GRID—A grid placed between a control grid and the plate and usually maintained at a fixed positive potential [6].

SCREENING—Process of applying nonconductive or semiconductive materials to a substrate to form thick film components [14].

SEA CLUTTER—Unwanted echoes from the irregular surface of the sea that appear on a radar indicator [18].

SEARCH RADAR SYSTEM—An early-warning device that searches a fixed volume of space [18].

SECAS (SHIP EQUIPMENT CONFIGURATION ACCOUNTING SYSTEM)—The Navy system that keeps track of the configuration of equipment in the fleet [16].

SECONDARY—The output coil of a transformer [2].

SECONDARY CELL—A cell that can be recharged by a current being passed through the cell in a direction opposite to the discharge current [1].

SECONDARY EMISSION—The liberation of electrons from an element, other than the cathode, as a result of being struck by other high-velocity electrons [6].

SECONDARY LOOP—In a cooling system, the loop that transfers the heat from the heat source, such as electronic equipment, to the primary loop; usually distilled water [18].

SECOND DETECTOR (DEMODULATOR)—The part of the receiver that separates the audio or video component from the modulated intermediate frequency [18].

SECOND-SWEEP ECHOES—See AMBIGUOUS RETURNS [18].

SELECTIVITY—The ability of a receiver to select the desired signal and reject unwanted signals [9] [17].

SELENIUM—A chemical element with light-sensitive properties that makes it useful as a semiconductor material in metallic rectifiers [7].

SELF-BIAS—In a vacuum tube circuit, the voltage developed by the flow of current through a resistor in the grid or cathode leads [6].

SELF-EXCITED GENERATORS—DC generators in which the generator output is fed to the field to produce field excitation [5].

SELF-EXCITED METER—A term used to describe meters that operate from their own power sources [16].

SELF-INDUCTION—(1) The production of a counterelectromotive force in a conductor when its own magnetic field collapses or expands with a change in current in the conductor [2]. (2) The phenomenon caused by the expanding and collapsing fields of an electron that encircle other electrons and retard the movement of the encircled electrons [10].

SELF-LUMINOUS BODIES—Objects that produce their own light [10].

SELF-SYNCHRONIZED RADAR—A type of radar in which the timing pulses are generated within the transmitter [18].

SENDING END—See INPUT END [10].

SENSITIVITY—(1) For an ammeter, the amount of current that will cause full-scale deflection of the meter. (2) For a voltmeter, the ratio of the voltmeter resistance divided by the full-scale reading of the meter; expressed in ohms per volt [3] [16]. (3) The ability of a receiver to reproduce very weak signals. The greater the receiver sensitivity, the weaker the signal that can be reproduced [17]. (4) Efficiency of a microphone. Describes microphone power delivered to a matched-impedance load as compared to the sound level being converted. Usually expressed in terms of the electrical power level [12].

SENSITIVITY TIME CONTROL (STC)—A circuit that varies the gain of a receiver as a function of time [18].

SERIES CIRCUIT—An arrangement where electrical devices are connected so that the total current must flow through all the devices; electrons have one path to travel from the negative terminal to the positive terminal [1].

SERIES-CONNECTED DUPLEXER—A configuration in which the tr spark gap is connected in series in one leg of the transmission line one-half wavelength away from the T-junction [18].

SERIES-DIODE DETECTOR—The semiconductor diode in series with the input voltage and the load impedance. Sometimes called a VOLTAGE-DIODE DETECTOR [12].

SERIES-FED OSCILLATOR—An oscillator in which dc power is supplied to the amplifier through the tank circuit or a portion of the tank circuit [9].

SERIES LIMITER—A diode connected in series with the output, in which the output is taken across the resistor. Either the positive or negative alternation of the input wave is eliminated [9].

SERIES-NEGATIVE LIMITER—A diode connected in series with the output, in which the output is taken across the resistor. It eliminates the negative alternation of the input wave [9].

SERIES-PARALLEL CIRCUIT—A circuit that consists of both series and parallel networks [1] [9].

SERIES PEAKING—A technique used to improve high-frequency response in which a peaking coil is placed in series with the output signal path [8].

SERIES-POSITIVE LIMITER—A diode connected in series with the output, in which the output is taken across a resistor. It eliminates the positive alternation of the input wave [9].

SERIES-RESONANT CIRCUIT—A resonant circuit in which the source voltage is connected in series with a capacitor and an inductor (also in series) to furnish a low impedance at the frequency at which the circuit is resonant [9] [10].

SERIES VOLTAGE REGULATOR—A regulator with a regulating device that is in series with the load resistance [7].

SERIES-WOUND MOTORS AND GENERATORS—Machines in which the armature and field windings are connected in series with each other [5].

SERVOAMPLIFIER—Either ac or dc amplifiers used in servosystems to build up signal strength. These amplifiers usually have relatively flat gain versus frequency response, minimum phase shift, low output impedance, and low noise level [15].

SERVOMOTOR—An ac or dc motor used in servosystems to move a load to a desired position or at a desired speed. The ac motor is usually used to drive light loads at a constant speed, while the dc motor is used to drive heavy loads at varying speeds [15].

SERVOSYSTEM—An automatic feedback control system that compares a required condition (desired value, position, and so forth) with an actual condition and uses the difference to drive a control device to achieve the required condition [15].

SET—A unit or units and the assemblies, subassemblies, and parts connected or associated together to perform a specific function [17].

SEXADECIMAL—Same as HEXADECIMAL [13].

SHADOW—A dead spot (minimum radiation) caused by the physical obstruction of transmitted waves by a feed horn [18].

SHAPING CIRCUIT—A circuit that alters the shapes of input waveforms [9].

SHARP-CUTOFF TUBE—The opposite of a remote-cutoff tube. An electron tube that has evenly spaced grid wires. The amplification of the sharp-cutoff tube is limited by the bias voltage and tube characteristics [6].

SHELF LIFE—The period of time that a cell or battery may be stored and still be useful [1].

SHIELDED PAIR—A line consisting of parallel conductors separated from each other and surrounded by a solid dielectric [10].

SHIELDING—(1) A metallic covering used to prevent magnetic or electromagnetic fields from affecting an object [1]. (2) Technique designed to minimize internal and external interference [14].

SHORT CIRCUIT—An unintentional current path between two components in a circuit or between a component and ground; usually caused by a circuit malfunction [1] [3] [16].

SHORT-CIRCUITED LINE—A transmission line that has a terminating impedance equal to 0 [10].

SHUNT—A resistive device placed in parallel with another component. Appreciable current may flow through it and an appreciable voltage may exist across it [12].

SHUNT-DIODE DETECTOR—A diode detector in which the diode is in parallel with the input voltage and the load impedance. Also known as a current detector because it operates with smaller input levels [12].

SHUNT-FED OSCILLATOR—An oscillator that receives its dc power for the transistor or tube through a path both separate from and parallel to the tank circuit [9].

SHUNT PEAKING—A technique used to improve high-frequency response in which a peaking coil is placed in parallel (shunt) with the output signal path [8].

SHUNT RESISTOR—A resistor in parallel. In an ammeter, shunt resistors are used to provide multiple ranges [3].

SHUNT VOLTAGE REGULATOR—A regulator whose regulating device is in parallel with the load resistance [7].

SHUNT-WOUND MOTORS AND GENERATORS—Machines in which the armature and field windings are connected in parallel (shunt) with each other [5].

SIEMENS—The new and preferred term for MHO [1].

SIGNAL—A general term used to describe any ac or dc of interest in a circuit; for example, input signal [8] [15].

SIGNAL DISTORTION—Any unwanted change to the signal [12].

SIGNIFICANT SIDEBANDS—Those sidebands with significantly large amplitude [12].

SILICON—A metallic element which, in its pure state, is used as a semiconductor [7].

SILICON-CONTROLLED RECTIFIER (SCR)—A semiconductor device that functions as an electrically controlled switch [7].

SINE WAVE—(1) The curve traced by the projection on a uniform time scale of the end of a rotating arm, or vector. Also known as a sinusoidal wave [2]. (2) The basic synchronous alternating waveform for all complex waveforms [12].

SINGLE-ENDED MIXER—See UNBALANCED CRYSTAL MIXER [18].

SINGLE LINE DIAGRAM—A diagram which shows, by means of single lines and graphic symbols, the course of an electric circuit or system of circuits and the component devices or parts used therein [4].

SINGLE, STATIONARY-LOBE SCANNING SYSTEM—Antenna (with a single, stationary beam) that is rotated to obtain 360-degree coverage [18].

SINK—See OUTPUT END [10].

SKIN EFFECT—The tendency for alternating current to concentrate in the surface layer of a conductor. The effect increases with frequency and serves to increase the effective resistance of the conductor [10] [11].

SKIP DISTANCE—The distance from a transmitter to the point where the sky wave is first returned to earth [10].

SKIP ZONE—A zone of silence between the point where the ground wave becomes too weak for reception and the sky wave is first returned to earth [10].

SKY WAVES—Radio waves reflected back to earth from the ionosphere [10].

SLANT RANGE—See RANGE [18].

SLIP—The difference between rotor speed and synchronous speed in an ac induction motor [5].

SLIP RINGS—Contacts that are mounted on the shaft of a motor or generator to which the rotor windings are connected and against which the brushes ride [5]. Devices for making electric connections between stationary and rotating contacts.

SLOPE DETECTOR—A tank circuit tuned to a frequency, either slightly above or below an FM carrier frequency, that is used to detect intelligence [12].

SLOT—Narrow opening in a waveguide wall used to couple energy in or out of the waveguide. Also called an aperture or a window [11].

SNAP-ACTING—Changing position quickly with the aid of a spring [3].

SOLENOID—An electromagnetic device that changes electrical energy into mechanical motion; based upon the attraction of a movable iron plunger to the core of an electromagnet [3].

SOLID—One of the three states of matter; it has definite volume and shape (ice is a solid) [1].

SOLID-STATE DEVICE—An electronic device that operates by the movement of elections within a solid piece of semiconductor material [7].

SONIC—Pertaining to sounds capable of being heard by the human ear [10].

SOURCE—(1) The object that produces the waves or disturbance. (2) The name given to them end of a two-wire transmission line that is connected to a source [10]. (3) The device which furnishes the electrical energy used by a load [1].

SOURCE, MAINTENANCE, AND RECOVERABILITY CODE (SM & R CODE)—Specifies maintenance level for repair of components or assemblies [14].

SPACE—Absence of an RF signal in cw keying. Key-open condition or lack of data in communications systems. Also a period of no signal [12].

SPACE CHARGE—An electrical charge distributed throughout a volume or space [6].

SPACE DIVERSITY—Reception of radio waves by two or more antennas spaced some distance apart [10].

SPACE WAVE—Radio waves that travel directly from the transmitter to the receiver and remain in the troposphere [10].

SPACING—The condition in teletypewriter operation where a circuit is open and no current flows [17].

SPARK-GAP MODULATOR—A modulator that consists of a circuit for storing energy, a circuit for rapidly discharging the storage circuit (spark gap), a pulse transformer, and a power source [12].

SPECIAL PURPOSE ELECTRONIC TEST EQUIPMENT (SPETE)—Test equipment that is specifically designed to generate, modify, or measure a range of electronic functions of a specific or peculiar nature on a single system or equipment [16].

SPECIFIC GRAVITY—The ratio between the density of a substance and that of pure water at a given temperature [1].

SPECIFIC RESISTANCE—The resistance measured in ohms of a unit volume of a substance to the flow of electric current. (The unit volume used is generally the circular mil-foot.) [4]

SPECTRUM—(1) The entire range of electromagnetic waves arranged in order of their frequencies. (2) The range of frequencies considered in a system [10].

SPECTRUM ANALYSIS—The display of electromagnetic energy arranged according to wavelength or frequency [12].

SPECTRUM ANALYZER—A test instrument that provides a visual display of the frequency distribution of an RF signal such as a transmitter output [18].

SPIN VECTOR—In a gyro, a vector representing the angular velocity of the gyro rotor. The spin vector lies along the spin axis of the rotor [15].

SPHERICAL WAVEFRONTS—Waves of energy that spread out in concentric circles [18].

SPLATTER—Unwanted sideband frequencies that are generated from overmodulation [12].

SPLICE—A joint formed by the connecting of two or more conductors [4].

SPORADIC E LAYER—Irregular, cloud-like patches of unusually high ionization. Often forms at heights near the normal E layer [10].

SPREADER—Insulator used with transmission lines and antennas to keep the parallel wires separated [10].

SPROCKET TUNER—A mechanical tuning device for magnetron tubes that changes the frequency of the cavities by changing the inductance. Also called a CROWN-OF-THORNS TUNER [11].

SQUARE MIL—The area of a square, the sides of which are each equal to 1 mil. One square mil is equal to 1.2732 circular mils [4].

SQUELCH—A circuit that cuts off the output of a receiver when there is no input [17].

SQUIRREL-CAGE WINDINGS—A type of rotor winding in which heavy conductors are imbedded in the rotor body. The conductors are shorted together at the ends by continuous rings. It is widely applied in ac induction motors. Physically, it appears as a rotating squirrel-cage, thus the name [5].

STABILITY—In a magnetron, the ability to maintain normal operating characteristics [18].

STAGE—One of a series of circuits within a single device; for example, first stage of amplification [8].

STAGGER TUNING—A method of klystron tuning in which the resonant cavities are tuned to slightly different frequencies to increase the bandwidth of the amplifier [11].

STANDING WAVE—The distribution of voltage and current, formed by the incident and reflected waves, that has minimum and maximum points on a resultant wave that appear to stand still [10].

STANDING-WAVE RATIO (SWR)—The ratio of the maximum (voltage, current) to the minimum (voltage, current) points of a transmission line. Indicates the impedance matching quality of the termination of the line [10] [11].

START—The first unit of a teletypewriter signal. It is always a space [17].

STATIC—(1) A fixed nonvarying condition, without motion [13]. (2) Atmospheric noise, as in a receiver.

STATIC ELECTRICITY—Stationary electricity that is in the form of a charge. The accumulated electric charge on an object [1].

STATOR—(1) The stationary part of a rotating electrical machine. The stator may be either the field or the armature, depending on the design of the machine [5]. (2) The stationary member of a synchro that consists of a cylindrical structure of slotted laminations on which three Y-connected coils are wound with their axes 120 degrees apart. Depending on the type of synchro, the stator's functions are similar to the primary or secondary windings of a transformer [15].

STATUTE MILE—5,280 feet [18].

STEP-BY-STEP COUNTER—A counter that provides an output for each cycle of the input in one-step increments [9].

STEP-TRANSMISSION SYSTEM—A data transmission system that operates on direct current. It consists of a step transmitter (rotary switch) and a step motor interconnected to transmit data (information) between remote locations [15].

STICKOFF VOLTAGE—A low voltage used in multispeed synchrosystems to prevent false synchronizations [15].

STOP—The last unit of a teletypewriter signal. It is always a mark [17].

STRANDED CONDUCTOR—A conductor composed of a group of wires. The wires in a stranded conductor are usually twisted together and not insulated from each other [4].

STRANDS—Fine metallic filaments twisted together to form a single wire [4].

STRATOSPHERE—Located between the troposphere and the ionosphere; it has little effect on radio waves [10].

STROBOSCOPE—An instrument that allows viewing of rotating or reciprocating objects by producing the optical effect of a slowing down or stopping motion [16].

STUB—Short section of a transmission line used to match the impedance of a transmission line to an antenna. Can also be used to produce desired phase relationships between connected elements of an antenna [10] [18].

SUBASSEMBLY—Consists of two or more parts that form a portion of an assembly or a unit [17].

SUBHARMONIC—An exact submultiple of the fundamental frequency. Even subharmonics are one-half, one-quarter, and so on. Odd subharmonics are one-third, one-fifth, and so on of the fundamental frequency [17].

SUBSTRATE—Mounting surface for integrated circuits. May be semiconductor or insulator material depending on type of IC [14].

SUDDEN IONOSPHERIC DISTURBANCE—An irregular ionospheric disturbance that can totally blank out hf radio communications [10].

SUMMING NETWORK—A combination of two or more parallel resistors used in servosystems as an error detector. The output of the network is the algebraic sum of the inputs [15].

SUPERHETERODYNE RECEIVER—A type of receiver that uses a mixer to convert the RF echo to an IF signal for amplification [18].

SUPERHIGH FREQUENCY—The band of frequencies from 3 gigahertz to 30 gigahertz [17].

SUPERSONIC—(1) Speed greater than the speed of sound [10]. (2) Ultrasonic.

SUPPORT SYSTEM—For a radar, a system that provides an auxiliary input, such as dry air, electrical power, or liquid cooling [18].

SUPPRESSION—The process of eliminating an undesired portion of a signal [17].

SURFACE WAVE—Radio waves that travel along the contours of the earth, thereby being highly attenuated [10].

SWAMPING RESISTOR—A resistor used to increase or "broaden" the bandwidth of a circuit [8].

SWITCH—(1) A device used to connect, disconnect, or change the connections in an electrical circuit [1]. (2) A device used to open or close a circuit [3].

SYMMETRICAL MULTIVIBRATOR—A circuit that generates square waves [18].

SYMPTOM ELABORATION—Using built-in indicating instruments or other aids to define equipment malfunction [16].

SYMPTOM RECOGNITION—Recognition of a situation in equipment operation that is not normal [16].

SYNCHRO—A small motorlike analog device that operates like a variable transformer and is used primarily for the rapid and accurate transmission of data among equipments and stations [15].

SYNCHRO CAPACITOR—A unit containing three delta-connected capacitors. The synchro capacitor is used in synchro systems to increase the system's accuracy by cancelling or reducing the phase shift introduced by synchro inductance [15].

SYNCHRONIZER—A circuit that supplies timing signals to other radar components [18].

SYNCHRONIZING NETWORK—A circuit, also called a crossover or switching network, used in servosystems to sense how far the load is from the point of correspondence; it then functions to switch the appropriate signal into control [15].

SYNCHRONOUS—A type of teletypewriter operation where both transmitter and receiver operate continuously [17].

SYNCHRONOUS MOTOR—An ac motor whose rotor is activated by dc. It is characterized by constant speed and requires squirrel-cage windings or some other method to be self-starting [5].

SYNCHRONOUS ORBIT—An orbit in which the satellite moves or rotates at the same speed as the earth [17].

SYNCHRONOUS SPEED—The speed at which the rotating field in an ac motor revolves. This speed is a function of the number of poles in the field and the frequency of the applied voltage [5].

SYNCHRONOUS TUNING—In a klystron amplifier, a method of tuning that tunes all the resonant cavities to the same frequency. High gain is achieved, but the bandwidth is narrow [11].

SYNCHRO SYSTEM—Two or more synchros interconnected electrically. The system is used to transmit data among equipments and stations [15].

SYNCHRO TESTER—A synchro receiver with a calibrated dial. This receiver is used primarily for locating defective synchros. It can also be used for zeroing synchros [15].

SYSTEM—A combination of sets, units, assemblies, subassemblies, and parts joined together to form a specific operational function or several functions [17].

TACHOMETER—(1) A small ac or dc generator, sometimes referred to as a rate generator, that converts its shaft speed into an electrical output. The tachometer is frequently used in servosystems to sense the velocity of a load [15]. (2) An instrument that measures the rate at which a shaft is turning [16].

TANK CIRCUIT—A tuned circuit used to temporarily store energy. Also referred to as a parallel-resonant circuit [9].

TAPPED RESISTOR—A wire-wound, fixed resistor having one or more additional terminals along its length, generally for voltage-divider applications [1].

TARGET—In radar, a specific object of radar search or detection [18].

TARGET RESOLUTION—The ability of a radar to distinguish between two or more targets that are close to each other [18].

TELECOMMUNICATIONS—The transmission, emission, or reception of signs, signals, writings, images, or sounds. This is done by visual, oral, wire, radio, or other means [17].

TELETYPEWRITER—A machine that can transmit and/or receive letters, numbers, or symbols. It may have a keyboard similar to a typewriter [17].

TEMPERATURE COEFFICIENT—The amount of change of resistance in a material per unit change in temperature [1] [4].

TEMPERATURE INVERSION—The condition in which warm air is formed above a layer of cool air that is near the earth's surface [10].

TEMPEST—A term normally used to describe compromising emanations. These emanations are unintentionally radiated signals that could disclose classified information [17].

TENSILE STRENGTH—The greatest stress a substance can withstand along its length without tearing apart [4].

TERMINAL—An electrical connection [1] [4].

TERMINAL BOARD—Also called a terminal strip. An insulating base or slab equipped with terminals for connecting wiring [4].

TERMINAL DIAGRAM—A diagram of a switch, relay, terminal board, or other component showing the connections to the equipment [4].

TERMINAL LUG—A device attached to a conductor to permit connection to a terminal [4].

TEST EQUIPMENT—A general term applied to devices used to test electrical and electronic circuits [3].

TEST EQUIPMENT INDEX—The Navy guide used to assist in identifying portable electrical/ electronic test equipment required for support of prime electrical/electronic, IC, weapons, and reactor instrumentation systems [16].

TEST POINTS—Locations in equipment that are accessible to the technician's test probes where operating voltages or signals can be monitored [16].

TETRODE TUBE—A four-electrode electron tube containing a plate, a cathode, a control grid, and a screen grid [6].

THERMAL INERTIA—The capacity of a soldering iron to generate and maintain a satisfactory soldering temperature while giving up heat to the material being soldered [4].

THERMAL-MAGNETIC TRIP ELEMENT—A single circuit breaker trip element that combines the action of a thermal and a magnetic trip element [3].

THERMAL RUNAWAY—A conduction that exists when heat causes more electron-hole pairs to be generated, which, in turn, causes more heat and which may eventually cause diode destruction [7].

THERMAL TRIP ELEMENT—A circuit breaker trip element that uses the increased bending of a bimetallic strip caused by increased current to open a circuit [3].

THERMIONIC EMISSION—Emission of electrons from a solid body as a result of elevated temperature [6].

THERMISTOR—(1) A semiconductor device whose resistance varies with temperature [4]. (2) A type of bolometer characterized by a decrease in resistance as the dissipated power increases [16].

THERMOCOUPLE—A junction of two dissimilar metals that produces a voltage when heated [1].

THERMOCOUPLE METER MOVEMENT—A meter movement that uses the current induced in a thermocouple by the heating of a resistive element to measure the current in a circuit; used to measure ac or dc [3].

THERMOPLASTIC—A synthetic mixture of rosins that is flexible and used as an insulting material. Generally used as an insulator for low- and medium-range voltages [4].

THETA—The Greek letter (!) used to represent phase angle [2].

THICK FILM COMPONENTS—Passive circuit components (resistors and capacitors) having a thickness of 0.001 centimeter [14].

THIN FILM COMPONENTS—Passive circuit elements (resistors and capacitors) deposited on a substrate to a thickness of 0.0001 centimeter [14].

THREE-ELEMENT ARRAY—An array with two parasitic elements (reflector and director) and a driven element [10].

THREE-DIMENSIONAL RADAR (3D)—A radar set that measures the range, bearing and altitudes of a target [18].

THROW—In a switch, the number of different circuits each pole can control; for example, single throw and double throw [3].

THYRATRON—A gas tube used as a modulator switching device [18].

THYRATRON TUBE—A gas-filled triode in which a sufficiently large positive pulse applied to the control grid ionizes the gas and causes the tube to conduct, after which the control grid has no effect in conduction [6] [12].

TICKLER COIL—A small coil connected in series with the collector or plate circuit of a transistor or tube and inductively coupled to the base or grid-circuit coil to establish feedback (regeneration) [9].

TIME CONSTANT—Time required for an exponential quantity to change by an amount equal to 63.2 percent of the total change that can occur [2] [9].

TIME-DIVISION MULTIPLEXING—The process that periodically samples the full 360 degrees of each sine wave. The sample can be of a received signal or of a signal to be transmitted [17].

TIME LAG—The delay in a servosystem between the application of the input signal and the actual movement of the load [15].

TIMER—See SYNCHRONIZER [18].

TINNING—The process of applying a thin coat of solder to materials prior to their being soldered; for example, application of a light coat of solder to the filaments of a conductor to hold the filaments in place prior to soldering of the conductor [4].

TOLERANCE—(1) The maximum permissible error or variation from the standard in a measuring instrument. (2) A maximum electrical or mechanical variation of specifications that can be tolerated without impairing the operation of a device [1].

TONES—Musical sounds [10].

TONE-TERMINAL SET—Equipment that converts TTY dc pulses into audio tones for modulation of a transmitter in audio-frequency-tone shift transmissions [17].

TOP-HAT—An antenna that is center-fed and capacitively loaded [17].

TORQUE—A measure of how much load a machine can turn. This measurement is expressed either in ounce-inches for torque synchro systems or in pound-feet for heavy machinery [15].

TORQUE DIFFERENTIAL RECEIVER (TDR)—A type of differential synchro that takes two electrical inputs, one to the rotor and one to the stator, and produces a mechanical output. The output is the angular position of the rotor that represents the algebraic sum or difference of the two electrical inputs [15].

TORQUE DIFFERENTIAL SYNCHRO SYSTEM—A synchro system containing either a TDX or a TDR. This system is used in applications where it is necessary to compare two signals, add or subtract the signals, and furnish an output proportional to the sum or difference between the two signals [15].

TORQUE DIFFERENTIAL TRANSMITTER (TDX)—This type of synchro is functionally the same as the CDX, except that it is used in torque systems rather than control systems [15].

TORQUE GRADIENT—A term used in the rating of torque synchros. It is expressed in the number of inch-ounces of torque required to pull a specific synchro 1 degree away from its normal position; for example, 0.4 inch-ounce per degree [15].

TORQUE RECEIVER (TR)—A type of synchro that converts the electrical input supplied to its stator back to a mechanical angular output through the movement of its rotor [15].

TORQUE SYNCHRO SYSTEM—A synchro system that uses torque synchros to move light loads such as dials, pointers, and other similar devices [15].

TORQUE TRANSMITTER (TX)—This type of synchro is functionally the same as the CX, except that it is used in torque synchro systems [15].

TORQUE VECTOR—In a gyro, a vector representing the rotary motion applied to change the direction of the rotor axis. The torque vector represents the axis about which the applied force is felt [15].

TOTAL RESISTANCE—(R_T) The equivalent resistance of an entire circuit. For a series circuit: $R_T = R_1 + R_2 + R_3 \ldots R_n$. For parallel circuits:

$$\frac{1}{R_T} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \ldots \frac{1}{R_n} \quad [1].$$

TOXIC VAPORS—Vapors emitted by a substance that can do bodily harm [4].

TR RECOVERY TIME—Time required for a fired tr or atr tube to deionize to a normal level of conductance [18].

TRACK—Operational phase of a fire-control or track radar during which the radar beam is kept on the target [18].

TRACK RADAR—Radar that provides continuous range, bearing, and elevation data by keeping the RF beam on the target [18].

TRANSCONDUCTANCE—Transconductance is a ratio of the change in plate current to a change in grid voltage with the plate voltage held constant. Transconductance (g_m) is usually expressed in micromhos or millimhos. Mathematically,

$$g_m = \frac{I_p}{E_g} \quad [6][16].$$

TRANSFORMER—A device composed of two or more coils, linked by magnetic lines of force, used to transfer energy from one circuit to another [2].

TRANSFORMER EFFICIENCY—The ratio of output power to input power, generally expressed as a percentage.

$$\text{Efficiency} = \frac{P_{out}}{P_{in}} \times 100 \quad [2].$$

TRANSFORMER, STEP-DOWN—A transformer so constructed that the number of turns in the secondary winding is less than the number of turns in the primary winding. This construction will provide less voltage in the secondary circuit than in the primary circuit [2].

TRANSFORMER, STEP-UP—A transformer so constructed that the number of turns in the secondary winding is more than the number of turns in the primary winding. This construction will provide more voltage in the secondary circuit than in the primary circuit [2].

TRANSISTOR—A semiconductor device with three or more elements [7].

TRANSITION—The time it takes to shift from a mark to a space condition or from a space to a mark condition [17].

TRANSIT TIME—The time an electron takes to cross the distance between the cathode and the plate [6] [11].

TRANSLATION—In a gyro, a force acting through the center of gravity of the gyro that causes no torque on the gyro rotor. Translation forces do not change the angle of the plane of rotation but move the gyroscope as a unit [15].

TRANSLUCENT—Those substances, such as frosted glass, through which some light rays can pass but through which objects cannot be seen clearly [10].

TRANSMISSION LINE—A device designed to guide electrical or electromagnetic energy from one point to another [10].

TRANSMISSION MEDIUM—A means of transferring intelligence from point to point; includes light, smoke, sound, wire lines, and radio-frequency waves [10] [12].

TRANSMIT-RECEIVE TUBE (TR)—A gas-filled RF switch that is used as a duplexer [18].

TRANSMITTER—Equipment that generates and amplifies an RF carrier, modulates the RF carrier with intelligence, and radiates the signal into space [17] [18].

TRANSMITTER DISTRIBUTOR—A device that reads Baudot code from paper tape and allows a message to be printed on a page printer [17].

TRANSMITTER END—See INPUT END [10].

TRANSMITTER FREQUENCY (CARRIER FREQUENCY)—The frequency of the unmodulated output of a transmitter [18].

TRANSMITTER TRANSFER SWITCHBOARD—Equipment that selectively transfers remote station functions and signals to transmitters [17].

TRANSMITTING ANTENNA—The device used to send the transmitted signal energy into space [10].

TRANSPARENT—Those substances, such as glass, that pass almost all of the light waves falling upon them [10].

TRANSVERSE ELECTRIC MODE—A waveguide mode in which the entire electric field is perpendicular to the wide dimension and the magnetic field is parallel to the length. Also called the TE mode [11].

TRANSVERSE MAGNETIC MODE—A waveguide mode in which the entire magnetic field is perpendicular to the wide dimension and some portion of the electric field is parallel to the length. Also called the TM mode [11].

TRANSVERSE WAVE MOTION—The up and down motion of a wave as the wave moves outward [10].

TRAVERSE (BEARING) SIGNAL—In a monopulse radar system, the combination of individual lobe signals that represents target-offset direction and amplitude from the antenna axis [18].

TREMENDOUSLY HIGH FREQUENCY—The band of frequencies from 300 gigahertz to 3,000 gigahertz.

TRIAC—A three-terminal device that is similar to two SCRs back to back with a common gate and common terminals. Although similar in construction and operation to the SCR, the triac controls and conducts current flow during both alternations of an ac cycle [7].

TRIATIC—A special type of monopole antenna array [17].

TRIGGER—A short pulse, either positive or negative, that can be used to cause an electronic function to take place [9].

TRIGGER GENERATOR—See SYNCHRONIZER [18].

TRIGGER PULSES—In radar, pulses that are used to initiate specific events [18].

TRIODE TUBE—A three-electrode electron tube containing a plate, a cathode, and a control grid [6].

TRIP-ELEMENT—The part of a circuit breaker that senses any overload condition and causes the circuit breaker to open the circuit [3].

TRIP-FREE CIRCUIT BREAKER—A circuit breaker that will open a circuit even if the operating mechanism is held in the ON position [3].

TRIVALENT IMPURITY—Acceptor impurities containing only three valence electrons [7].

TROPOSPHERE—The portion of the atmosphere, closest to the earth's surface, where all weather phenomena take place [10].

TROPOSPHERIC SCATTER—The propagation of radio waves in the troposphere by means of scatter [10].

TROUBLE INDICATORS—Signal lights used to aid maintenance personnel in locating troubles quickly [15].

TROUBLESHOOTING—The process of locating and diagnosing faults in equipment by means of systematic checking or analysis [3] [15] [16].

TROUBLE TABLES—Tables of trouble symptoms and probable causes, furnished by many manufacturers to help technicians isolate problems [15].

TROUGH (BOTTOM)—The peak of the negative alternation (maximum value below the line) of a sine wave [10].

TRUE BEARING—Angle between a target and true north measured clockwise in the horizontal plane [18].

TRUE NORTH—Geographic north [18].

TRUE POWER—The power dissipated in the resistance of the circuit, or the power actually used in the circuit [2].

TRUNCATED PARABOLOID—A paraboloid reflector that has been cut away at the top and bottom to increase beam width in the vertical plane [18].

TRUTH TABLE—A table that describes a logic function by listing all possible combinations of input values and indicating, for each combination, the true output values [13].

TUBE DYNAMIC CONDITION—Refers to the testing condition in which a vacuum tube is actually performing its function [16].

TUBE STATIC CONDITION—Refers to the testing condition in which a tube has certain voltages applied but is not in its normal operating condition [16].

TUNED CIRCUIT—(1) A circuit consisting of inductance and capacitance that can be adjusted for resonance at a desired frequency [9]. (2) A circuit that is used as a filter which passes or rejects specific frequecies [16]. (3) An LC circuit used as a frequency-determining device [8].

TUNED LINE—Another name for the resonant line. This line uses tuning devices to eliminate the reactance and transfer maximum power from the source to the line [10].

TUNNEL DIODE—A heavily doped semiconductor device that has high gain and fast switching capabilities [7]. See NEGATIVE-RESISTANCE ELEMENT [11].

TUNNELING—The piercing of a potential barrier in a semiconductor by a particle (current carrier) that does not have sufficient energy to go over the barrier [11].

TURN—One complete loop of a conductor about a core [2].

TURNS RATIO—The ratio of the number of turns in the primary winding to the number of turns in the secondary winding of a transformer [2].

TURNSTILE ANTENNA—A type of antenna used in vhf communications that is omnidirectional and consists of two horizontal half-wave antennas mounted at right angles to each other in the horizontal plane [10].

TWISTED PAIR—A line consisting of two insulated wires twisted together to form a flexible line without the use of spacers [10].

TWO-DIMENSIONAL RADAR (2D)—Measures the range and bearing to a target [18].

TWO-M (2M)—Miniature/microminiature repair program [14].

TWO-WIRE OPEN LINE—A parallel line consisting of two wires that are generally spaced from 2 to 6 inches apart by insulating spacers [10].

TWO-WIRE RIBBON (TWIN LEAD)—A parallel two-wire line in which uniform spacing is assured by two wires imbedded in a low-loss dielectric [10].

ULTRAHIGH FREQUENCY—The band of frequencies from 300 megahertz to 3 gigahertz [17].

ULTRASONIC—(1) Sounds above 20,000 hertz [10]. (2) Supersonic.

UNBALANCED CRYSTAL MIXER—A circuit consisting of a section of coaxial transmission line one-half wavelength long that is tuned to the difference (intermediate) frequency between the local oscillator and RF echo signals [18].

UNIDIRECTIONAL—In one direction only [1].

UNIDIRECTIONAL ARRAY—An antenna array that radiates in only one general direction [10].

UNIJUNCTION TRANSISTOR (UJT)—A three-terminal, semiconductor device with a negative resistance characteristic that is used in switching circuits, oscillators, and wave-shaping circuits [7].

UNIT—(1) An assembly or any combination of parts, subassemblies, and assemblies mounted together. Normally capable of independent operation [17]. (2) A single object or thing [13].

UNIT SIZE—The standards adopted to make comparisons between things of like value (for example, the unit size for conductors is the mil-foot) [4].

UNIVERSAL TIME CONSTANT CHART—A chart used to find the time constant of a circuit if the impressed voltage and the values of R and C or R and L are known [2].

UNTUNED LINE—Another name for the flat or nonresonant line [10].

UP LINK—The frequency used to transmit a signal from earth to a satellite [17].

UPPER-FREQUENCY CUTOFF—The highest frequency a circuit can pass [9].

UPPER SIDEBAND—All of the sum frequencies above the carrier [12].

VACUUM EVAPORATION—Process of producing thin film components [14].

VALENCE—The measure of the extent to which an atom is able to combine directly with other atoms. It generally depends on the number and arrangement of the electrons in the outermost shell of the atom [1].

VALENCE SHELL—The electrons that form the outermost shell of an atom [1].

V ANTENNA—A bidirectional antenna, shaped like a V, which is widely used for communications [10].

VAR—Abbreviation for volt-amperes reactive [2].

VARACTOR—A PN junction semiconductor, designed for microwave frequencies, in which the capacitance varies with the applied voltage [7] [11] [12].

VARACTOR FM MODULATOR—An FM modulator that uses a voltage-variable capacitor (varactor) [12].

VARIABLE—A representative symbol that can assume any of a given set of values [13].

VARIABLE ATTENUATOR—An attenuator for reducing the strength of an ac signal either continuously or in steps, without causing signal distortion [11].

VARIABLE-MU-TUBE—Same as REMOTE-CUTOFF TUBE [6].

VARIABLE RESISTOR—A wire-wound or composition resistor, the value of which may be changed over a designed range [1].

VARNISHED CAMBRIC—Cotton cloth coated with insulation varnish. An insulation used on high-voltage conductors [4].

VECTOR—A line used to represent both direction and magnitude [2] [12].

VEITCH DIAGRAM—A diagram consisting of joined squares, which is used to give a graphic representation of basic logic relations [13].

VELOCITY—The rate at which a disturbance travels through a medium [10].

VELOCITY MODULATION—Modification of the velocity of an electron beam by the alternate acceleration and deceleration of electrons [11].

VELOCITY SERVOSYSTEM—A servosystem which controls the speed of the load it is driving [15].

VERTICAL AXIS—On a graph, the straight line axis that is plotted from bottom to top [10].

VERTICAL DEFLECTION PLATES—A pair of parallel electrodes in a CRT that moves the electron beam up and down [6].

VERTICAL PATTERN—The part of a radiation pattern that is radiated in the vertical plane [10].

VERTICAL PLANE—An imaginary plane that is perpendicular to the horizontal plane [11] [18].

VERTICALLY POLARIZED—Waves that are radiated with the E field component perpendicular to the earth's surface [10].

VERY HIGH FREQUENCY—The band of frequencies from 30 megahertz to 300 megahertz [17].

VERY LARGE SCALE INTEGRATION (vlsi)—An integrated circuit containing over 2,000 logic gates or 64,000 bits of memory [14].

VERY LOW FREQUENCY—The band of frequencies from 3 kilohertz to 30 kilohertz [17].

VIDEO AMPLIFIER—An amplifier designed to amplify the entire band of frequencies from 10 hertz (10 Hz) to 6 megahertz (6 MHz). Also called a WIDE-BAND AMPLIFIER [8].

VIDEO ENHANCEMENT FEATURES—See ANTIJAMMING CIRCUITS [18].

VINCULA—Plural of vinculum (see below) [13].

VINCULUM—A straight horizontal line placed over one or more members of a compound logic expression to negate or complement. Also, used to join two or more members together [13].

VIRTUAL GROUND—A point in a circuit that is at ground potential (0 V) but is not connected to ground [8].

VOLT—The unit of electromotive force or electrical pressure. One volt is the pressure required to send 1 ampere of current through a resistance of 1 ohm [1].

VOLTAGE—(1) The term used to signify electrical pressure. Voltage is a force that causes current to flow through an electrical conductor. (2) The voltage of a circuit is the greatest effective difference of potential between any two conductors of the circuit [1].

VOLTAGE AMPLIFIER—An amplifier in which the output-signal voltage is greater than the input-signal voltage [8].

VOLTAGE-DIODE DETECTOR—A series-diode detector in which the diode is in series with the input voltage and the load impedance [12].

VOLTAGE DIVIDER—A series network in which desired portions of the source voltage may be tapped off for use in the circuit [1].

VOLTAGE DROP—The difference in voltage between two points. It is the result of the loss of electrical pressure as a current flows through a resistance [1] [4].

VOLTAGE-FEED METHOD—Same as END-FEED METHOD [10].

VOLTAGE GAIN—The ratio of output voltage to input voltage in an amplifier [6].

VOLTAGE MULTIPLIERS—Methods of increasing voltages; used primarily where low current is required [7].

VOLTAGE REGULATION—A measure of the ability of a generator or power supply to maintain a constant output voltage from no-load to full-load operation. Expressed as a percentage of full-load voltage; the better the regulation, the lower the percent [5].

VOLTAGE STANDING WAVE RATIO (VSWR)—In a waveguide, the ratio of the electric field (voltage) at a maximum point to that of an adjacent minimum point [10] [18].

VOLTMETER—A meter used to measure voltage [3] [16].

WAFER—A slice of semiconductor material upon which monolithic ICs are produced [14].

WAFER SWITCH—A rotary switch in which the contacts are arranged on levels. Each level (wafer) is electrically independent but mechanically connected by the shaft of the switch [3].

WATT—The unit of electrical power that is the product of voltage and current [16].

WATTAGE RATING—A rating expressing the maximum power that a device can safely handle [1].

WATT-HOUR—A practical unit of electrical energy equal to one watt of power for one hour [1].

WATT-HOUR METER—A meter used to measure electrical energy [3].

WATTMETER—A meter used to measure electrical power [3] [16].

WAVE ANTENNA—Same as BEVERAGE ANTENNA [10].

WAVEFORM—The shape of the wave obtained when instantaneous values of an ac quantity are plotted against time in rectangular coordinates [2].

WAVEFORM ANALYSIS—Observation displays of voltage and current variations with respect to time or by harmonic analysis of complex signals [16].

WAVEFRONT—A small section of an expanding sphere of electromagnetic radiation that is perpendicular to the direction of travel of the energy [10].

WAVEGUIDE—A rectangular, circular, or elliptical metal pipe designed to transport electromagnetic waves through its interior [10] [11].

WAVEGUIDE DUPLEXER—TR and atr tubes housed in a resonant cavity attached to a waveguide system.

WAVEGUIDE MODE OF OPERATION—Any particular field configuration in a waveguide that satisfies the boundary conditions. Usually divided into two broad types: the transverse electric (TE) and the transverse magnetic (TM) modes [11].

WAVEGUIDE POST—A rod of conductive material used as impedance changing devices in waveguides [11].

WAVEGUIDE SCREW—A screw that projects into a waveguide for the purpose of changing the impedance [11].

WAVELENGTH—The distance, usually expressed in meters, traveled by a wave during the time interval of one complete cycle. It is equal to the velocity divided by the frequency [2] [10] [12].

WAVEMETERS—Calibrated resonant circuits that are used to measure frequency [16]. An instrument for measuring the wavelength of an RF wave [18].

WAVE MOTION—A recurring disturbance advancing through space with or without the use of a physical medium [10].

WAVE TRAIN—A continuous series of waves with the same amplitude and wavelength [10].

WAVE WINDING—An armature winding in which the two ends of each coil are connected to commutator segments separated by the distance between poles [5].

WEBER'S THEORY—A theory of magnetism which assumes that all magnetic material is composed of many tiny magnets. A piece of magnetic material that is magnetized has all of the tiny magnets aligned so that the north pole of each magnet points in one direction [1].

WHEATSTONE BRIDGE—An ac bridge circuit used to measure unknown values of resistance, inductance, or capacitance [16].

WIDE-BAND AMPLIFIER—An amplifier designed to pass an extremely wide band of frequencies, such as a video amplifier [8].

WINDOW—See SLOT [11].

WIRE—An insulated conductor, with low resistance to current flow, that is either solid or stranded [1] [4].

WIRING DIAGRAM—A diagram that shows the connections of an equipment or its component devices or parts. It may cover internal or external connections, or both, and contains such detail as is needed to make or trace connections that are involved [4].

WOBBLE FREQUENCY—The frequency at which an electron wobbles on its axis under the influence of an external magnetic field of a given strength [11].

WORDS-PER-MINUTE—An approximate rate of speed. It means the number of five letter words with a space between them that can be transmitted or received in a one-minute period [17].

WORK—The product of force and motion [1].

WORKING VOLTAGE—The maximum voltage that a capacitor may operate at without the risk of damage [2].

WYE (Y)—A 3-phase connection in which one end of each phase winding is connected to a common point. Each free end is connected to a separate phase wire. The diagram of this connection often resembles the letter Y [5].

X-AXIS—In a gyro, the spin axis of the gyro [15].

X-RAY EMISSION—Penetrating radiation similar to light, but with shorter wavelength, that can penetrate human tissue [18].

YAGI ANTENNA—A multielement parasitic array. The elements lie in the same plane as those of the end-fire array [10].

Y-AXIS—In a gyro, an axis through the center of gravity and perpendicular to the spin axis [15].

Z-AXIS—In a gyro, an axis through the center of gravity and mutually perpendicular to both the X (spin) and Y axes [15].

ZENER DIODE—A PN-junction diode designed to operate in the reverse-bias breakdown region [7].

ZENER EFFECT—A reverse breakdown effect in diodes in which breakdown occurs at reverse voltages below 5 volts. The presence of a high energy field at the junction of a semiconductor produces the breakdown [7].

ZEROING—The process of adjusting a synchro to its electrical zero position [15].

ZONE OF MUTUAL VISIBILITY—The area where the satellite can be seen by both the up- and down-link earth terminals [17].

PREFACE

By enrolling in this self-study course, you have demonstrated a desire to improve yourself and the Navy. Remember, however, this self-study course is only one part of the total Navy training program. Practical experience, schools, selected reading, and your desire to succeed are also necessary to successfully round out a fully meaningful training program.

COURSE OVERVIEW: To introduce the student to the subject of Test Methods and Practices who needs such a background in accomplishing daily work and/or in preparing for further study.

THE COURSE: This self-study course is organized into subject matter areas, each containing learning objectives to help you determine what you should learn along with text and illustrations to help you understand the information. The subject matter reflects day-to-day requirements and experiences of personnel in the rating or skill area. It also reflects guidance provided by Enlisted Community Managers (ECMs) and other senior personnel, technical references, instructions, etc., and either the occupational or naval standards, which are listed in the *Manual of Navy Enlisted Manpower Personnel Classifications and Occupational Standards,* NAVPERS 18068.

THE QUESTIONS: The questions that appear in this course are designed to help you understand the material in the text.

VALUE: In completing this course, you will improve your military and professional knowledge. Importantly, it can also help you study for the Navy-wide advancement in rate examination. If you are studying and discover a reference in the text to another publication for further information, look it up.

Sailor's Creed

"I am a United States Sailor.

I will support and defend the Constitution of the United States of America and I will obey the orders of those appointed over me.

I represent the fighting spirit of the Navy and those who have gone before me to defend freedom and democracy around the world.

I proudly serve my country's Navy combat team with honor, courage and commitment.

I am committed to excellence and the fair treatment of all."

TABLE OF CONTENTS

CREDITS

Many of the figures included in this edition of NEETS, Module 21, *Test Methods and Practices*, were provided by the companies listed below. Permission to use these illustrations is gratefully acknowledged.

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

INSTRUCTIONS FOR TAKING THE COURSE

ASSIGNMENTS

The text pages that you are to study are listed at the beginning of each assignment. Study these pages carefully before attempting to answer the questions. Pay close attention to tables and illustrations and read the learning objectives. The learning objectives state what you should be able to do after studying the material. Answering the questions correctly helps you accomplish the objectives.

SELECTING YOUR ANSWERS

Read each question carefully, then select the BEST answer. You may refer freely to the text. The answers must be the result of your own work and decisions. You are prohibited from referring to or copying the answers of others and from giving answers to anyone else taking the course.

SUBMITTING YOUR ASSIGNMENTS

To have your assignments graded, you must be enrolled in the course with the Nonresident Training Course Administration Branch at the Naval Education and Training Professional Development and Technology Center (NETPDTC). Following enrollment, there are two ways of having your assignments graded: (1) use the Internet to submit your assignments as you complete them, or (2) send all the assignments at one time by mail to NETPDTC.

Grading on the Internet: Advantages to Internet grading are:

- you may submit your answers as soon as you complete an assignment, and
- you get your results faster; usually by the next working day (approximately 24 hours).

In addition to receiving grade results for each assignment, you will receive course completion confirmation once you have completed all the assignments. To submit your assignment answers via the Internet, go to:

https://courses.cnet.navy.mil

COMPLETION TIME

Courses must be completed within 12 months from the date of enrollment. This includes time required to resubmit failed assignments.

PASS/FAIL ASSIGNMENT PROCEDURES

If your overall course score is 3.2 or higher, you will pass the course and will not be required to resubmit assignments. Once your assignments have been graded you will receive course completion confirmation.

If you receive less than a 3.2 on any assignment and your overall course score is below 3.2, you will be given the opportunity to resubmit failed assignments. **You may resubmit failed assignments only once.** Internet students will receive notification when they have failed an assignment—they may then resubmit failed assignments on the web site. Internet students may view and print results for failed assignments from the web site. Students who submit by mail will receive a failing result letter and a new answer sheet for resubmission of each failed assignment.

COMPLETION CONFIRMATION

After successfully completing this course, you will receive a letter of completion.

STUDENT FEEDBACK QUESTIONS

We value your suggestions, questions, and criticisms on our courses. If you would like to communicate with us regarding this course, we encourage you, if possible, to use e-mail.

NAVAL RESERVE RETIREMENT CREDIT

If you are a member of the Naval Reserve, you may earn retirement points for successfully completing this course, if authorized under current directives governing retirement of Naval Reserve personnel. For Naval Reserve retirement, this course is evaluated at 6 points. (Refer to *Administrative Procedures for Naval Reservists on Inactive Duty,* BUPERSINST 1001.39, for more information about retirement points.)

CHAPTER 1

BASIC MEASUREMENTS

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions and answers are based on the objectives and enable you to check your progress through the reading assignments. By successfully completing the OCC/ECC, you demonstrate that you have met the objectives and have learned the information. The learning objectives for this chapter are listed below.

Upon completion of this chapter, you will be able to do the following:

1. Explain the importance of performing basic electronic measurements.
2. Explain the importance of voltage measurements in troubleshooting.
3. Identify the various methods of performing voltage measurements.
4. Identify the various methods of performing current measurements.
5. Identify the various methods of performing resistance measurements.
6. Identify the various methods of performing capacitance measurements.
7. Identify the various methods of measuring inductance.

INTRODUCTION TO MEASUREMENTS

In today's modern Navy, a large part of a ship's, submarine's, or aircraft's ability to complete its mission depends on the efficiency of sophisticated electronic systems. As the technician responsible for these systems, you are the focal point in ensuring their reliability. In the event of a system failure, it is your responsibility to repair the system and to do so in a timely manner. Whether you are troubleshooting a faulty system or performing preventive maintenance, you are required to perform basic electronic measurements on a regular basis. This chapter will acquaint you with various alternative methods of performing measurements and discuss the relative merits and demerits of each method.

No discussion of electronic test equipment or electronic measurements would be complete without mentioning the Navy's Metrology Calibration (METCAL) program. Figure 1-1 shows the METCAL structure. Basically, the METCAL program is an elaborate quality control system designed to compare your electronic test equipment with test equipment of much greater accuracy. When you submit your piece of test equipment for calibration, it is compared with the calibration laboratory's equipment (referred to as STANDARDS), which are generally at least four times more accurate than yours. If your equipment does not meet specifications, it is either repaired, adjusted, or rejected with an explanation of why the calibration laboratory was unable to calibrate it. The accuracy of equipment at your local calibration laboratory is ensured by calibration of the test equipment to the standards of the next higher echelon calibration laboratory. The accuracies of test equipment at each higher echelon is increased by a ratio of approximately 4 to 1.

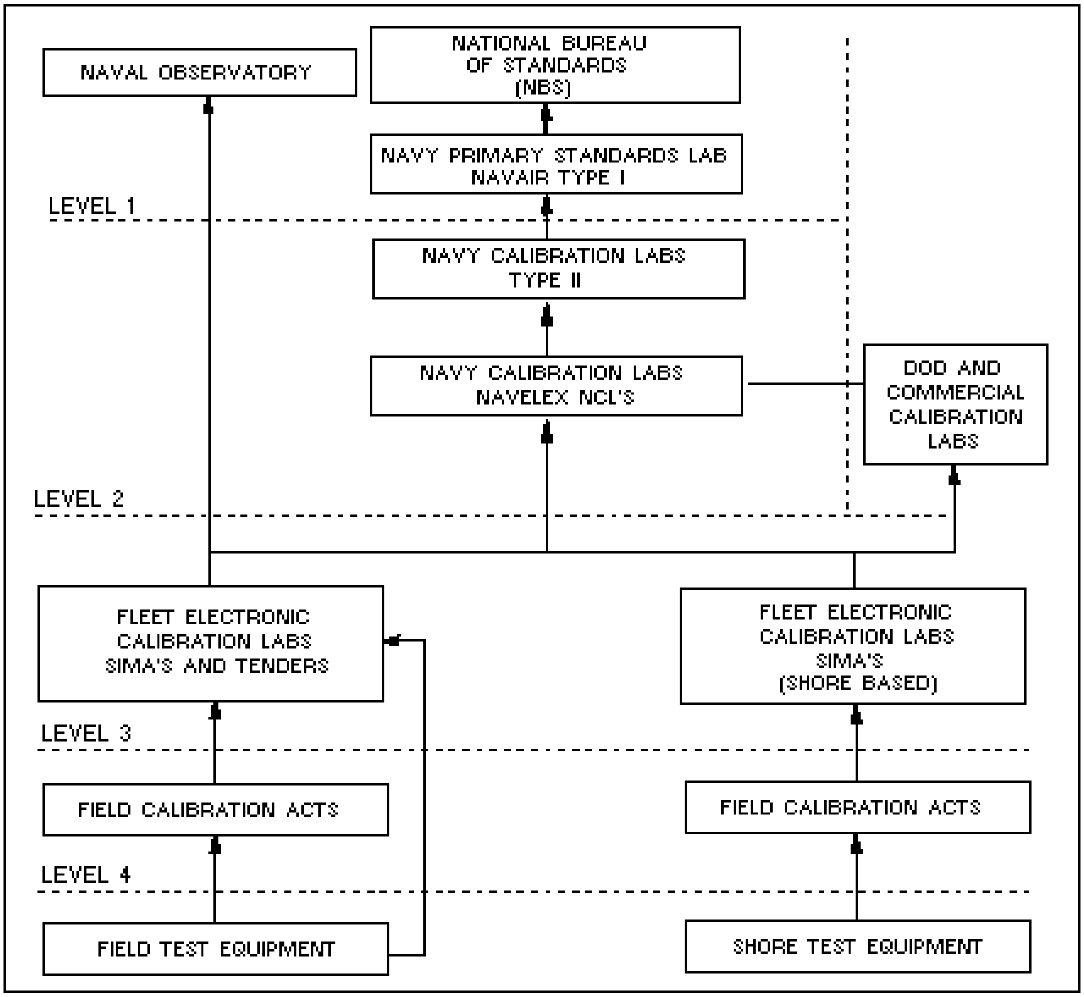

Figure 1-1.—Calibration laboratory structure.

METCAL provides assurance that your test equipment is in top-notch shape. Remember, your measurements are only as accurate as your test equipment; be fully aware of the limitations of your test equipment and never use equipment that isn't properly calibrated when performing measurements or adjustments.

Q-1. What assures the accuracy of your electronic test equipment?

Now that we have discussed the advantages of calibrated test equipment, let's review the reason for all this concern. The fundamental electrical quantities of a circuit are voltage and current and are dependent on the circuit characteristics of resistance, capacitance, and inductance. In addition to these three individual characteristics, don't forget that many electronic components exhibit more than one circuit characteristic at the same time. An example would be a piece of coaxial cable that is engineered by its manufacturer to meet characteristic specifications for impedance, capacitance, and inductance. But let's keep it simple and begin by covering voltage measurements.

Operation and use of common test equipment was covered in NEETS Module 16, *Introduction to Test Equipment,* NAVEDTRA B72-16-00-95. It is recommended that you review this module before continuing.

VOLTAGE MEASUREMENTS

Most Navy technical manuals provide voltage charts that list correct voltages at all primary test points in a piece of equipment. Voltage measurements, when compared with these charts, provide a valuable aid in locating troubles quickly and easily. However, if the sensitivity of the test equipment differs from that of the test equipment used in preparing the chart, the voltage measurements may not reflect true circuit conditions. You must keep in mind that a voltmeter with low sensitivity used on a low range may disturb circuits under test or provide a false indication. Most technical manuals will tell you what type and model of test equipment was used to prepare the voltage charts. As a rule of thumb, the input impedance of the voltmeter should exceed the impedance of the circuit by a ratio of at least 10 to 1. Technicians have spent uncounted hours of wasted time because they have selected improper test equipment.

Q-2. The input impedance of your test equipment should exceed the impedance of the circuit under test by what ratio?

DC VOLTAGE MEASUREMENTS

Direct current voltage may be steady, pulsating, or have ac superimposed on it. The average value of a dc waveform depends on the symmetry of the wave and other aspects of the wave shape. It can vary from 63.6% of peak value for a rectified full sine wave to 50% of peak value for a triangular wave. For a superimposed sine wave, the average value can be zero. Regardless of whether the dc is steady, pulsating, or the ac is superimposed on the dc, a rectifier form of measuring device will indicate its *average value*.

Voltages are usually measured by placing the measuring device in parallel with the component or circuit (load) to be measured. The measuring device should have an infinite internal resistance (input impedance) so that it will absorb *no* energy from the circuit under test and, therefore, measure the true voltage. The accuracy of the voltage measurement depends on the total resistance of the measuring device compared to the load being measured. When the input impedance of the measuring device is 10 times greater than the load being measured, the error usually can be tolerated. If this error cannot be tolerated, a high input impedance measuring device, such as a vacuum tube voltmeter (vtvm), should be used. Alternatively, using two voltmeters in series increases the voltage range and, because of the increase in total voltmeter resistance, provides a more accurate measurement of voltage across the load. If the voltage to be measured is sufficiently high, more than two similar voltmeters can be connected in series across the load to provide greater accuracy; the total voltage measurement is the sum of the individual meter indications.

Q-3. What are the advantages of using two voltmeters in series?

Multimeter Method

A common piece of test equipment used in the Navy is the Simpson 260 analog multimeter, as shown in figure 1-2. It is capable of measuring both ac and dc voltages of up to 5,000 volts.

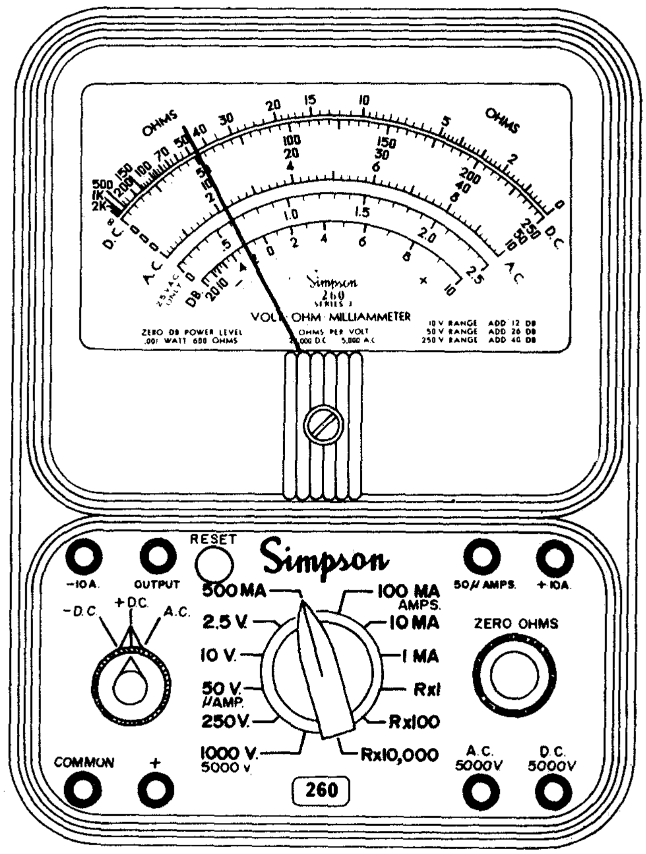

Figure 1-2.—Simpson 260 multimeter.

Two obvious advantages of the Simpson 260 are its portability and ease of operation. Among its disadvantages are its low input impedance and the inherent low accuracy associated with D'Arsonval meter movements, which are used in the meter. When performing measurements with any analog multimeter, remember that the most accurate readings are taken with the pointer midscale. You should also be aware of inaccuracies introduced as a result of parallax. PARALLAX is defined as the apparent displacement of the position of an object because of the difference between two points of view. In the case of meters, this means the position of a meter's pointer will appear to be at different positions on the scale depending on the angle from which the meter is viewed. Some of the Simpson 260 and 270 series multimeters have effectively eliminated the problem of parallax by incorporating a mirror on the scale that accurately reflects the position of the pointer of the meter movement.

Q-4. At what point on a meter movement are the most accurate readings taken?

Oscilloscope Method

A dc voltage measurement can be made with an oscilloscope, as shown in figure 1-3, that has a direct-coupled deflection amplifier or terminals for connection directly to the deflection plates of the cathode-ray tube. Measuring a dc voltage with an oscilloscope is convenient only under certain circumstances; for example, when other measurements are being made on the same equipment with the oscilloscope or when a vacuum tube voltmeter is not available and a high-impedance measuring device is required.

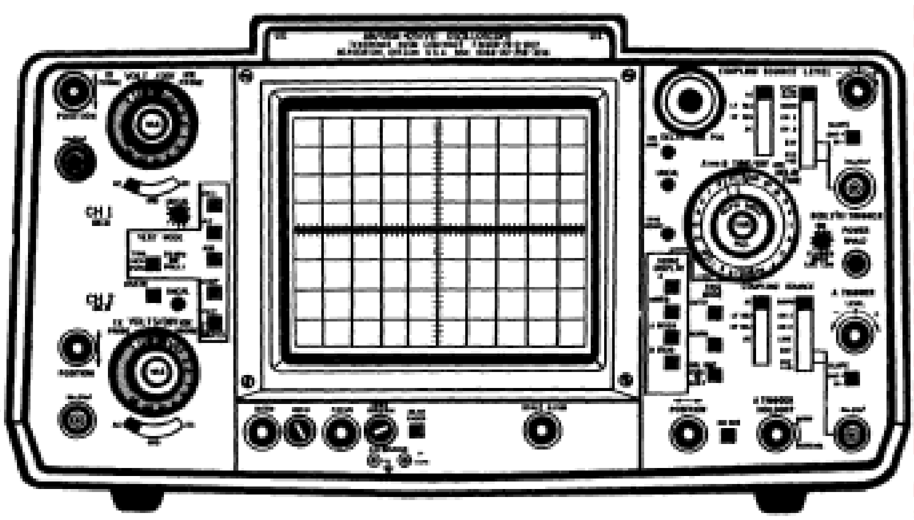

Figure 1-3.—Dual-trace oscilloscope.

Oscilloscopes have a high input impedance and normally will not load down the circuit under test. However, oscilloscopes are primarily designed for waveform observation and are typically less accurate than other pieces of test equipment used to measure dc voltages. A distinct advantage of the oscilloscope is its ability to monitor the level of ac ripple voltage riding the dc voltage. This feature makes the oscilloscope an indispensable aid in troubleshooting dc power supplies with excessive ripple caused by component failure.

Digital Multimeter Method

Most analog voltmeters (that use D'Arsonval meter movements) in common use today are accurate to approximately ±2% of full-scale reading. Most digital multimeters, as shown in figure 1-4, have a high input impedance and are not likely to disturb the circuit being tested. The digital multimeter in most cases provides an accuracy of at least ±0.1%.

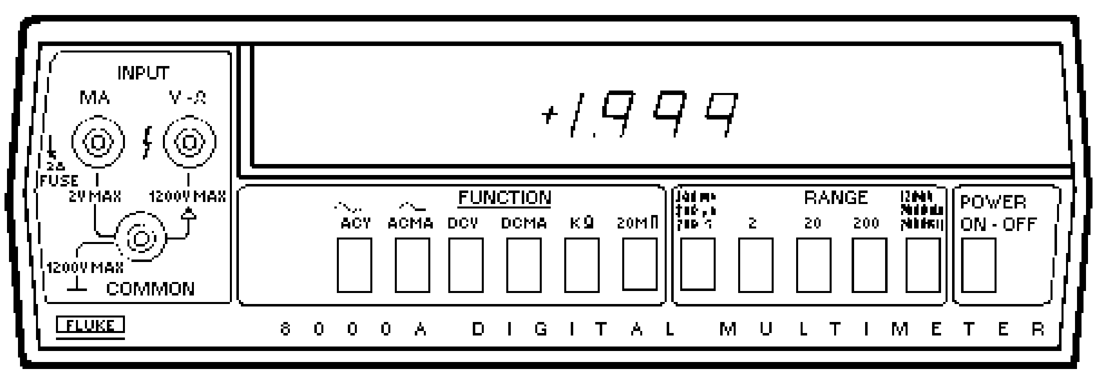

Figure 1-4.—Digital multimeter.

Digital multimeters display the reading numerically. These direct-reading displays, along with automatic range- and polarity-changing features, eliminate the problem of parallax, reduce error and tedium, and increase measurement speed. Data from these meters in digital format can also be processed by computers, printers, tape and card punches, and magnetic-tape equipment. Digital multimeters are typically compact and lightweight; many come with rechargeable batteries, making them ideal for portable field use. The disadvantages are that they are not rugged and will not tolerate abuse and that some models do not produce sufficient bias voltage to test a diode or transistor junction. The John Fluke Model 77 A/N digital multimeter is presently being purchased by the Navy and will eventually phase out the older and less accurate analog meters.

Differential Voltmeter Method

Using the differential voltmeter, as shown in figure 1-5, provides one of the most accurate methods of measuring dc voltage. Typical accuracies attained by this method are ±0.005%. These extremely high accuracies are achieved by the design of the voltmeter with precision internal reference voltages and precision resistors. As discussed earlier in NEETS, module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies*, most differential voltmeters can be operated as transistor voltmeters (tvm) or as differential null voltmeters. The tvm mode is used to measure the *approximate* voltage and polarity of the unknown voltage being measured. The approximate voltage, as measured in the tvm mode, is then used to make the initial range and mode switch selections for nulling the input voltage.

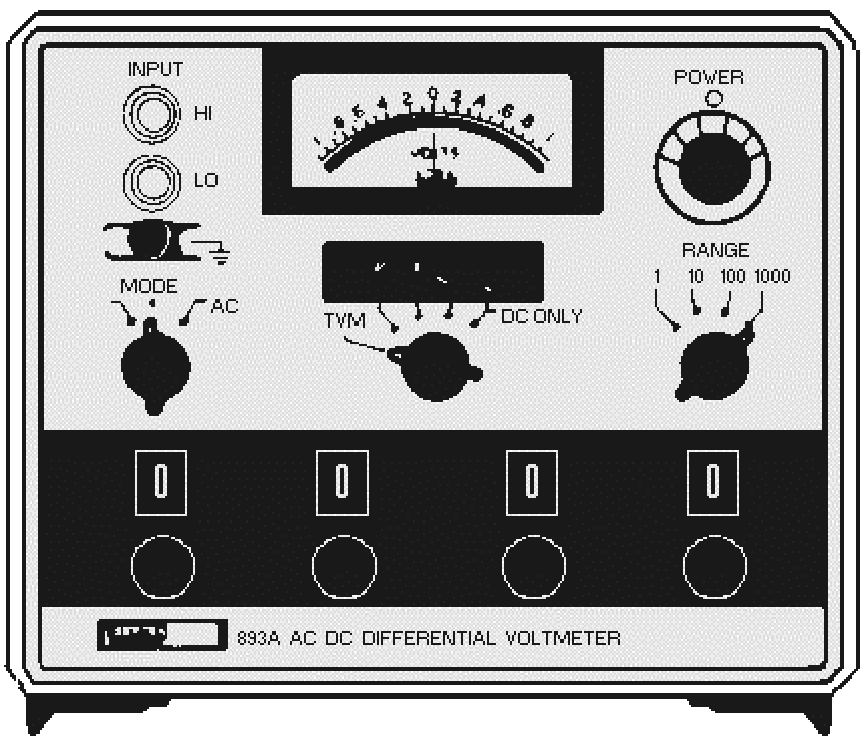

Figure 1-5.—Ac-dc differential voltmeter.

The advantages of using a differential voltmeter for measuring dc voltages are the extreme accuracy and minimal circuit loading made possible by the high input impedance of the meter. However, differential voltmeters are less portable, heavier, and require greater skill and time when performing measurements than other types of voltmeters. Additionally, they require long warm-up periods and are susceptible to variations in temperature and humidity.

Q-5. What are the advantages of using a differential voltmeter?

AC VOLTAGE MEASUREMENTS

When ac voltage measurements are performed, the input impedance of the selected test equipment determines the amount of energy removed from the circuit under test. If an ac meter is placed across a high-impedance circuit, the meter may load the high-impedance circuit and disturb circuit conditions, possibly to the point of causing the circuit to cease functioning. A dc electronic voltmeter, used in conjunction with a rectifying probe, extracts only a small amount of energy from the circuit under test. Another advantage of an electronic voltmeter over the analog voltmeter is that voltages of low values can be accurately measured.

If the circuit being measured is a relatively high-frequency circuit, the internal capacitance of an analog voltmeter rectifier could produce a disturbance by detuning the circuit. Figure 1-6 depicts the frequency response of a Simpson 260. Note the percent of error introduced at different frequencies. For high-frequency voltage measurements, an electronic voltmeter or an oscilloscope should be used. The sensitivity of the meter (or oscilloscope) determines the lowest voltage it can measure accurately, and the shunt capacitance of its input determines the upper frequency limits. It should be clear that the frequency response of a piece of test equipment is just as important as its range limitations. If you exceed the *range limitations* of a meter, it will either "peg" the meter or belch out the smell of smoke that many of us are intimately acquainted with. This, however, is not the case when you exceed the *frequency limitations* of your test equipment. Your test equipment will normally show a response, but that response will be grossly inaccurate. The lesson to be learned here is that you should be fully aware of the limitations of your test equipment and adhere to them.

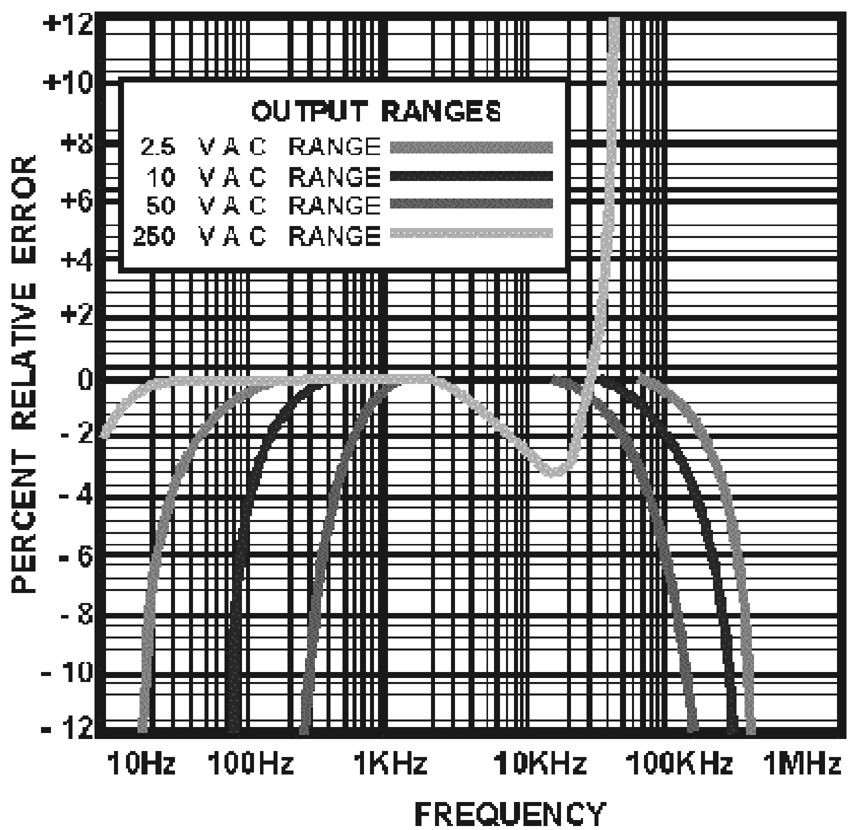

Figure 1-6.—Simpson 260 frequency response for ac voltage ranges.

Q-6. The frequency response of test equipment refers to what aspect of ac voltage measurements?

Multimeter Method

As previously stated, an analog multimeter's usefulness is limited by its low input impedance and poor accuracy (typically ±2%). However, rugged construction and ease of operation make analog multimeters extremely useful whenever poor accuracy and low input impedance can be tolerated. When performing ac voltage measurements with a multimeter, be certain that the frequency of the signal being measured falls within the upper and lower frequency limitations of the meter.

Oscilloscope Method

A major advantage of using an oscilloscope for ac voltage measurements is that the waveform can be observed; consequently, errors in measuring complex peak voltages are minimized. An oscilloscope may be used as a high-impedance ac voltmeter. In standard oscilloscopes, the vertical amplifier input impedance is generally greater than 1 megohm, making it possible to measure voltages in high-impedance circuits. If the signal is applied directly to the plates, rather than at the vertical amplifier input, the input impedance is increased considerably.

Voltage measurements are most easily made when the deflection of the trace extends across the major portion of the oscilloscope screen; whenever possible, the trace should cover at least 60% of the vertical viewing area of the screen. If the amplitude of the measured voltage is very low, the trace dimensions may be small. If a voltage to be measured is large and cannot be attenuated to a usable value by attenuation circuits within the oscilloscope, an external resistive or capacitive voltage divider can be used. Such voltage dividers are often furnished with oscilloscope test sets and are called HIGH VOLTAGE PROBES. When the voltage of pulses or other complete waveforms is being measured, the high voltage probe selected must be so designed as not to distort the measured signal. Most probes have adjustable (compensating) capacitors that are used to adjust the symmetry of the displayed waveform. You adjust the probe by monitoring either the calibrator output of the oscilloscope or a known good signal and adjusting the probe for a symmetrical display. Oscilloscopes are calibrated to display peak-to-peak values. To determine the rms voltage of a sinusoidal signal, divide the number of graticule units from the positive to the negative peaks by two and multiply this value by 0.707. When using the oscilloscope for ac voltage measurements, ensure the upper frequency range of the oscilloscope is not exceeded; otherwise, inaccurate values will be displayed. Most commonly used oscilloscopes have a frequency response from dc up to 100 megahertz.

Q-7. Ideally, an oscilloscope presentation should cover what vertical portion of the screen?

Digital Multimeter Method

As previously mentioned, digital multimeters present a high input impedance to the circuit under test and are fairly accurate. Many earlier models had very limited frequency responses. Even today the upper frequency limitations of digital multimeters vary from 20 kilohertz to over 300 kilohertz, depending on the model. Their upper frequency limitations can, however, be significantly extended by using optional rf probes. When you perform ac voltage measurements with a digital multimeter, remember that they are *true rms* indicating devices.

Differential Voltmeter Method

Most differential voltmeters can be used to measure both ac and dc voltages. The differential voltmeter method of measuring ac voltage is the most accurate of the common measurement techniques. Typical accuracies are ±0.05% when operated in the ac mode.

CURRENT MEASUREMENTS

Unless an ammeter is already an integral part of the circuit under test, current measurements are rarely taken. In the case of a high-resistance circuit, it will contain such a small amount of current that it cannot be measured accurately with ordinary field test equipment. In lower resistance circuits, current measurements can be taken only if the ammeter is placed in series with the circuit under test. These measurements require that a circuit connection be unsoldered or otherwise opened to insert the meter in series with the circuit. An easier method you may use to obtain a current measurement is to take a voltage measurement across a known resistance and calculate the current with Ohm's law. The accuracy of current measurements depends on the internal resistance of the meter as compared with the resistance of the external circuit. If the total circuit current is decreased by increasing the load, then the percentage of error will decrease. Therefore, greater accuracy is obtained if the meter resistance is considerably less than the load resistance. A method of obtaining greater accuracy of current measurement is to decrease the total internal meter resistance with respect to load resistance. This is accomplished by connecting two ammeters in parallel with each other and in series with the circuit in which the current is being measured. Additional ammeters may be connected in parallel in the same manner for increased accuracy. This method also increases the range of measurements that can be taken. The arithmetical sum of the indications of all the parallel meters represents the total current flow in the circuit. You should note that this is not a common test method and that your test equipment may be damaged if connected incorrectly.

MULTIMETER METHOD

As previously mentioned, current measurements are usually taken by breaking the current path of the circuit under test and electrically inserting a meter in series. This is normally accomplished by disconnecting a wire from a terminal or unsoldering one end of a component and electrically inserting the meter in series using the meter leads. This method is both time consuming and usually requires the use of a soldering iron, which can damage components. Most analog multimeters cannot be used for measuring ac current and are only accurate to within ±2% on dc ranges.

Q-8. What are the advantages of connecting ammeters in parallel when performing current measurements?

DIGITAL MULTIMETER METHOD

Unlike the analog multimeter, the digital multimeter will measure ac current as well as dc current. Again, current measurements are taken by breaking the current path and inserting the meter in series. Regardless of whether you're using an analog multimeter or digital multimeter, this procedure for measuring current is time consuming. However, there is a major advantage to be gained by using the digital multimeter — its high degree of accuracy. The Fluke 8000A digital multimeter, for example, is accurate to within ±0.3% when measuring dc current and ±1% when measuring ac current. These accuracies are representative of most medium-priced digital multimeters.

CURRENT TRACERS

For the purpose of discussion, we have selected the Hewlett-Packard 547A, shown in figure 1-7, as a representative current tracer. A current tracer will not actually measure current; it is designed to indicate the presence of current and the relative magnitude of one source of current as compared to another. The Hewlett-Packard 547A is a hand-held probe that enables you to precisely localize low-impedance faults in a circuit. The probe senses the magnetic field generated by a pulsing current and lights an indicator lamp near the current tracer tip. The brightness of the indicator lamp is proportional to the magnitude of the current. The sensitivity of the indicator lamp can be adjusted with a thumb-wheel potentiometer located on the probe. Figure 1-8 depicts a typical logic circuit application for a current tracer. Current tracers are ideally suited for locating shorted or opened printed-circuit-board runs, wires, or components. In the absence of a suitable pulsing current to drive the current tracer, a logic pulser or pulse generator may be used as a signal source. The inherent disadvantage of a current tracer is that it requires an external power supply. They can, however, be connected to the power supply of the equipment under test if the voltage is correct.

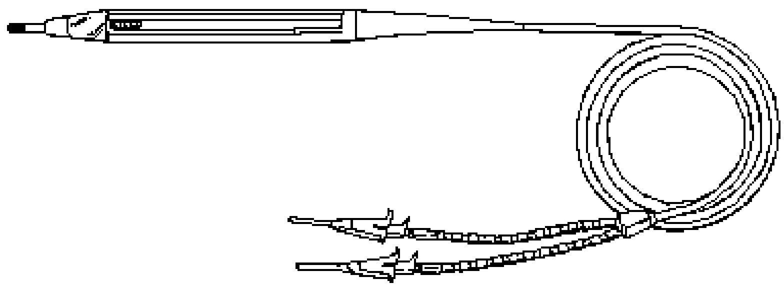

Figure 1-7.—Current tracer.

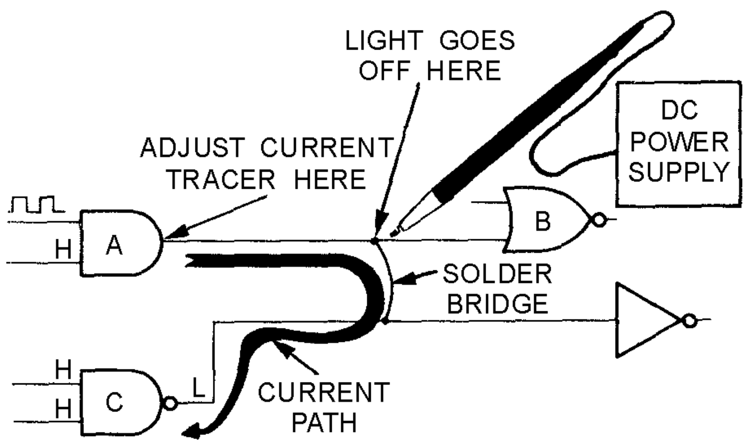

Figure 1-8.—Current tracer application.

CURRENT PROBES

Current probes, as shown in figure 1-9, are primarily designed to be used with an oscilloscope or milliammeter for measuring current. Although not used very often by Navy technicians, current probes are available. The primary advantage in using a current probe is that it does not need to be in series with the current being measured. Unsoldering wires or connections to terminals is not necessary; current probes are designed to be clamped onto insulated conductors. They are able to sense, through inductive action, the magnitude of the current flowing in the conductor. Current probes are designed for performing small ac current measurements. Also, when you use them in conjunction with current probe amplifiers, the capabilities of the current probe are extended to measurement of both ac and dc currents with large magnitudes. Current probes are extremely useful when you measure the current drain on a power supply, start-up current of a motor, or current flow in relays. These probes can be divided into three basic types: passive, active, and Hall effect. Each type has advantages and disadvantages peculiar to its method of operation. Prior to using a current probe, you should thoroughly understand its instructions.

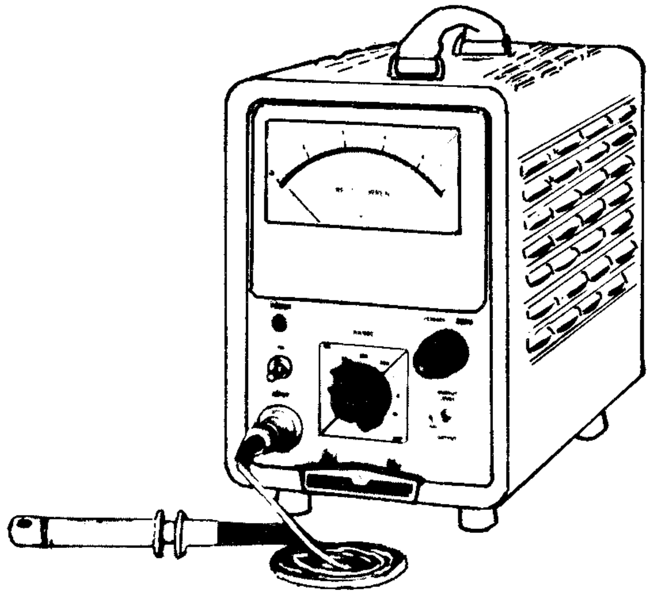

Figure 1-9.—Current probe used with electronic ammeter.

Q-9. What is the primary advantage of using a current probe?

OSCILLOSCOPE METHOD

Current can be measured with an oscilloscope by shunting the input terminals with a low-value resistor. The input terminals must then be connected in series with the circuit being tested. The value of the resistor must be small enough not to interfere with the operation of the circuit under test. At the same time, it must be large enough that the voltage developed will cause adequate deflection of the oscilloscope trace. For example, if an oscilloscope with a vertical deflection sensitivity of 0.1volt rms per centimeter (cm) is used in conjunction with a 10-ohm shunt resistor to measure a 25-milliamp current, the vertical trace will be deflected 2.5 centimeters, as shown in the following example:

Where:

$$I = 25 \text{ mA}$$

$$R = 10 \text{ ohms}$$

$$\text{Sensitivity} = 0.1 \text{ volt/cm}$$

First we'll figure the applied voltage:

$$E = IR$$

$$E = 0.025 \text{ A} \times 10 \text{ ohms} = 0.25 \text{ volts}$$

Now let's figure the deflection in cm:

$$\text{Deflection} = \frac{\text{voltage applied}}{\text{sencitivity}}$$

$$\text{Deflection} = \frac{0.25 \text{ volt}}{0.1 \text{ volt/cm}} = 2.5 \text{ cm}$$

For current measurements the oscilloscope can be calibrated by connecting an ammeter in series with the input terminals and the calibration signal source. An alternate method is to determine the value of the shunt resistor and measure the calibration signal voltage developed across it with an accurate voltmeter. The calibration signal current can then be calculated by means of Ohm's law. Since the oscilloscope merely indicates the voltage developed across the shunt resistor, the measurements for alternating or direct current will be similar to voltage measurements using an oscilloscope.

RESISTANCE MEASUREMENTS

A high percentage of technical manuals contain point-to-point resistance charts that list correct resistance readings for major test points. These resistance charts are extremely useful when you troubleshoot faulty equipment. Without them, equipment resistance measurements within a complicated circuit would not mean much. Many circuits contain other circuit elements, such as capacitors, coils, or other resistors in parallel with the resistances being measured. This, of course, is a possible source of measurement error that you eliminate when you disconnect or unsolder one side of the resistor or a group of resistors under test.

You should be thoroughly familiar with the calibration of your ohmmeter. Analog meters are typically more accurate and easier to read at midscale. With the exception of bridge circuits, a meter may provide only approximate resistance readings. However, these readings may be adequate when you also consider the wide tolerances of resistors themselves. An ohmmeter that you use in field testing should be portable, convenient, and simple to operate - factors that usually are more important than extreme accuracy.

When an ohmmeter is used, completely de-energize the circuit under test and remove any current-sensitive elements before the resistance measurement is performed. Low-resistance measurements that require precision readings should be taken with a bridge type of instrument.

An ohmmeter consists of a galvanometer, batteries, and resistors of known value that are connected in such a way that unknown resistors to be measured are compared with standard values. Figure 1-10 illustrates three basic ohmmeter circuits: (A) single range type, (B) series multirange type, and (C) shunt type.

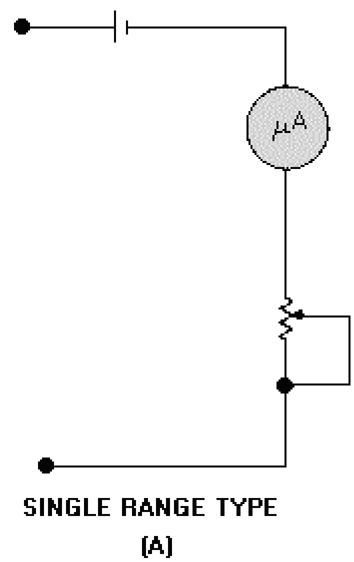

Figure 1-10A.—Basic ohmmeter circuits.

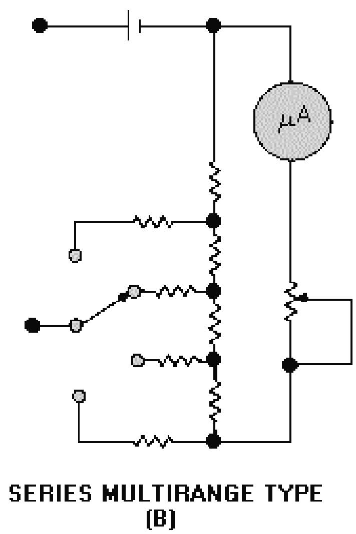

Figure 1-10B.—Basic ohmmeter circuits.

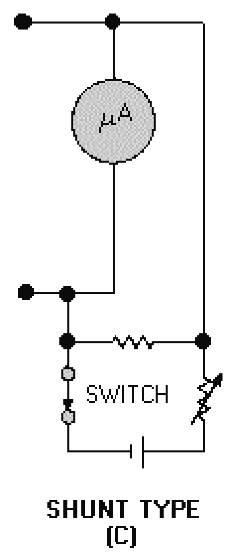

Figure 1-10C.—Basic ohmmeter circuits.

MULTIMETER METHOD

When you use an analog multimeter to perform resistance measurements, the first thing you do is zero the meter. The meter indication varies greatly depending on the resistance of the test leads, the condition of the batteries within the meter, and the resistance range selected on the multimeter. The meter should be zeroed every time you change range settings. To zero a multimeter you short the leads together and adjust the meter for a full-scale deflection. Scale markings are spaced closer together toward the infinity point on the meter; therefore, more accurate readings are obtained near center scale. You should select a range setting that will give you a mid-scale indication.

Ohmmeter applications include resistance measurements; continuity checks; and inductor, capacitor, and transformer checks. A transformer, for example, may be tested by checking whether there is an open or short, low-insulation resistance to ground, or improper continuity between transformer windings. A capacitor may be tested to determine whether it is open or shorted. Ensure that capacitors are properly discharged before you test them; otherwise, damage to the multimeter may occur. When an ohmmeter is placed in series with a capacitor, the changing current will cause a meter deflection that is proportional to the capacitance. The deflection obtained is compared with the deflection from a similar capacitor of known value. This deflection may be small or large, depending on the type and size of the capacitor and the voltage of the battery within the meter. An external series battery will increase the sensitivity of the instrument.

Q-10. How do you compensate for the resistance of the test leads of a meter?

DIGITAL MULTIMETER

The two major advantages of using a digital multimeter are its ease of operation and accuracy. Most digital multimeters can be ordered with an optional battery pack, which makes them just as portable as an analog multimeter. Another advantage is that their LED or LCD readouts are much easier to read than the scale on an analog multimeter. Digital multimeters also are ideally suited for measuring sensitive devices that might otherwise be damaged by the excessive current associated with analog multimeters — maximum current flow through the component being tested is typically limited to less than 1 milliamp. When measuring small values of resistances, remember to consider the resistance of your test leads. Most digital multimeters cannot be zeroed in the way analog multimeters can. With digital multimeters, you have to short the leads, read the lead resistance displayed, and then subtract the reading from subsequent component measurements that you make.

Q-11. Why are digital multimeters well suited for testing sensitive devices?

RCL BRIDGES

The 250DE+1325 is a typical resistance, capacitance, inductance (rcl) bridge. Like the vtvm, the rcl bridge has several disadvantages. It requires ac power and a lengthy warm-up period, and its accuracy is limited to ±2%. The rcl bridge uses a tuning indicator electron tube, commonly referred to as the bridge's "eye," and an internal arrangement of resistors that form a Wheatstone bridge. As discussed in NEETS, module 16, the rcl bridge can be a time-consuming method of performing resistance measurements.

Difficulty may be experienced when you attempt to measure wire-wound resistors. To obtain a sharp balance on the indicator, you can shunt the resistor with a variable capacitor and adjust the capacitor for the clearest indication. The resistance measurement will not be affected by this reactance neutralization.

MEGGERS

Meggers produce the large voltages that are required to measure resistances as high as 10,000 megohms — only high resistance values can be measured. The unknown resistance is connected between the megger terminals, and the hand generator part of the meter is cranked. Some meggers are capable of producing in excess of 500 volts, so use caution when you operate them. Typical applications for a megger are testing unterminated transmission lines and ac power cords for insulation breakdown.

DIFFERENTIAL VOLTMETERS

It is a seldom-known fact that the Fluke 893 ac-dc differential voltmeter can be used for measuring extremely high resistances from 10 megohms to 10^6 megohms with a typical accuracy of ±5%. This measurement method, however, requires some basic calculations on your part. The obvious advantage of the differential voltmeter is its capability of measuring extremely high resistances. Consult the Fluke 893 technical manual for initial switch settings and a more detailed explanation of its operation.

CAPACITOR MEASUREMENTS

Capacitance is that property of a circuit that produces an electrostatic field when two conducting bodies separated by a dielectric material have a potential applied to them. Capacitors are made by compressing an insulating material (dielectric) between two conductors (plates). The farad is the basic measurement of capacitance. It is dependent upon the area of the plates, the distance between the plates, and the type of dielectric used. Electrically, the farad is a measure of 1 coulomb of potential charged by 1 volt. A coulomb (the amount of current flow maintained at 1 ampere that passes a given point of a circuit in 1 second) is a large charge. Most capacitors are measured in millionths of a farad (microfarad), expressed as ∝F, or in one-millionth of a microfarad (picofarad), expressed as pF.

Capacitors incur various losses as a result of such factors as resistance in the conductors (plates) or leads, current leakage, and dielectric absorption, all of which affect the power factor of the capacitor. Theoretically, the power factor of an ideal capacitor should be zero; however, the losses listed above cause the power factors of practical capacitors to range from near 0 to a possible 100%. The average power factor for good capacitors, excluding electrolytics, is 2% to 3%. Current leakage, which is an inverse function of frequency, is important only at the lower frequencies and becomes negligible at higher frequencies. Dielectric absorption (sometimes referred to as dielectric viscosity) results in losses that produce heat. The effect of this type of loss is the same as resistance in series with the capacitor.

You have probably learned the hard way that some capacitors can retain a charge long after the voltage has been removed. The electrical charge retained by capacitors in de-energized electronic circuits is, in many cases, sufficient to cause a lethal shock. Be sure you and those working with you consider this hazard before performing any type of maintenance on any electrical or electronic circuit and before making connections to a seemingly dead circuit. Use extreme caution prior to working on or near de-energized circuits that employ large capacitors. Be safe—discharge and ground all high-voltage capacitors and exposed high-voltage terminal leads by using only an authorized shorting probe, as shown in figure 1-11. Repeat discharge operations several times to make sure that all high-voltage terminations are completely discharged. It is of the utmost importance that you use only an *authorized* safety shorting probe to discharge the circuits before performing any work on them. An authorized *general-purpose* safety shorting probe for naval service application may be requisitioned using the current stock number listed in the ELECTRONICS INSTALLATION AND MAINTENANCE BOOK (EIBM), *General* NAVSEA 0967-LP-000-0100, Section 3, Safety Equipment. Certain electronic equipment are provided with built-in, special-purpose safety shorting probes. These probes are *not* considered general purpose. Use them only with the equipment for which they are provided and only in a manner specified by the technical manuals for the equipment. It is considered to be poor practice to remove them for use elsewhere.

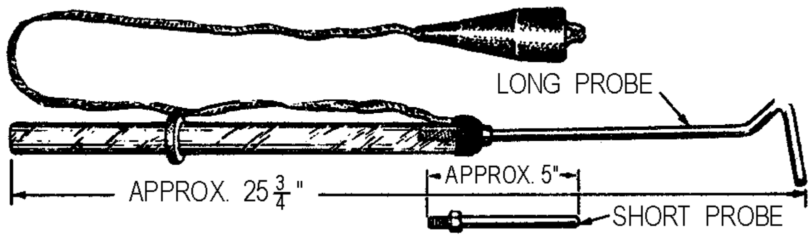

Figure 1-11.—Safety shorting probe.

When using the general-purpose safety shorting probe, always be sure first to connect the grounding clip to a good ground connection (if necessary, scrape the paint off the grounding metal to make a good contact — paint can be replaced, lives can't). Then, while holding the safety shorting probe by the handle behind the protective shield, touch the end of the metal rod to the points to be discharged. Touch each point several times to ensure that the circuit is completely discharged. Be extremely careful that *you* do not touch any of the metal parts of the safety shorting probe while touching the probe to the exposed "hot" terminal. Don't develop a nonchalant or routine attitude about these procedures. It pays to be safe; use the safety shorting probe with care.

Large capacitors, dormant in storage, can also develop a large static charge. This charge is caused by environmental conditions such as a close proximity to an rf field. An easy way to avoid this condition is to short the stored capacitor's terminals with a piece of wire before putting it in storage. Remember to remove the wire before installing the capacitor. If you receive a large capacitor that is not shorted, short the terminals together. Remember, CHARGED CAPACITORS CAN KILL.

Q-12. Charged capacitors can kill. True or false?

BRIDGE-TYPE MEASUREMENTS

Capacitor tests involving quality and value must be made in the course of everyday troubleshooting. You must make the important decision of whether to reject or continue to use a certain capacitor after it has been tested. Capacitance measurements are usually accomplished by either a bridge-type or a reactance-type capacitance meter. The bridge-type capacitance meter is much more accurate than the reactance-type meter. You may want to review rcl bridges in chapter 1 of NEETS, module 16, before reading further. Capacitance tolerances vary more widely than resistance tolerances and are dependent upon the type of capacitor, the capacitance value, and the voltage rating. The results of capacitance tests must be evaluated to determine whether a particular capacitor will fulfill the requirements of the circuit in which it is used.

The power factor of a capacitor is important because it is an indication of the various losses attributable to the dielectric, such as current leakage and dielectric absorption. Current leakage is of considerable importance, especially in electrolytic capacitors.

Figure 1-12 is a simplified schematic of a capacitance bridge. As you can see, a capacitance bridge is very similar in construction to a resistance bridge with the exception of the standard capacitor (C_S) and the unknown capacitor (C_X). Because current varies inversely with resistance and directly with capacitance, an inverse proportion exists between the four arms of the bridge. The following expression shows the inverse proportion between resistors A and B and capacitors C_S and C_X:

$$\frac{A}{B} = \frac{C_X}{C_S}$$

Solving for C_X:

$$C_X = \frac{AC_S}{B}$$

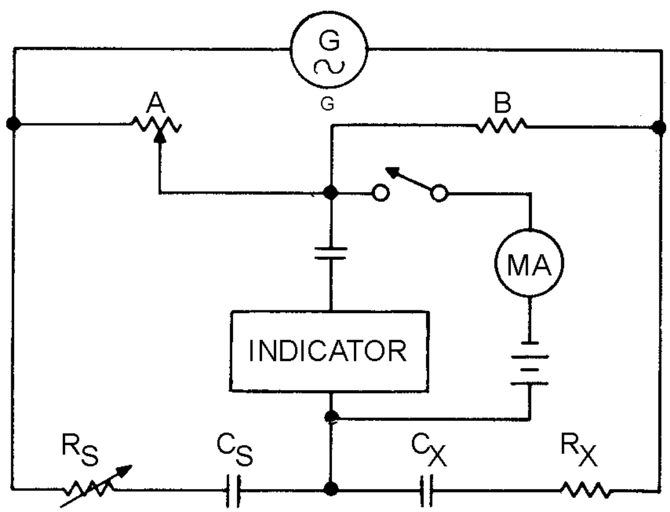

Figure 1-12.—Simplified capacitance bridge.

It is actually the capacitive reactance, rather than the capacitance, that is balanced in this circuit.

In addition to its reactive properties, the capacitor under test always exhibits some loss. This loss may have the characteristics of either a shunt or series resistance, or it may be a combination of both. Regardless of its true nature, the loss can always be represented as a simple series resistance, which is shown in figure 1-12 as R_X. This loss is balanced by the calibrated resistor R_S. Rather than calibrate this control in terms of resistance, it is convenient to calibrate it in terms of the dissipation factor (the ratio of the energy dissipated to the energy stored in a capacitor). The R_S control then provides the means for completing the capacitance balance, and its dial reading indicates a loss figure for the capacitor under test.

Q-13. Which is more accurate, the bridge- or reactance-type meter?

REACTANCE-TYPE MEASUREMENTS

The reactance type of capacitance measuring equipment makes use of the following principle: If an ac voltage (usually 6.3 volts) at a fixed frequency is applied across a capacitor and resistor in series, the voltage drop produced across the reactance of the capacitor by the resulting current flow is inversely proportional to the capacitance. The voltage drop is used to actuate a meter that is calibrated in capacitance values. This test equipment gives approximate values only and, like the ohmmeter, is used mostly when portability and speed are more important than precision. The accuracy of the reactance-type measurement is less for capacitors that have a high power factor. In capacitors with high power factors, the losses incurred effectively place a certain amount of resistance in series with the capacitive reactance. The effect of this resistance, when the capacitor is measured, is to cause a greater voltage drop across the capacitor. This drop is not because of the reactance above, but is the result of the impedance, which of course is made up of both the reactance and the resistance. Therefore, the capacitance indicated by the analyzer will be lower than the actual value.

Figure 1-13 shows a simplified schematic diagram of the capacitance-measuring section of a typical reactance-type electronic volt-ohm-capacitance milliammeter. A 6.3-vac voltage is taken from the filament source and applied across the resistive voltage divider network to determine the designated value of the capacitor. Because of a particular use or circuit application, some capacitors are permitted an even wider variation of capacitance value than is indicated by their rated tolerances.

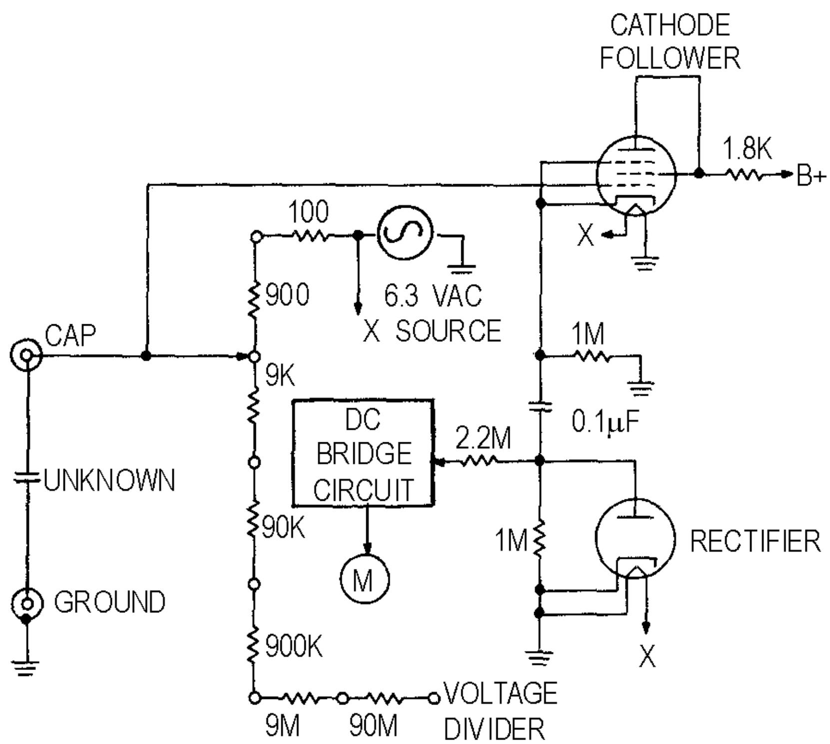

Figure 1-13.—Reactance-type capacitance meter.

INDUCTANCE MEASUREMENT

A current flowing through a conductor produces a magnetic field around that conductor. If the conductor is formed into a coil, a stronger magnetic field is set up. The relationship between the strength of the field and the intensity of the current causing it is expressed by the inductance of the coil (or conductor). When the current producing the magnetic field ceases, the energy of the magnetic field is returned in part to the circuit source in the form of a reverse current. Inductance, then, is the ability of a coil to function as a storehouse of energy in magnetic form and is determined by the shape and dimensions of the coil. Inductance is measured in henries, millihenries, or microhenries. Inductors can be described generally as circuit elements used to introduce inductive reactance into ac circuits.

An inductor is essentially a coil of wire wound around a form using a core of air, magnetic metal, or nonmagnetic metal. A core of magnetic metal produces greater inductance (for a coil of given size and number of turns) than does an air core; a core of nonmagnetic metal produces less inductance than does an air core. At frequencies in the hf and higher regions of the frequency spectrum, coils of small size and high *Q* (discussed briefly at the end of this section) are generally required. These coils usually are single-layered with air or metallic cores. Since comparatively low values of inductance are required, this type of coil is very compact, and relatively high values of *Q* are obtained.

At frequencies in the lf and mf regions of the frequency spectrum, single-layered, universal, spiral, and other types of windings are used. When size is a factor, the more compact windings are preferred to the single-layered type of coil. At frequencies below 500 kilohertz, the single-layered type is too large for practical use; therefore, the more compact types are used exclusively.

The inherent resistance of the conductor with which an inductor is wound is the most important factor contributing to the losses of the inductor. Losses caused by this resistance increase with frequency. This results in a concentration of current near the outer surface of the wire, called SKIN EFFECT. Skin effect is negligible at low frequencies, but can be an important factor at high frequencies. Other contributing factors to inductor losses are (1) eddy currents set up in the core and surrounding objects (if they are conductors); (2) the dielectric properties of the form used for the coil and surrounding objects; and (3) hysteresis in the core and surrounding objects, if they are magnetic metals. Losses occur as a result of the dielectric properties of the coil form because of the distributed capacitance of the inductor (for example, between turns and between the terminals and leads). To some extent the core and surrounding objects serve as a dielectric of the distributed capacitance, and the resulting dielectric losses contribute to the overall losses of the inductor.

As we discussed earlier, an inductor has the ability to act as a storehouse of magnetic energy. However, because of the various loss factors described above, all of the energy stored in the magnetic field is not returned to the source when the applied voltage decreases to zero. The losses of an inductor may be represented by an equivalent series resistance. The value that it would dissipate would be an amount of energy equal to the total amount dissipated by the inductor. The losses of an inductor may be expressed in terms of the ratio of its inductive reactance to its equivalent series resistance. This ratio is referred to as the Q of the inductor and is stated in equation form as shown below:

$$Q = \frac{X_L}{R}$$

Q-14. What type of core produces the greatest inductance?

HAY BRIDGE

Inductance measurements are seldom required in the course of troubleshooting. However, in some cases inductance measurements are useful and instruments are available for making this test. Many capacitance test sets can be used to measure inductance. Most manufacturers of capacitance test sets furnish inductance conversion charts if the test equipment scale is not calibrated to read the value of inductance directly. For the measurement of inductance, the following basic types of test equipment circuitry are used: (1) the bridge-circuit type, which is the most accurate, and (2) the reactance type, which is often an additional test circuit incorporated into another piece of test equipment to increase its utility. The measurement of capacitance using the capacitance-inductance-resistance bridge instrument was discussed. Since the measurement of capacitance and inductance are interrelated, the existing capacitance standards and loss controls of this test equipment are used whenever possible. A wider range of dissipation must be provided to accommodate the practical value of inductors. The 250DE+1325 (view A of fig. 1-14), a typical rcl bridge and our reference in this discussion, uses two basic bridge circuits (Hay bridge and Maxwell bridge) to accommodate the extensive range in inductor loss factors. You should take time to review the bridges in NEETS, module 16, or other bridge-circuit descriptions before continuing.

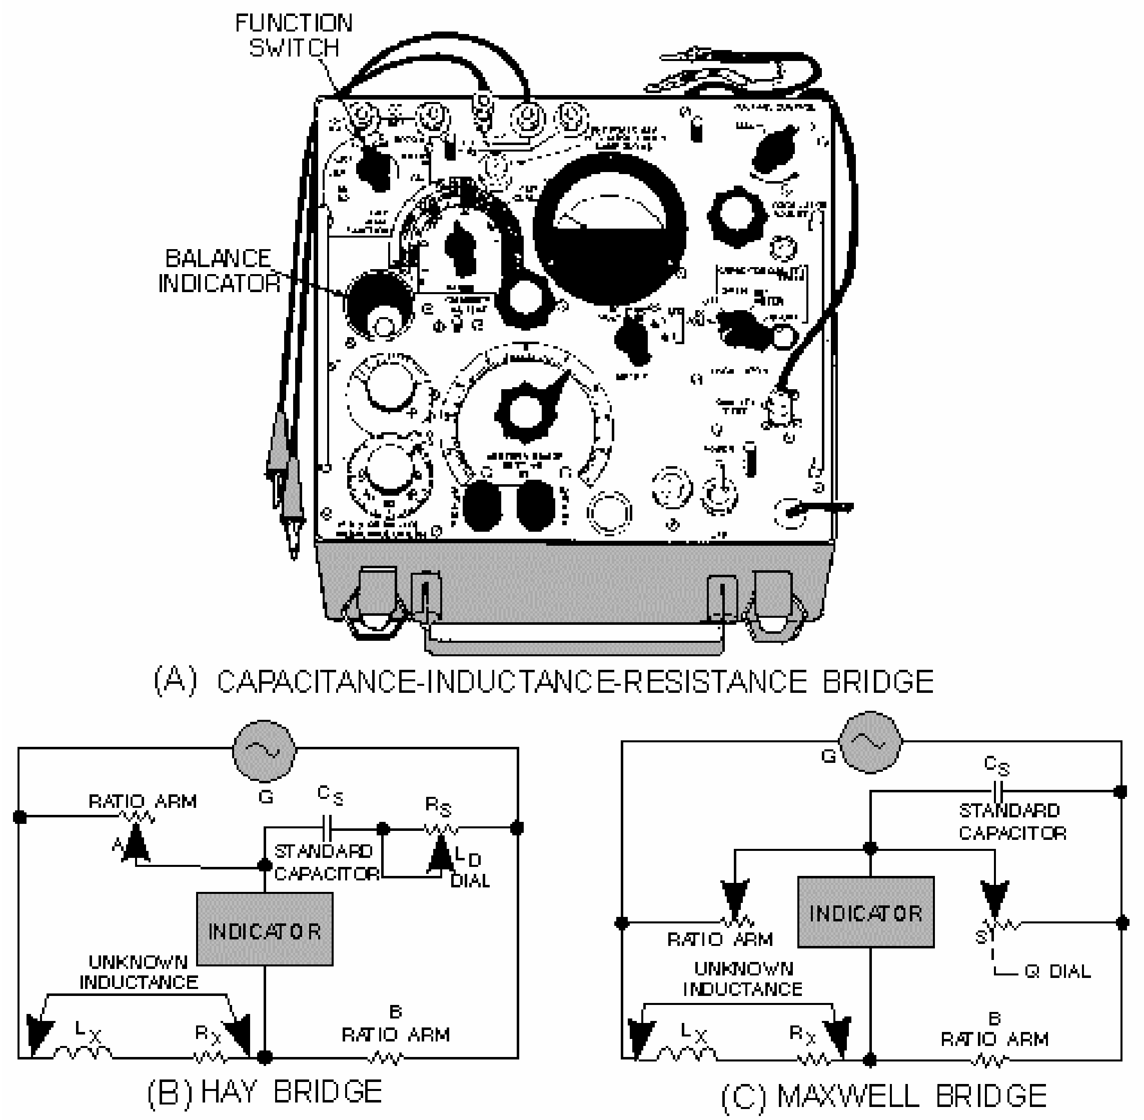

Figure 1-14.—Bridge circuits.

The Hay bridge (view B of fig. 1-14) measures inductance by comparing it with a capacitance; it differs from the Maxwell bridge (view C) in that the resistance associated with the capacitance is a series instead of a shunt resistance. The inductance balance depends upon the losses (*Q*) of the inductor. The Hay bridge is used for inductors with low losses low D dial reading or high *Q*) at 1 kilohertz. This circuit is in effect when the FUNCTION switch is turned to the L(D) position. For a D dial reading up to 0.05, the error is 0.25%. Above this point the error increases rapidly and affects the basic accuracy of the test equipment. This limitation is expressed on the front panel of the test equipment as follows: IF D>0.05 ON L(D)—REBALANCE ON L(Q) . In other words, if the dissipation of an inductor, as read on the D dial when using the Hay bridge (FUNCTION switch set to L(D) position), exceeds 0.05, then you should change to the Maxwell bridge (FUNCTION switch set to L(Q) position), which is discussed in the following paragraph. The loss factor of the inductor under test is then balanced in terms of the *Q* of the inductor.

Q-15. A Hay bridge measures inductance by comparing an inductor to what component?

MAXWELL BRIDGE

The Maxwell bridge, shown in view C of figure 1-14, measures inductance by comparing it with a capacitance and (effectively) two resistances.] This bridge circuit is employed for measuring inductances having losses greater than 0.05 (expressed by the D dial reading). For such inductors it is necessary to introduce, in place of the series control (D dial), a new loss control (Q dial), which shunts the standard capacitor. This control, which becomes effective when the FUNCTION switch is turned to the L(Q) position, is conveniently calibrated in values of Q, the storage factor of the inductor under measurement. The balance for inductance is the same for either bridge circuit. This permits the use of the same markings on the RANGE switch for both the L(D) and L(Q) positions of the FUNCTION switch.

REACTANCE MEASURING EQUIPMENT

The reactance type of inductance measuring equipment makes use of the following principle: If an ac voltage of fixed frequency is applied across an inductor (and a resistor in series), the voltage drop produced across the reactance of the inductor by the resulting current flow is directly proportional to the value of the inductance. An inductance measurement using the reactance method is identical to capacitance measurements using the same method, except that current flow is directly proportional to the value of inductance, rather than inversely proportional as in the case of capacitance. It follows then that if a reactance-type capacitance measuring equipment is provided with a chart that converts the capacitance readings to equivalent inductance values and a proper range multiplying factor, the same test setup can be used to measure both capacitance and inductance. In practice, test equipment using the reactance method for capacitance measurements usually provides an inductance conversion chart. Because the current flowing through the inductance under test is directly proportional to the value of inductance, the reciprocals of the capacitance range multipliers must be used; for example, a multiplier of 0.1 becomes

$$\frac{1}{0.1} \text{ or } 10$$

and a multiplier of 100 becomes

$$\frac{1}{100} \text{ or } 0.01$$

The reactance-type equipment gives approximate values only. Like the analog multimeter, it is used only when portability and speed are more important than precision. If the ohmic resistance of the inductor is low, the inductance value obtained from the conversion chart can be used directly. If the ohmic value (as measured with an ohmmeter) is appreciable, a more accurate value of inductance can be obtained by use of the following formula:

$$L = \frac{(Z_L)^2 - (R_L)^2}{2\pi f}$$

Where:

L = the inductance

Z_L = the impedance of the inductance under test

f = the frequency

R_L = the ohmic resistance

Q-16. Is the current flow through an inductor directly proportional or inversely proportional to its inductance value?

MEASUREMENT OF INDUCTANCE USING THE VTVM

If you do not have a 250DE+1325 at your disposal, the inductance of a coil can be determined by using a vtvm and a decade resistance box, as shown in figure 1-15. In the following example the inductance of an unknown coil in the secondary winding of a 6.3-volt filament transformer will be determined with a vtvm and decade resistance box. The unknown coil must be connected in series with the decade resistance box. The voltage across the decade box and across the coil must be monitored as the decade box is adjusted. When equal voltages are reached, read the resistance of the decade box. Since the voltage across the inductor equals the voltage across the decade box, the X_L of the coil must be equal to the resistance read on the decade box. For example, assume that the resistance reading on the decade box is 4 kilohms and the frequency is 60 hertz. This must mean that the X_L of the coil is also equal to 4,000 ohms. The inductance formula $L = X_L/2\pi f$ can be used to find the inductance of the coil in henries:

$$L = \frac{4000\Omega}{(6.28)(60)}$$

$$L = \frac{4000\Omega}{376.8}$$

$$L = 10.62H$$

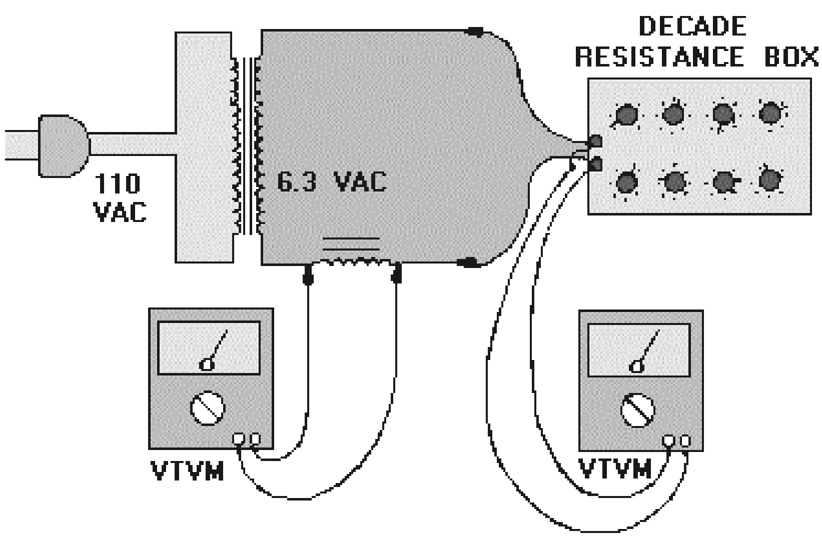

Figure 1-15.—Determining inductance with a vtvm and decade resistance box.

SUMMARY

This chapter has presented information on basic measurements. The information that follows summarizes the important points of this chapter.

The five basic measurements are **VOLTAGE, CURRENT, RESISTANCE, CAPACITANCE**, and **INDUCTANCE**. The accuracy of all measurements depends upon YOUR SKILL as a technician and the accuracy of your TEST EQUIPMENT.

Accuracy of different types of test equipment varies greatly and depends on design characteristics, tolerances of individual components, and YOUR KNOWLEDGE of test equipment applications.

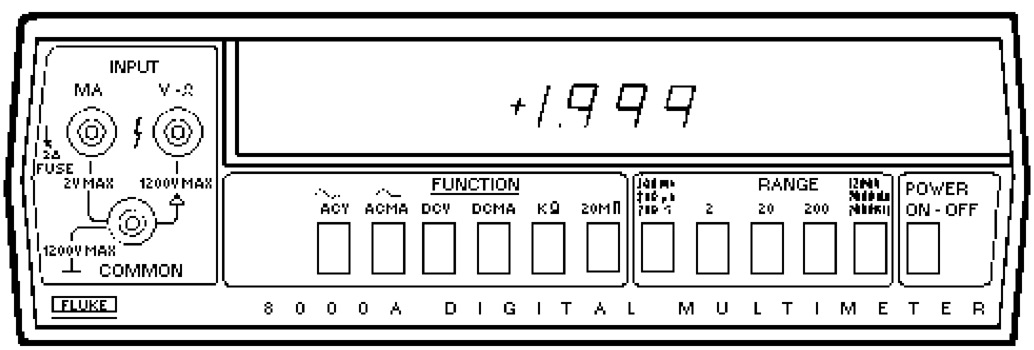
The **METCAL** program ensures that your calibrated test equipment meets established specifications.

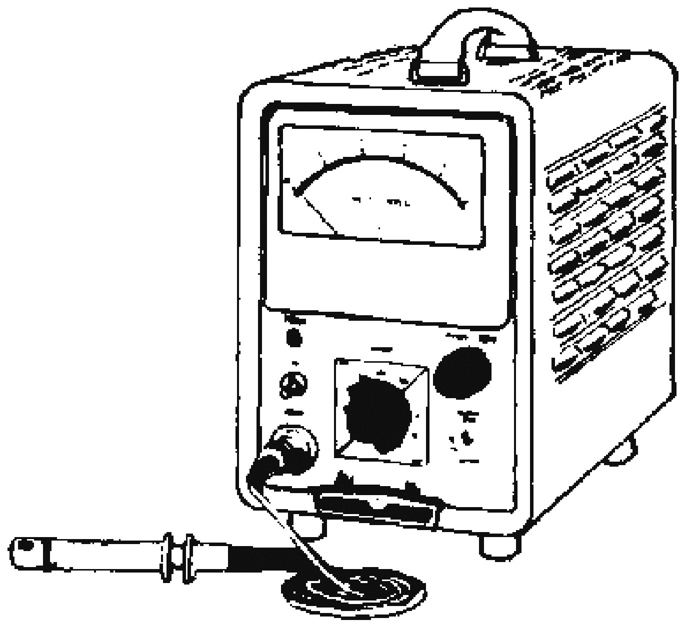
Most equipment technical manuals contain VOLTAGE CHARTS which list correct voltages that should be obtained at various test points.

It is important to remember that the **INPUT IMPEDANCE** of your test equipment must be high enough to prevent circuit loading.

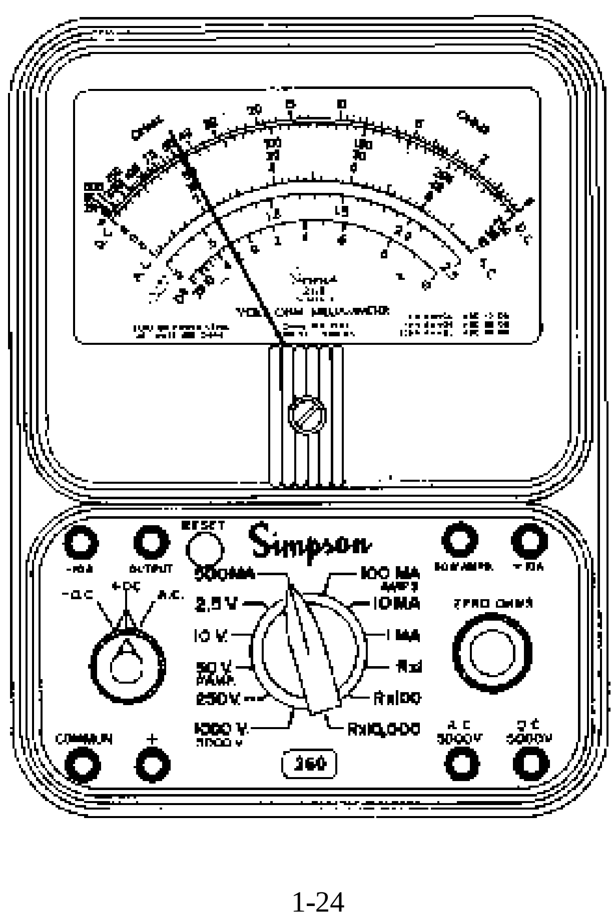
When you are performing ac voltage measurements, an additional consideration that greatly affects the accuracy of your measurements is the **FREQUENCY LIMITATIONS** of your test equipment.

Ac and dc CURRENT MEASUREMENTS can be performed using a wide variety of test equipment. Most current measurements require you to break the current path by unsoldering components and wires and inserting an ammeter in series with the current path. One alternative method is to compute (using OHM'S LAW) the current through a circuit by measuring the voltage drop across a known resistance. Another alternative is to use a CURRENT PROBE that requires no unsoldering.





When performing resistance measurements, your primary concerns are the **RANGE AND DEGREE OF ACCURACY** of your test equipment. In most instances, an analog multimeter is accurate enough to perform basic troubleshooting. When measuring extremely large resistances, you are sometimes required to use a MEGGER or a DIFFERENTIAL VOLTMETER.



When testing current-sensitive devices, you must be certain that the current produced by your test equipment does not exceed the current limitations of the device being tested.

Capacitance and inductance measurements are seldom required in the course of troubleshooting. These measurements are usually performed with various types of BRIDGES or with a reactance type of measuring device. The bridge -measuring techniques are more commonly used and are more accurate than reactance types of measurements.

CHAPTER 2

COMPONENT TESTING

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to do the following:

1. Explain the importance of testing individual electronic components.
2. Identify the various methods of testing electron tubes.
3. Identify the various methods of testing semiconductors.
4. Identify the various methods of testing integrated circuits.
5. Identify the various types of testing batteries and their characteristics.
6. Identify the various methods of testing rf attenuators and resistive loads.
7. Identify the various methods of testing fiber-optic devices.

INTRODUCTION TO COMPONENT TESTING

It is imperative that you be able to troubleshoot an equipment failure to the component level. In the majority of cases, Navy technicians are expected to troubleshoot and identify faulty components. This chapter, "Component Testing," will acquaint you with alternative methods of testing various components and their parameters. A quick glance at the Navy's mission and concept of operation explains why we, in most cases, must be able to troubleshoot to the faulty component level. A ship must be a self-sustaining unit when deployed. Storage space is a primary consideration on most ships and a limiting factor for storage of bulky items or electronic modules as ready spares. Therefore, it is practical to store only individual components common to a great number of equipment types. This of course, limits the larger replacement modules available to you during troubleshooting.

Q-1. Why are most ships limited in their ability to stock replacement modules for repair of electronic equipment?

TESTING ELECTRON TUBES

In equipment that uses vacuum tubes, faulty tubes are responsible for more than 50% of all electronic equipment failures. As a result, testing of electronic tubes is important to you. You can determine the condition of a tube by substituting an identical tube known to be good for the questionable one. However, indiscriminate substitution of tubes is to be avoided for at least the following two reasons: (1) detuning of circuits may result and (2) a tube may not operate properly in a high-frequency circuit even though it performs well in a low-frequency circuit. Therefore, your knowledge of tube-testing devices and their limitations, as well as correct interpretation of the test results obtained, is indispensable for accurate and rapid maintenance.

Because the operating capabilities and design features of a tube are demonstrated by its electrical characteristics, a tube is tested by measuring those characteristics and comparing them with representative values established for that type of tube. Tubes that read abnormally high or low with respect to the standard are suspect. Practical considerations, which take into account the limitations of the tube test in predicting actual tube performance in a particular circuit, make it unnecessary to use complex and costly test equipment with laboratory accuracy. For most applications, testing of a single tube characteristic is good enough to determine tube performance. Some of the more important factors affecting the life expectancy of an electron tube are listed below:

- The circuit function of the tube
- Deterioration of the cathode coating
- A decrease in emission of impregnated emitters in aging filament-type tubes
- Defective seals that permit air to leak into the envelope and oxidize the emitting surface
- Internal short circuits and open circuits caused by vibration or excessive voltage

If the average receiving tube is not overdriven or operated continuously at maximum rating, it can have a life of at least 2,000 hours before the filament opens. Because of the expansion and contraction of tube elements during the process of heating and cooling, electrodes may lean or sag, which causes excessive noise or microphonics to develop. Other electron-tube defects are cathode-to-heater leakage and nonuniform electron emission of the cathode. These common tube defects contribute to about 50% of all electronic equipment failures. For this reason you should immediately eliminate any tube known to be faulty. However, avoid blind or random replacement of good tubes with fresh spares. The most common cause of tube failure is open filaments. Evidence of a tube defect is often obvious when the filament is open in glass-envelope tubes. You will also notice the brighter-than-normal cherry-red glow of the plate when the plate current is excessive. Also, when the tube becomes gassy or when arcing occurs between electrodes, you will probably have visual indication. Metal-encased tubes can be felt for warmth to determine if the heater is operating. You can tap a tube while it is operating in a circuit to reveal an aural indication of loose elements within the tube or microphonics, which are produced by loose elements.

Most tubes are extremely fragile and subject to damage during shipment. When you replace a tube, never make the assumption that the new tube is good because it’s new. You should always test tubes before installing them.

Q-2. What is the most common cause of electron tube failure?

SUBSTITUTION METHODS

Substituting with a tube known to be in good condition is a simple method of testing a questionable tube. However, in high-frequency circuits tube substitution should be carried out in a logical sequence. Replace tubes one at a time so that you can observe the effect of differences in interelectrode capacitance in the substituted tubes on tuned circuits. The tube substitution test method cannot be used to advantage in locating more than one faulty tube in a single circuit for two reasons: (1) If both an rf amplifier tube and IF amplifier tube are defective in a receiver, replacing either one will not correct the trouble; and (2) if all the tubes are replaced, there is no way for you to know what tubes were defective. Under these conditions, using test equipment designed for testing the quality of a tube saves you valuable time.

Q-3. What is the most accurate method of determining the condition of an electron tube?

NOTE ON SYMBOLS USED IN THE FOLLOWING SECTIONS: IEEE and ANSI standards (see inside front cover) are used to define various terms, such as anode (plate) current, anode voltage, and anode resistance. This book uses E_a for anode voltage, I_a for anode current, and r_a for anode resistance. These are the same as E, I_p, and $_{rp}$ that you will see elsewhere. This module uses the terms anode and plate interchangeably.

ELECTRON TUBE TESTERS

A representative field type of electron tube tester designed to test all common low-power tubes is shown in figure 2-1. The tube test conditions are as close as possible to actual tube operating conditions and are programmed on a prepunched card. The card switch (S101, fig. 2-1) automatically programs the tube test conditions when it is actuated by a card. A card compartment on the front panel of the tester provides storage for the most frequently used cards. The cover of the tester (not shown) contains the operating instructions, the brackets for storing the technical manual, the power cord, the calibration cell for checking the meter and short tests, the calibration cards, the blank cards, and a steel hand punch.

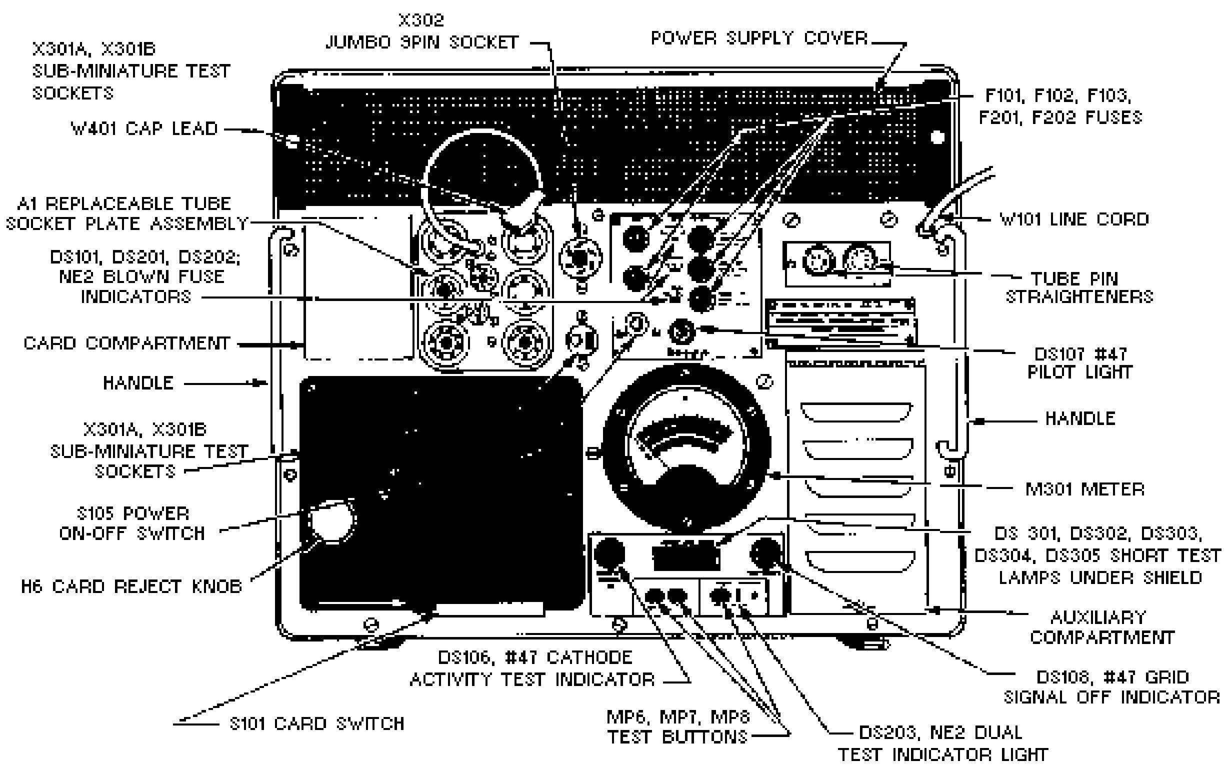

Figure 2-1.—Electron tube tester.

Front Panel

When a prepunched card is fully inserted into the card switch (S101), a microswitch is actuated that energizes a solenoid, causing the card switch contacts to complete the circuit. The card switch has 187 single-pole, single-throw switches arranged in 17 rows with 11 switches in each row. The card is used to push the switches closed; thus, the absence of a hole in the card is required to actuate a switch.

The meter (M301) contains four scales. The upper scale is graduated from 0 to 100 for direct numerical readings. The three lower scales, numbered 1, 2, and 3, are read for LEAKAGE, QUALITY, and GAS, respectively. Each numbered scale includes green and red areas marked GOOD and REPLACE. Inside a shield directly in front of the meter are five neon lamps (DS301 through DS305), which indicate shorts between tube elements.

The number 2 pushbutton (MP6) is used for transconductance, emission, and other quality tests (described later). The number 3 pushbutton (MP7) is used to test for the presence of gas in the tube envelope. The number 4 pushbutton (MP8) is used for tests on dual tubes. A neon lamp (DS203) lights when pushbutton number 4 is to be used. Eleven tube test sockets are located on the panel, plus tube pin straighteners for the 7- and 9-pin miniature tubes.

The power ON-OFF spring-return toggle switch (S105) turns the tester on by energizing a line relay. The pilot light (DS107) lights when this relay closes. Above the power ON-OFF switch are five fuses. Fuses F101, F201, and F202 protect circuits in the tester not protected by other means and have neon lamps to indicate when they have blown. Fuses F102 and F103 protect both sides of the power line.

Auxiliary Compartment

A group of auxiliary controls covered by a hinged panel is used for special tests and for calibration of the tester. Two of these controls, labeled SIGNAL CAL (R152 and R155, fig. 2-2), are used with special test cards for adjusting the regulation and amplitude of the signal voltage. A pushbutton labeled CATH ACT (S302D) is used for making cathode activity tests. When this button is pressed, DS106 on the front panel (fig. 2-1) lights, and the filament voltage of the tube under test is reduced by 10%. Results of the test are read as a change in reading on the numerical meter scale.

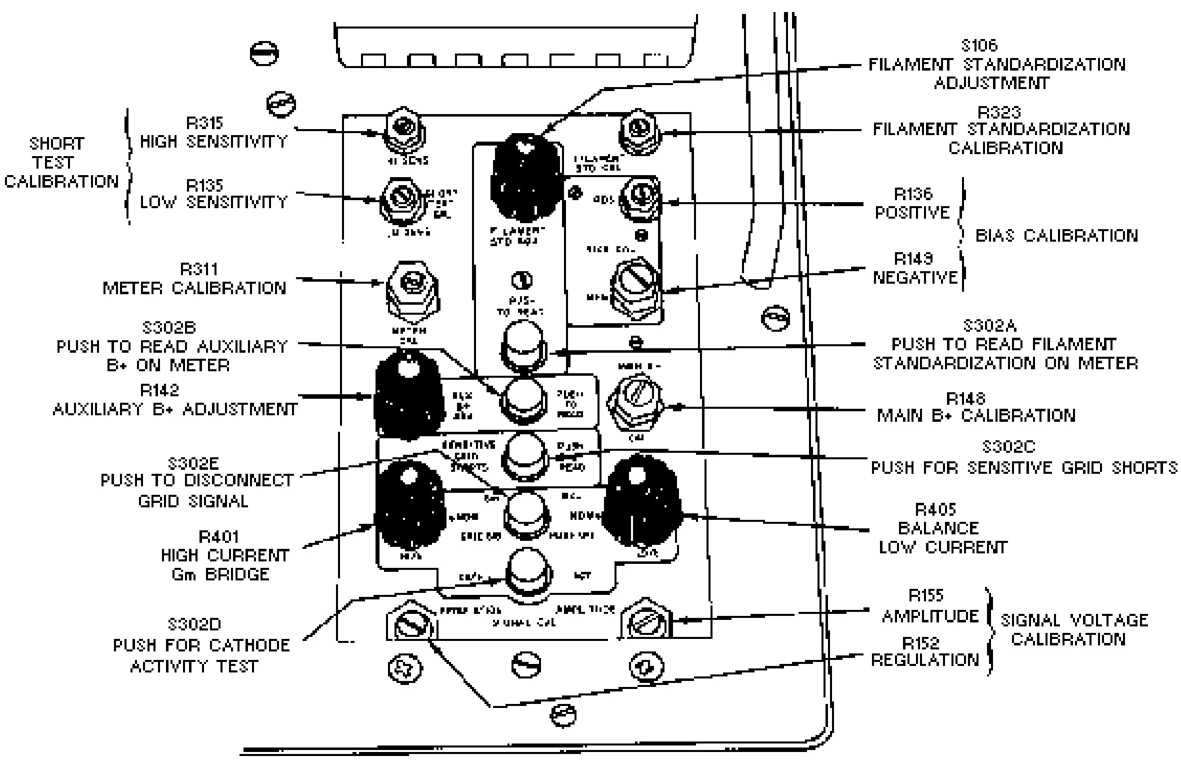

Figure 2-2.—Auxiliary compartment.

Pushbutton S302E and potentiometers R401 and R405 (fig. 2-2) are used for balancing the transconductance (Gm) bridge circuit under actual tube operating current. Pressing S302E removes the grid signal and allows a zero balance to be made with one potentiometer or the other, depending upon whether the tube under test is passing high or low plate current. Lamp DS108 on the front panel lights when S302E is pressed. Pushbutton S302C is used for checking grid-to-cathode shorts at a sensitivity much higher than the normal tests. Results of this test are indicated by the short test lamps on the front panel.

Certain special tests require the use of a continuously adjustable auxiliary power supply. By pressing pushbutton S302B, you may use meter M301 to read the voltage of the auxiliary power supply on meter M301. This voltage may be adjusted by the use of the potentiometer R142. The rest of the potentiometer controls are calibration controls and are adjusted by the use of special calibration cards and a calibration test cell.

All circuits in the tester, except the filament supply, are electronically regulated to compensate for line voltage fluctuations. The filament supply voltage is adjusted by pressing pushbutton S302A and rotating the filament standardization adjustment switch S106 until meter M301 reads midscale.

Program Cards

The circuits to be used in testing are selected by a prepunched card. These cards are made of tough vinyl plastic material. The tube numbers are printed in color on the tabs of the cards and also at the edge of the card for convenience in filing. A special card is provided to use as a marker when a card is removed for use. Blank cards are provided so that additional test cards may be punched for new tubes that are developed or to replace cards that have become unserviceable.

Operation

Before operating the tester for the first time, and periodically thereafter, you should calibrate it using the calibration test cards as described in the equipment technical manual.

NORMAL TESTS.—The tester is equipped with a three-conductor power cord, one wire of which is chassis ground. It should be plugged into a grounded 105- to 125-volt, 50- to 400-hertz outlet.

Before operating the tester, open the auxiliary compartment (fig. 2-2) and ensure that the FILAMENT STD ADJ and the Gm BAL knobs are in the NOM position. The GRID SIG and CATH ACT buttons (S302E and S302D) should be up and lamps DS108 and DS106 on the front panel should be out.

Turn on the tester and allow it to warm up for 5 to 10 minutes, then press the CARD REJECT KNOB (fig. 2-1) down until it locks. If a nontest card is installed in the card switch, remove it. This card is used to keep the switch pins in place during shipment and should be inserted before transporting the tester.

Plug the tube to be tested into its proper socket. (Use the pin straighteners before plugging in 7- and 9-pin miniature tubes.) Select the proper card or cards for the tube to be tested. Insert the card selected into the slot in the card switch until the CARD REJECT KNOB pops up. The card will operate the tester only if it is fully inserted and the printing is up and toward the operator. Do not put paper or objects other than program cards into the card switch, because they will jam the switch contacts. If the overload shuts off the tester when the card is inserted in the switch, check to see that the proper card is being used for the tube under test and that the tube under test has a direct interelement short.

As soon as the card switch is actuated, the tube under test is automatically subjected to an interelement short test and a heater-to-cathode leakage test. A blinking or steady glow of any of the short test lamps is an indication of an interelement short. If the short test lamps remain dark, no interelement shorts exist within the tube. If a short exists between two or more elements, the short test lamp or lamps connected between these elements remain dark, and the remaining lamps light. The abbreviations for the tube elements are located on the front panel just below the short test shield so that the neon lamps are between them. This enables the operator to tell which elements are shorted. Heater-to-cathode shorts are indicated as leakage currents on the #1 meter scale. If the meter reads above the green area, the tube should be replaced. A direct heater-to-cathode short causes the meter to read full scale.

To make the QUALITY test, push the number 2 button (fig. 2-1) and read the number 2 scale on meter M301 to determine if the tube is good. (This test may be one of various types, such as transconductance, emission, plate current, or voltage drop, depending upon the type of tube under test.)

To test the tube for GAS, press the number 3 button and read the number 3 meter scale. The number 2 button also goes down when number 3 is pressed. If a dual tube having two identical sections is being tested, the neon lamp (DS203) will light, indicating that both sections of the tube may be tested with one card. To do this, check the tube for shorts, leakage, quality, and gas as described previously; then hold down button number 4 and repeat these tests to test the second section of the tube. Dual tubes with sections that are not identical require two cards for testing. A second card is also provided to make special tests on certain tubes.

AUXILIARY TEST.—As mentioned previously, two special tests (cathode activity and sensitive grid shorts) may be made by use of controls located in the auxiliary compartment (fig. 2-2). The cathode activity test (CATH ACT) is used to indicate the amount of useful life remaining in the tube. By reducing the filament voltage by 10 percent and allowing the cathode to cool off slightly, the ability of the cathode as an emitter of electrons can be estimated. This test is made in conjunction with the normal quality test.

To make the CATH ACT test, allow the tube under test to warm up, press button number 2 (fig. 2-1), and note the reading of scale number 2 on meter M301. Note also the numerical scale reading on M301. Next, lock down the CATH ACT button (fig. 2-2), wait for about 1.5 minutes, then press button number 2 (fig. 2-1) again and note the numerical and number 2 scale readings on meter M301. The tube should be replaced if the numerical reading on M301 differs from the first reading by more than 10 percent or if the reading is in the red area on the number 2 scale.

It is sometimes desirable to check certain tubes for shorts at a sensitivity greater than normal. To make the SENSITIVE GRID SHORTS test, push S302C (fig. 2-2) and note if any short test lamps (fig. 2-1) light.

HIGH-POWER HF AMPLIFIER TUBE TESTS

You normally test high-power amplifier tubes, which operate in the low-to-high frequency range, in the transmitter in which they are to be used. When you operate the tube in a transmitter, its condition can be determined by using built-in meters to measure the grid current, plate current, and power output and comparing those values with those obtained when using tubes known to be good.

Q-4. Normally, how are high-power rf tubes tested?

Klystron Tube Tests

You can check low-power klystron tubes for gas, frequency of the output signal, and output power by placing them in the equipment where they are to be used. You measure the beam current, output frequency, and output power with the transmitter's built-in test equipment. You can check the output of klystrons used as receiver local oscillators by measuring the current in the crystal mixer unit.

Klystron tubes that remain inoperative for more than 6 months may become gassy. This condition occurs in klystrons installed in stored or spare equipment as well as in klystrons stored as stock supplies. Operation of a gassy klystron at its rated voltages will ionize the gas molecules and may cause excessive beam current to flow. This excessive beam current may shorten the life of the klystron or produce immediate failure. You can detect gas in a klystron tube by setting the applied reflector voltage to zero and slowly increasing the beam voltage while observing a meter that indicates the beam current - excessive beam current for a specific value of voltage indicates that the tube is gassy.

A gassy klystron tube can usually be restored to serviceable condition if you temporarily operate it at reduced beam voltage. Eight hours or more of reduced voltage operation may be required for klystrons that have been inoperative for periods in excess of 6 months.

The beam current is also an indication of the power output of the klystron. As klystrons age they normally draw less beam current; when this current decreases to a minimum value for a specific beam voltage, the tube must be replaced. You can usually determine the power output of transmitter klystrons by measuring the transmitter power output during equipment performance checks.

Q-5. What should you do if a klystron becomes gassy?

Traveling-Wave Tube

You can usually test a traveling-wave tube (twt) in the equipment in which it is used. When the twt is installed, you can usually measure the collector current and voltage and check the power output for various inputs. Any deviation greater than 10% from normal specifications may be considered to be an indication of a defective tube. Most amplifiers are supplied with built-in panel meters and selector switches so that the cathode, anode, helix, focus, and collector currents may be measured. Thus, continuous monitoring of amplifier operation and tube evaluation is possible. Adjustments usually are provided for you to set the helix, grid bias, and collector voltages for optimum operation. If variation of these controls will not produce normal currents and if all voltages are normal, you should consider the tube to be defective and replace it with a new tube or one known to be in good operating condition. To avoid needless replacement of tubes, however, you should make an additional check by measuring the input power and output power and determining the tube gain. If, with normal operating conditions, the gain level drops below the minimum indicated value in the equipment technical manual, the tube is defective.

Q-6. When used as an amplifier, what is the best indication that a twt is operating properly?

In the absence of special field-test sets, you may construct a laboratory test mock-up similar to that shown in figure 2-3. Because of the variations in power and gain between tubes and the large frequency ranges offered, we can illustrate only a general type of equipment. The equipment you select must have the proper range, impedance, and attenuation to make the test for a specific type of twt. To make gain measurements, you turn the switch shown in figure 2-3 to position 1 and set the precision attenuator to provide a convenient level of detector output. Then turn the switch to position 2 and insert attenuation until the detector output level is identical to that obtained without the twt in the circuit. The gain of the traveling-wave tube is equal to the amount of added attenuation.

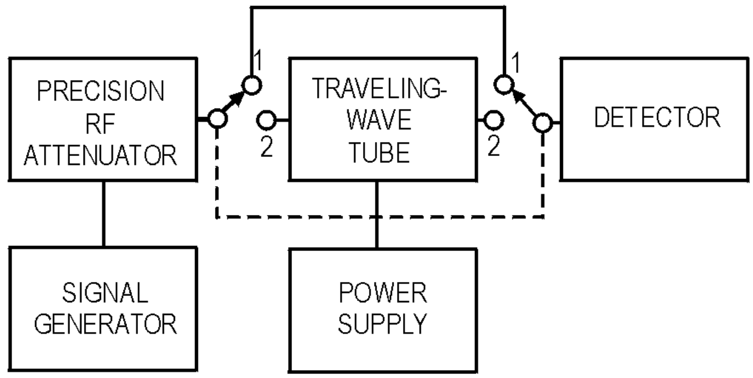

Figure 2-3.—Traveling-wave tube test arrangement.

When you use the twt as an oscillator, failure of the tube to break into oscillations when all other conditions are normal usually indicates a defective tube. In the case of a tube used as a receiving amplifier, an increase of noise with a normal or reduced output can indicate that the tube is failing but is still usable. All the general rules applying to klystron tubes mentioned previously are also applicable to the twt.

Magnetron Tube Tests

You test a magnetron tube while it is in the transmitter equipment in which it is to be used. When you install the magnetron in the transmitter, the condition of the tube can be determined by the normal plate-current measurement and the power, frequency spectrum, and standing-wave-ratio tests of the output signal. An unusual value for any of these measurements may indicate a defective tube.

Crossed-Field Amplifier

You usually test a crossed-field amplifier (cfa) tube while it is in the equipment in which it is used. Like the klystron, if you do not operate the cfa for more than a few months, the tube may become gassy. If a cfa tube is suspected of being gassy, we recommend that you consult the technical manual for the particular piece of equipment in which the crossed-field amplifier is used.

TESTING SEMICONDUCTORS

Unlike vacuum tubes, transistors are very rugged in that they can tolerate vibration and a rather large degree of shock. Under normal operating conditions, they will provide dependable operation for a long period of time. However, transistors are subject to failure when they are subjected to relatively minor overloads. Crystal detectors are also subject to failure or deterioration when subjected to electrical overloads and will deteriorate from a long period of normal use. To determine the condition of semiconductors, you can use various test methods. In many cases you may substitute a transistor of known good quality for a questionable one to determine the condition of a suspected transistor. This method is highly accurate and sometimes efficient. However, you should avoid indiscriminate substitution of semiconductors in critical circuits. When transistors are soldered into equipment, substitution becomes impractical - generally, you should test these transistors while they are in their circuits.

Q-7. What is the major advantage of a transistor over a tube?

Since certain fundamental characteristics indicate the condition of semiconductors, test equipment is available that allows you to test these characteristics with the semiconductors in or out of their circuits. Crystal-rectifier testers normally allow you to test only the forward-to-reverse current ratio of the crystal. Transistor testers, however, allow you to measure several characteristics, such as the collector leakage current ($_{Ic}$), collector to base current gain (β), and the four-terminal network parameters. The most useful test characteristic is determined by the type of circuit in which the transistor will be used. Thus, the alternating-current beta measurement is preferred for ac amplifier or oscillator applications; and for switching-circuit applications, a direct-current beta measurement may prove more useful.

Many common transistors are extremely heat sensitive. Excess heat will cause the semiconductor to either fail or give intermittent operation. You have probably experienced intermittent equipment problems and know them to be both time consuming and frustrating. You know, for example, that if a problem is in fact caused by heat, simply opening the equipment during the course of troubleshooting may cause the problem to disappear. You can generally isolate the problem to the faulty printed-circuit board (pcb) by observing the fault indications. However, to further isolate the problem to a faulty component, sometimes you must apply a minimal amount of heat to the suspect pcb by carefully using a low wattage, heat shrink gun; an incandescent drop light; or a similar heating device. Be careful not to overheat the pcb. Once the fault indication reappears, you can isolate the faulty component by spraying those components suspected as being bad with a nonconductive circuit coolant, such as Freon. If the alternate heating and cooling of a component causes it to operate intermittently, you should replace it.

Q-8. Name two major disadvantages of transistors.

TRANSISTOR TESTING

When trouble occurs in solid-state equipment, you should first check power supplies and perform voltage measurements, waveform checks, signal substitution, or signal tracing. If you isolate a faulty stage by one of these test methods, then voltage, resistance, and current measurements can be made to locate defective parts. When you make these measurements, the voltmeter impedance must be high enough that it exerts no appreciable effect upon the voltage being measured. Also, current from the ohmmeter you use must not damage the transistors. If the transistors are not soldered into the equipment, you should remove the transistors from the sockets during a resistance test. Transistors should be removed from or reinserted into the sockets only after power has been removed from the stage; otherwise damage by surge currents may result.

Transistor circuits, other than pulse and power amplifier stages, are usually biased so that the emitter current is from 0.5 milliampere to 3 milliamperes and the collector voltage is from 3 to 15 volts. You can measure the emitter current by opening the emitter connector and inserting a milliammeter in series. When you make this measurement, you should expect some change in bias because of the meter resistance. You can often determine the collector current by measuring the voltage drop across a resistor in the collector circuit and calculating the current. If the transistor itself is suspected, it can be tested by one or more of the methods described below.

Resistance Test

You can use an ohmmeter to test transistors by measuring the emitter-collector, base-emitter, and base-collector forward and reverse resistances. A back-to-forward resistance ratio on the order of 100 to 1 or greater should be obtained for the collector-to-base and emitter-to-base measurements. The forward and reverse resistances between the emitter and collector should be nearly equal. You should make all three measurements for each transistor you test, because experience has shown that transistors can develop shorts between the collector and emitter and still have good forward and reverse resistances for the other two measurements. Because of shunting resistances in transistor circuits, you will normally have to disconnect at least two transistor leads from the associated circuit for this test. Exercise caution during this test to make certain that current during the forward resistance tests does not exceed the rating of the transistor — ohmmeter ranges requiring a current of more than 1 milliampere should not be used for testing transistors. Many ohmmeters are designed such that on the R × 1 range, 100 milliamperes or more can flow through the electronic part under test. For this reason, you should use a digital multimeter. Be sure you select a digital multimeter that produces enough voltage to properly bias the transistor junctions.

Q-9. When you are using an ohmmeter to test a transistor, what range settings should be avoided?

Transistor Testers

Laboratory transistor test sets are used in experimental work to test all characteristics of transistors. For maintenance and repair, however, it is not necessary to check all of the transistor parameters. A check of two or three performance characteristics is usually sufficient to determine whether a transistor needs to be replaced. Two of the most important parameters used for transistor testing are the transistor current gain (beta) and the collector leakage or reverse current (I_c).

The semiconductor test set (fig. 2-4) is a rugged, field type of tester designed to test transistors and semiconductor diodes. The set measures the beta of a transistor, resistance appearing at the electrodes, reverse current of a transistor or semiconductor diode, shorted or open conditions of a diode, forward transconductance of a field-effect transistor, and condition of its own batteries.

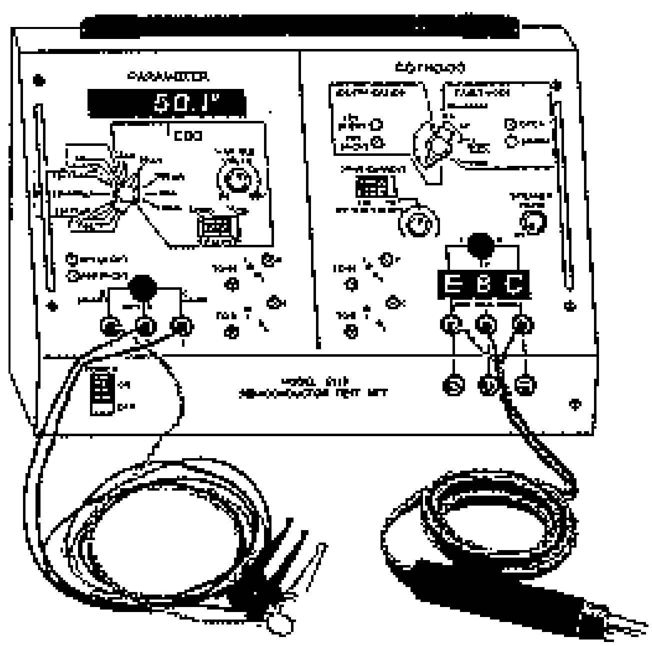

Figure 2-4.—Semiconductor test set.

In order to assure that accurate and useful information is gained from the transistor tester, the following preliminary checks of the tester should be made prior to testing any transistors.

With the POLARITY switch (fig. 2-4) in the OFF position, the meter pointer should indicate exactly zero. (When required, rotate the meter adjust screw on the front of the meter to fulfill this requirement.) When measurements are not actually being made, the POLARITY switch must always be left in the OFF position to prevent battery drain.

Always check the condition of the test set batteries by disconnecting the test set power cord, placing the POLARITY switch in the PNP position and placing the FUNCTION switch first to BAT.1, then to BAT.2. In both BAT positions the meter pointer should move so as to indicate within the red BAT range.

BETA MEASUREMENTS.—If the transistor is to be tested out of the circuit, plug it into the test jack located on the right-hand side below the meter shown in figure 2-4. If the transistor is to be tested in the circuit, it is imperative that at least 300 ohms exist between E-B, C-B, and C-E for accurate measurement. Initial settings of the test set controls are as follows:

1. FUNCTION switch to BETA
2. POLARITY switch to PNP or NPN (dependent on type of transistor under test)
3. RANGE switch to X10
4. Adjust METER ZERO for zero meter indication (transistor disconnected)

NOTE: The POLARITY switch should remain OFF while the transistor is connected to or disconnected from the test set. If you determine that the beta reading is less than 10, reset the RANGE switch to X1 and reset the meter to zero.

After connecting the yellow test lead to the emitter, the green test lead to the base, and the blue test lead to the collector, plug the test probe (not shown) into the jack located at the lower right-hand corner of the test set. When testing grounded equipment, unplug the 115 vac line cord and use battery operation. The beta reading is attained by multiplying the meter reading times the RANGE switch setting. Refer to the transistor characteristics book provided with the tester to determine if the reading is normal for the type of transistor under test.

ELECTRODE RESISTANCE MEASUREMENTS.—Connect the in-circuit probe test leads to the transistor with the yellow lead to the emitter, the green lead to the base, and the blue lead to the collector. Set the FUNCTION switch to the OHMS E-B position, and read the resistance between the emitter and base electrode on the center scale of the meter.

To read the resistance between the collector and base and the collector and emitter, set the FUNCTION switch to OHMS C-B and OHMS C-E. These in-circuit electrode resistance measurements are used to correctly interpret the in-circuit beta measurements. The accuracy of the BETA X1, X10 range is ±15 percent only when the emitter-to-base load is equal to or greater than 300 ohms.

I_c MEASUREMENTS.—Adjust the METER ZERO control for zero meter indication. Plug the transistor to be tested into the jack or connect test leads to the device under test. Set the PNP/NPN switch to correspond with the transistor under test. Set the FUNCTION switch to I_c and the RANGE switch to X0.1, X1, or X10 as specified by the transistor data book for allowable leakage. Read the amount of leakage on the bottom scale, and multiply this by the range setting figure as required.

DIODE MEASUREMENTS.—Diode qualitative in-circuit measurements are attained by connecting the green test lead to the cathode and the yellow test lead to the anode. Set the FUNCTION switch to DIODE IN/CKT and the RANGE switch to X1. (Ensure that the meter has been properly zeroed on this scale.) If the meter reads down scale, reverse the POLARITY switch. If the meter reads less than midscale, the diode under test is either open or shorted. The related circuit impedance of this test is less than 25 ohms.

PRECAUTIONS.—Transistors, although generally more rugged mechanically than electron tubes, are susceptible to damage by excessive heat and electrical overload. The following precautions should be taken in servicing transistorized equipment:

1. Test equipment and soldering irons must be checked to make certain that there is no leakage current from the power source. If leakage current is detected, isolation transformers must be used.
2. Ohmmeter ranges that require a current of more than 1 milliampere in the test circuit are not to be used for testing transistors.
3. Battery eliminators should not be used to furnish power for transistor equipment because they have poor voltage regulation and, possibly, high ripple voltage.
4. The heat applied to a transistor, when soldered connections are required, should be kept to a minimum by using a low-wattage soldering iron and heat shunts (such as long-nose pliers) on the transistor leads.
5. All circuits should be checked for defects before a transistor is replaced.
6. The power should be removed from the equipment before replacing a transistor or other circuit part.
7. When working on equipment with closely spaced parts, you will find that conventional test probes are often the cause of accidental short circuits between adjacent terminals. Momentary short circuits, which rarely cause damage to an electron tube, may ruin a transistor. To avoid accidental shorts, a test probe can be covered with insulation for all but a very short length of the tip.

Electrostatic Discharge Sensitive (ESDS) Care

Devices that are sensitive to electrostatic discharge (ESD) require special handling. You can readily identify ESD-sensitive (ESDS) devices by the symbols shown in figure 2-5. Static electricity is created whenever two substances (solid or fluid) are rubbed together or separated. The rubbing or separating of substances causes the transfer of electrons from one substance to the other; one substance then becomes positively charged, and the other becomes negatively charged. When either of these charged substances comes in contact with a grounded conductor, an electrical current flows until that substance is at the same electrical potential as ground.

Figure 2-5.—Warning symbols for ESDS devices.

You commonly experience static build-up during the winter months when you walk across a vinyl or carpeted floor. (Synthetics, especially plastics, are excellent generators of static electricity.) If you then touch a doorknob or any other conductor, an electrical arc to ground may result, and you may receive a slight shock. For you to experience such a shock, the electrostatic potential created must be 3,500 to 4,000 volts. Lesser voltages, although present and similarly discharged, normally are not apparent to your nervous system. Some typical measured static charges caused by various actions are shown in table 2-1.

Table 2-1.—Typical Measured Static Charges (in volts)

ITEM	RELATIVE HUMIDITY	
	LOW (10 - 20%)	HIGH (65 - 90%)
WALKING ACROSS CARPET	35,000V	1,500V
WALKING OVER VINYL FLOOR	12,000V	250V
WORKER AT BENCH	6,000V	100V
VINYL ENVELOPES FOR WORK INSTRUCT.	7,000V	600V
POLY BAG PICKED UP FROM BENCH	20,000V	1,200V
WORK CHAIR PADDED WITH URETHANE FORM	18,000 V	1,500 V

Q-10. At approximately what minimum voltage potential should you be able to feel an electrostatic discharge?

Metal oxide semiconductor (MOS) devices are the most susceptible to damage from ESD. For example, an MOS field-effect transistor (MOSFET) can be damaged by a static voltage potential of as little as 35 volts. Commonly used discrete bipolar transistors and diodes (often used in ESD-protective circuits), although less susceptible to ESD, can be damaged by voltage potentials of less than 3,000 electrostatic volts. Damage does not always result in sudden device failure but sometimes results in device degradation and early failure. Table 2-1 clearly shows that electrostatic voltages well in excess of

3,000 volts can be easily generated, especially under low-humidity conditions. ESD damage of ESDS parts or circuit assemblies is possible whenever two or more pins of any of these devices are electrically exposed or have low impedance paths. Similarly, an ESDS device in a printed-circuit board or even in another pcb that is electrically connected in a series can be damaged if it provides a path to ground. ESD damage can occur during the manufacture of equipment or during the servicing of the equipment. Damage can occur anytime devices or assemblies are handled, replaced, tested, or inserted into a connector.

Q-11. A MOSFET can be damaged by an electrostatic discharge at approximately what minimum potential?

ESD-sensitive devices can be grouped by their sensitivity to ESD. Semiconductors fall within the following categories:

- VERY SENSITIVE DEVICES. These include MOS and CMOS devices without input diode protection circuitry on all input circuits; dielectrically isolated semiconductors with internal capacitor contacts connected to external pins; and microcircuits using N + guard-ring construction (with metalization crossing over the guard ring).
- SENSITIVE DEVICES. These include all low-power Schottky-barrier and Schottky-TTL devices; all ECL devices; high input-impedance linear microcircuits; all small-signal transistors that operate at 500 MHz or higher; all discrete semiconductors that use silicon dioxide to insulate metal paths over other active areas; MOS or CMOS devices with input diode protection on all input terminals; junction field-effect transistors; and precision resistive networks.
- MODERATELY SENSITIVE DEVICES. These include all microcircuits and small-signal discrete semiconductors with less than 10 watts dissipation at 25º C, and thick-film resistors.

The following procedure is an example of some of the protective measures used to prevent ESD damage:

1. Before servicing equipment, you should be grounded to discharge any static electricity from your body. This can be accomplished with the use of a test lead (a single-wire conductor with a series resistance of 1 megohm) equipped with alligator clips on each end. After the equipment has been completely de-energized, one clip end is connected to the grounded equipment frame; the other clip end is touched with your bare hand. Figure 2-6 shows a more refined ground strap, which frees both hands for work.

NOTE: When wearing a wrist strap, you should *never use ac-powered test equipment* because of your increased chance of receiving an electrical shock.

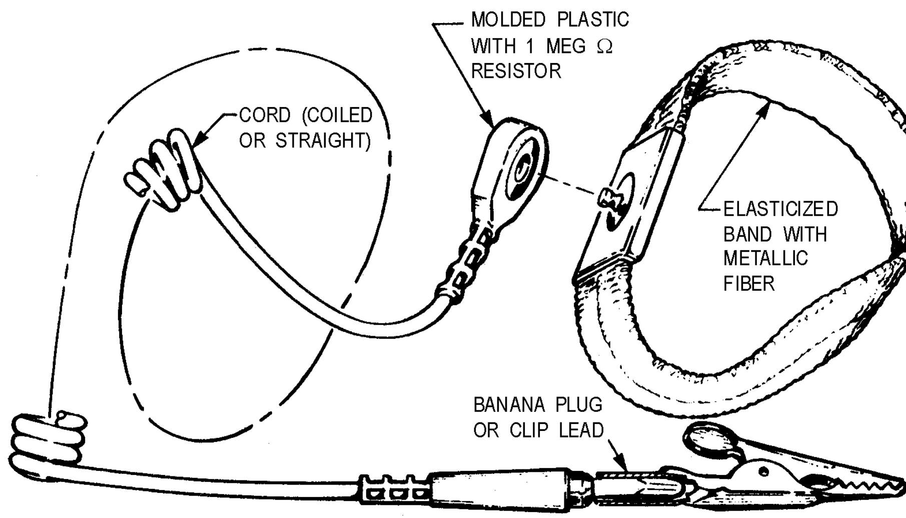

Figure 2-6.—ESD wrist strap.

2. Equipment technical manuals and packaging material should be checked for ESD warnings and instructions.

3. Prior to opening an electrostatic unit package of an ESDS device or assembly, clip the free end of the grounded test lead to the package. This will cause any static electricity that may have built up on the package to discharge. The other end remains connected to the equipment frame or other ESD ground. Keep the unit package grounded until the replacement device or assembly is placed in the unit package.

4. Minimize handling of ESDS devices and assemblies. Keep replacement devices or assemblies, with their connector-shorting bars, clips, and so forth, intact in their electrostatic-free packages until needed. Place removed repairable ESDS devices or assemblies, with their connector shorting bars or clips installed, in electrostatic-free packages as soon as they are removed from the equipment. ESDS devices or assemblies should be transported and stored only in protective packaging.

5. Always avoid unnecessary physical movement, such as scuffing the feet, when handling ESDS devices or assemblies. Such movement will generate additional charges of static electricity.

6. When removing or replacing an ESDS device or assembly in the equipment, hold the device or assembly through the electrostatic-free wrap if possible. Otherwise, pick up the device or assembly by its body only. DO NOT TOUCH component leads, connector pins, or any other electrical connections or paths on boards, even though they are covered by conformal coating.

7. Do not permit ESDS devices or assemblies to come in contact with clothing or other ungrounded materials that could have an electrostatic charge. The charges on a nonconducting material are not equal. A plastic storage bag may have a −10,000 volt potential one-half inch from a +15,000 volt potential, with many other such charges all over the bag. Placing a circuit card inside the bag allows the charges to equalize through the pcb conductive paths and components, thereby causing failures. Do not hand an ESDS device or assembly to another person until the device or assembly is protectively packaged.

8. When moving an ESDS device or assembly, always touch (with your bare skin) the surface on which it rests for at least 1 second before picking it up. Before placing it on any surface, touch the

surface with your free hand for at least 1 second. The bare skin contact provides a safe discharge path for electrostatic charges accumulated while you are moving around.

9. While servicing equipment containing ESDS devices, do not handle or touch materials such as plastic, vinyl, synthetic textiles, polished wood, fiber glass, or similar items that could create static charges; or, be sure to repeat the grounding action with the bare hands after contacting these materials. These materials are prime electrostatic generators.

10. If possible, avoid repairs that require soldering at the equipment level. Soldering irons must have heater and tip assemblies grounded to ac electrical ground. Do not use ordinary plastic solder suckers (special antistatic solder suckers are commercially available).

11. Ground the leads of test equipment momentarily before you energize the test equipment and before you probe ESDS items.

Q-12. Why should you avoid using ac-powered test equipment when wearing a wrist strap?

DIODE TESTING

Because of the reliability of semiconductor devices, servicing techniques developed for transistorized equipment differ from those used for electron-tube circuits. Electron tubes are usually considered to be the circuit component most susceptible to failure and are normally the first to be tested. Transistors, however, are capable of operating in excess of 30,000 hours at maximum ratings without appreciable degradation. They are often soldered into equipment in the same manner as resistors and capacitors. Substitution of a diode or transistor known to be in good condition is a simple method of determining the quality of a questionable semiconductor device. You should use this technique only after voltage and resistance measurements indicate that no circuit defect exists that might damage the substituted semiconductor device. If more than one defective semiconductor is present in the equipment section where trouble has been localized, substitution becomes cumbersome since several semiconductors may have to be replaced before the trouble is corrected. To determine which stages failed and which semiconductors are not defective, you must test all of the removed semiconductors. This can be accomplished by observing whether the equipment operates correctly as each of the removed semiconductor devices is reinserted into the equipment.

Q-13. Prior to substituting a diode, what measurements should you take to determine its condition?

DIODE TESTERS

Diodes, such as general-purpose germanium and silicon diodes, power silicon diodes, and microwave silicon diodes, are most effectively tested under actual operating conditions. However, rectifier testers are available for you to determine direct-current characteristics that provide an indication of diode quality.

Rf Diode Test

A common type of diode test set is a combination ohmmeter-ammeter. You can make measurements of forward resistance, back resistance, and reverse current with this equipment. You can determine the condition of the rectifier under test by comparing its actual values with typical values obtained from test information furnished with the test set or from the manufacturer’s data sheets. Comparing the diode’s back and forward resistance at a specified voltage provides you with a rough indication of the rectifying property of a diode. A typical back-to-forward resistance ratio is on the order of 10 to 1, and a forward-resistance value of 50 to 80 ohms is common.

Switching Diode Test

To effectively test diodes used for computer applications, you must obtain back-resistance measurements at a large number of different voltage levels. This can be done efficiently by using a dynamic diode tester in conjunction with an oscilloscope, which is used to display the diode's back-current-versus-voltage curve. You can easily interpret diode characteristics, such as flutter, hysteresis, and negative resistance, through use of the dynamic current and voltage display.

DIODE CHARACTERISTIC GRAPHICAL DISPLAY

You can use an oscilloscope to graphically display the forward- and back-resistance characteristics of a diode. A test circuit used in conjunction with an oscilloscope is shown in figure 2-7. This circuit uses an audio-signal generator as the test signal. It should be adjusted for an approximate 2-volt, 60-hertz signal, as measured across R1.

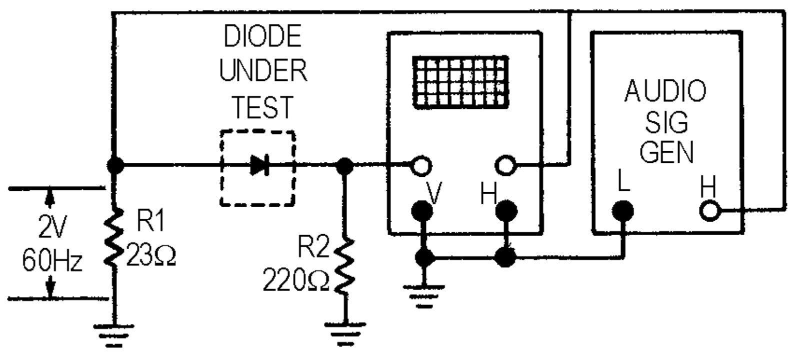

Figure 2-7.—Display circuit used with an oscilloscope.

The test signal you apply to the diode is also connected to the horizontal input of the oscilloscope. The horizontal sweep will then display the voltage applied to the diode under test. The voltage developed across current-measuring resistor R2 is applied to the vertical input of the oscilloscope. Since this voltage is proportional to the current through the diode under test, the vertical deflection will indicate diode current. The resulting oscilloscope trace will be similar to the curve shown in figure 2-8.

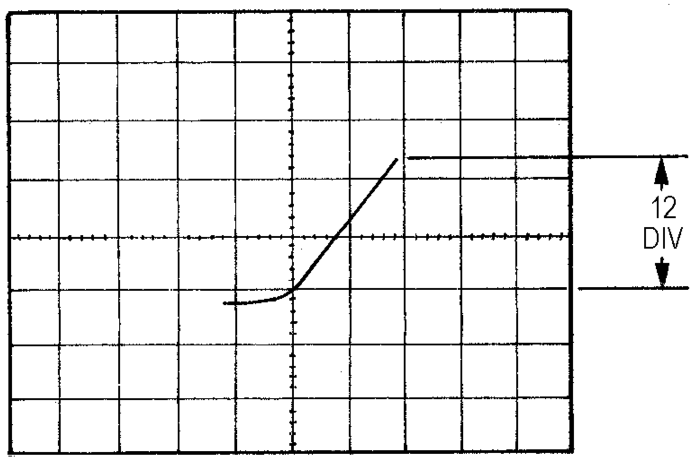

Figure 2-8.—Typical characteristic curve of a silicone diode.

Reverse Voltage-Current Analysis

You can make an analysis of the reverse voltage-current portion of the characteristic curve for a diode with the method described above or with a diode test set. This test is very important for diodes used in computer applications, where stability of operation is essential. Various diode conditions that may be detected by this test are shown in figure 2-9, view A, view B, view C, and view D.

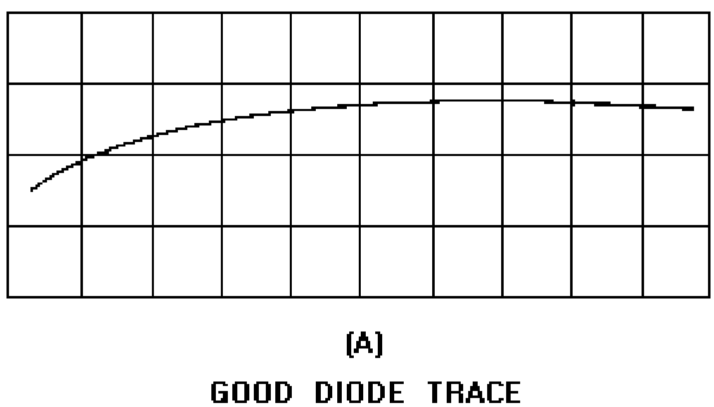

Figure 2-9A.—Diode reverse current-voltage characteristics. GOOD DIODE TRACE.

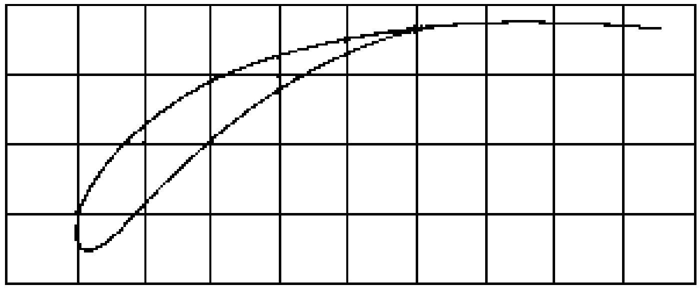

Figure 2-9B.—Diode reverse current-voltage characteristics. HYSTERESIS CHARACTERISTIC.

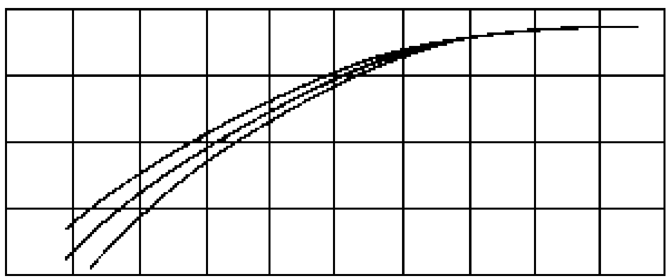

Figure 2-9C.—Diode reverse current-voltage characteristics. FLUTTER (OR DRIFT) CHARACTERISTIC.

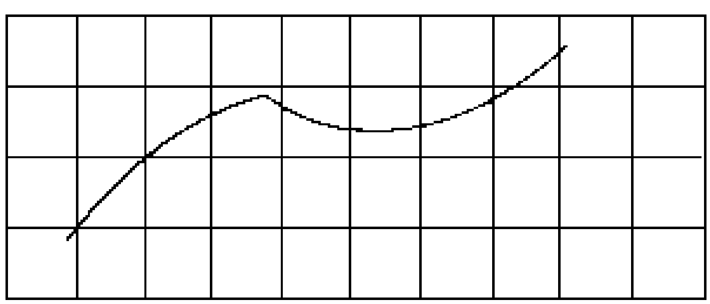

Figure 2-9D.—Diode reverse current-voltage characteristics. NEGATIVE RESISTANCE TRACE.

Zener Diode Test

An audio signal generator may not be able to produce a high enough voltage for you to test Zener diodes. You can, however, make this test with a diode test set or with the circuit shown in figure 2-10. In this circuit, R1 is used to adjust the input voltage to a suitable value for the Zener diode being tested. Resistor R2 limits the current through the diode. The signal voltage applied to the diode is also connected to the horizontal input of the oscilloscope. The voltage developed across current-measuring resistor R3 is applied to the vertical input of the oscilloscope. The horizontal sweep will therefore represent the applied voltage, and the vertical deflection will indicate the current through the diode under test. Figure 2-11 shows the characteristic pattern of a Zener diode (note the sharp increase in current at the avalanche breakdown point). For the Zener diode to be acceptable, this voltage must be within the limits specified by the manufacturer.

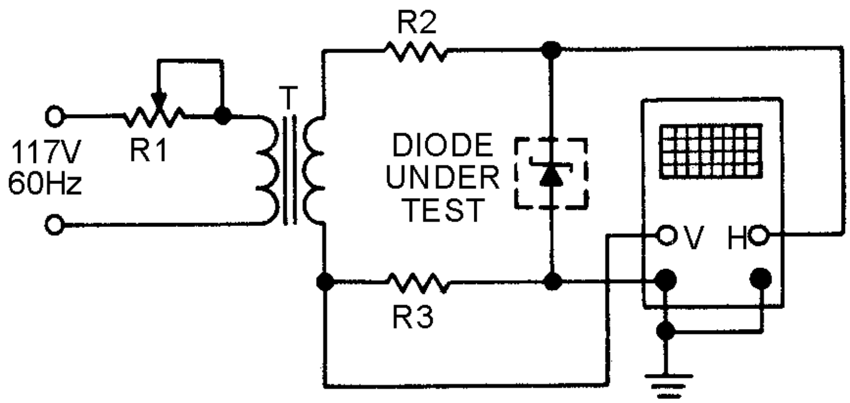

Figure 2-10.—Zener diode test circuit.

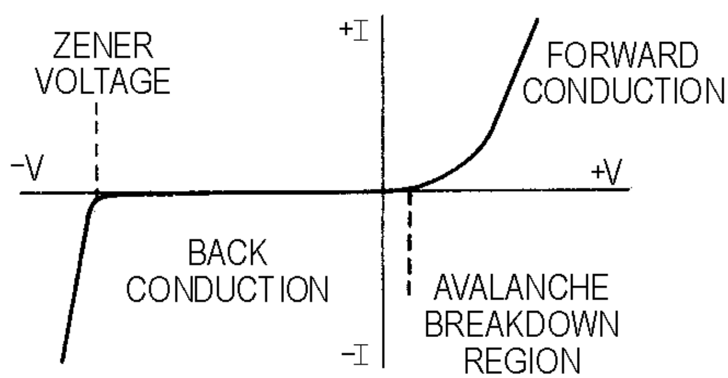

Figure 2-11.—Zener diode characteristic pattern.

STATIC RESISTANCE MEASUREMENTS

One convenient method of testing a diode requires only your ohmmeter. The forward and back resistances can be measured at a voltage determined by the battery potential of the ohmmeter and the resistance range at which the meter is set. When the test leads of the ohmmeter are connected to the diode, a resistance will be measured that is different from the resistance indicated if the leads are reversed. The smaller value is called the forward resistance, and the larger value is called the back resistance. If the ratio of back-to-forward resistance is greater than 10 to 1, the diode should be capable of functioning as a rectifier. This is a very limited test, which does not take into account the action of the diode at voltages of different magnitudes and frequencies. Some diodes may be damaged by the excessive current produced by some range settings of a standard multimeter. Therefore, you should use a digital multimeter when performing this measurement.

Q-14. As a rule of thumb, what is an acceptable ratio of back-to-forward resistance for a diode?

SILICON-CONTROLLED RECTIFIERS (SCR)

Many naval electronic equipments use silicon-controlled rectifiers (SCRs) for the control of power. Like other solid-state components, SCRs are subject to failure. You can test most SCRs with a standard ohmmeter, but you must understand just how the SCR functions.

As shown in figure 2-12, the SCR is a three-element, solid-state device in which the forward resistance can be controlled. The three active elements shown in the figure are the anode, cathode, and gate. Although they may differ in outward appearance, all SCRs operate in the same way. The SCR acts like a very high-resistance rectifier in both forward and reverse directions without requiring a gate signal. However, when the correct gate signal is applied, the SCR conducts only in the forward direction, the same as any conventional rectifier. To test an SCR, you connect an ohmmeter between the anode and cathode, as shown in figure 2-12. Start the test at $R \times 10,000$ and reduce the value gradually. The SCR under test should show a very high resistance, regardless of the ohmmeter polarity. The anode, which is connected to the positive lead of the ohmmeter, must now be shorted to the gate. This will cause the SCR to conduct; as a result, a low-resistance reading will be indicated on the ohmmeter. Removing the anode-to-gate short will not stop the SCR from conducting; but removing either of the ohmmeter leads will cause the SCR to stop conducting — the resistance reading will then return to its previous high value. Some SCRs will not operate when you connect an ohmmeter. This is because the ohmmeter does not supply enough current. However, most of the SCRs in Navy equipment can be tested by the ohmmeter method. If an SCR is sensitive, the $R \times 1$ scale may supply too much current to the device and damage it. Therefore, try testing it on the higher resistance scales.

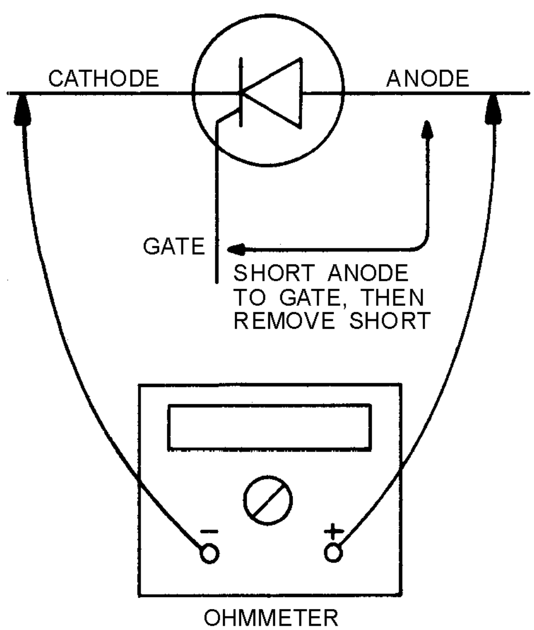

Figure 2-12.—Testing an SCR with an ohmmeter.

Q-15. When testing an SCR with an ohmmeter, the SCR will conduct if what two elements are shorted together?

TRIAC

Triac is General Electric's trade name for a silicon, gate-controlled, full-wave, ac switch, as shown in figure 2-13. The device is designed to switch from a blocking state to a conducting state for either polarity of applied voltages and with either positive or negative gate triggering. Like a conventional SCR, the Triac is an excellent solid-state device for controlling current flow. You can make the Triac conduct by using the same method used for an SCR, but the Triac has the advantage of being able to conduct equally well in either the forward or reverse direction.

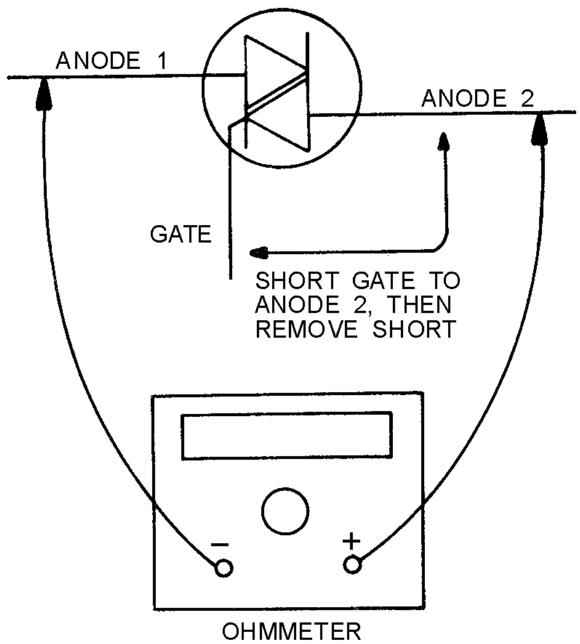

Figure 2-13.—Testing a Triac with an ohmmeter.

To test the Triac with an ohmmeter (R × 1 scale), you connect the ohmmeter's negative lead to anode 1 and the positive lead to anode 2, as shown in figure 2-13. The ohmmeter should indicate a very high resistance. Short the gate to anode 2; then remove it. The resistance reading should drop to a low value and remain low until either of the ohmmeter leads is disconnected from the Triac. This completes the first test.

The second test involves reversing the ohmmeter leads between anodes 1 and 2 so that the positive lead is connected to anode 1 and the negative lead is connected to anode 2. Again, short the gate to anode 2; then remove it. The resistance reading should again drop to a low value and remain low until either of the ohmmeter leads is disconnected.

Q-16. When a Triac is properly gated, what is/are the direction(s) of current flow between anodes 1 and 2?

UNIJUNCTION TRANSISTORS (UJTs)

The unijunction transistor (UJT), shown in figure 2-14, is a solid-state, three-terminal semiconductor that exhibits stable open-circuit, negative-resistance characteristics. These characteristics enable the UJT to serve as an excellent oscillator. Testing a UJT is a relatively easy task if you view the UJT as being a diode connected to the junction of two resistors, as shown in figure 2-15. With an ohmmeter, measure the resistance between base 1 and base 2; then reverse the ohmmeter leads and take another reading. Readings should show the same high resistance regardless of meter lead polarity. Connect the negative lead of the ohmmeter to the emitter of the UJT. Using the positive lead, measure the resistance from the emitter to base 1 and then from the emitter to base 2. Both readings should indicate high resistances that are approximately equal to each other. Disconnect the negative lead from the emitter and connect the positive lead to it. Using the negative lead, measure the resistance from the emitter to base 1 and then from the emitter to base 2. Both readings should indicate low resistances approximately equal to each other.

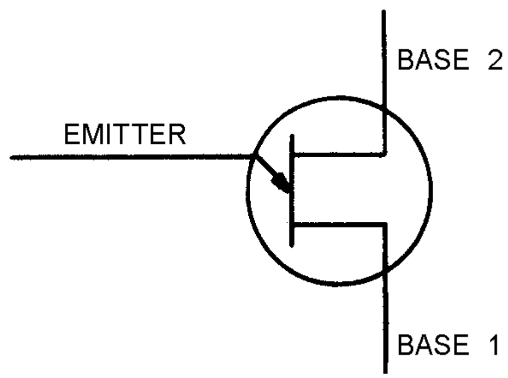

Figure 2-14.—Unijunction transistor.

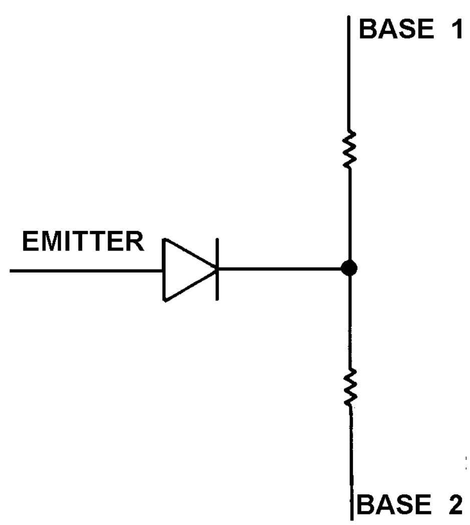

Figure 2-15.—Unijunction transistor equivalent circuit.

JUNCTION FIELD-EFFECT TRANSISTOR (JFET) TESTS

The junction field-effect transistor (JFET) has circuit applications similar to those of a vacuum tube. The JFET has a voltage-responsive characteristic with a high input impedance. Two types of JFETs that you should become familiar with are the junction p-channel and the junction n-channel types, as shown in figure 2-16. Their equivalent circuits are shown in figures 2-17 and 2-18, respectively. The only difference in your testing of these two types of JFETs involves the polarity of the meter leads.

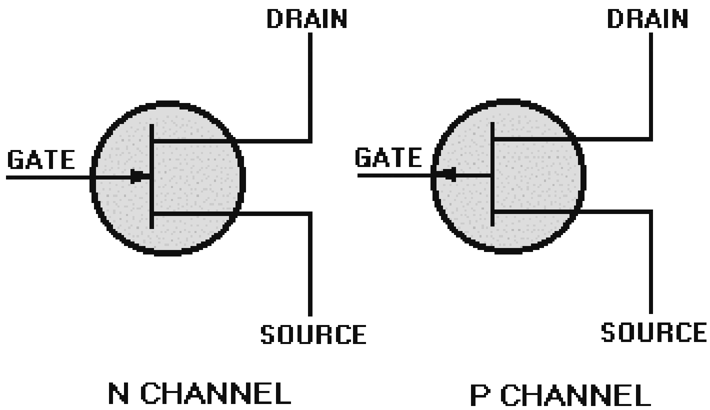

Figure 2-16.—Junction FETs.

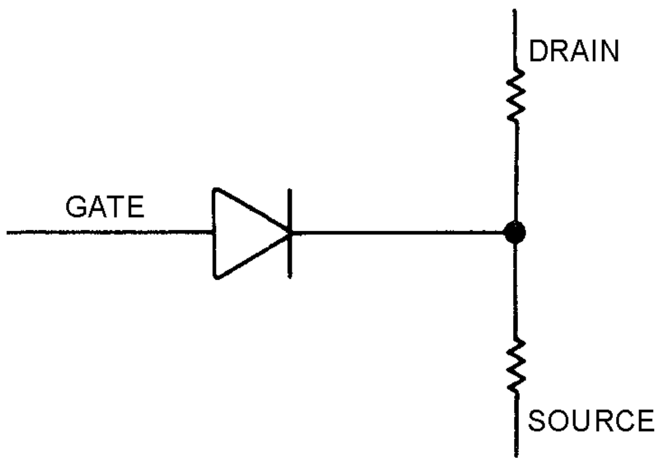

Figure 2-17.—N-channel JFET equivalent circuit.

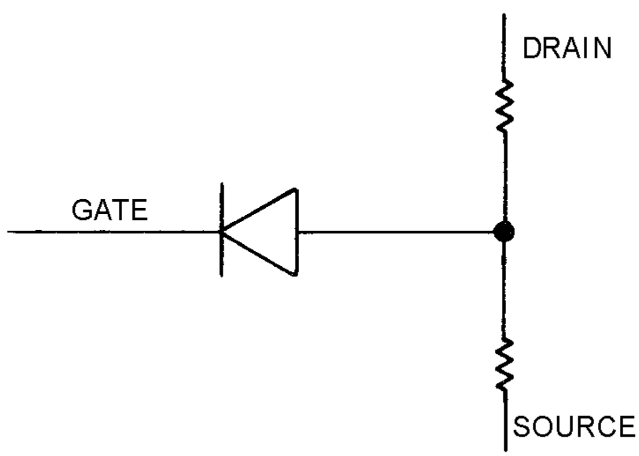

Figure 2-18.—P-channel JFET equivalent circuit.

N-Channel Test

Using an ohmmeter set to the R $\times$ 100 scale, measure the resistance between the drain and the source; then reverse the ohmmeter leads and take another reading. Both readings should be equal (in the 100- to 10,000-ohm range), regardless of the meter lead polarity. Connect the positive meter lead to the gate. Using the negative lead, measure the resistance between the gate and the drain; then measure the resistance between the gate and the source. Both readings should indicate a low resistance and be approximately the same. Disconnect the positive lead from the gate and connect the negative lead to the gate. Using the positive lead, measure the resistance between the gate to the drain; then measure the resistance between the gate and the source. Both readings should show infinity.

P-Channel Test

Using an ohmmeter set to the R $\times$ 100 scale, measure the resistance between the drain and the source; then reverse the ohmmeter leads and take another reading. Both readings should be the same (100 to 10,000 ohms), regardless of meter lead polarity. Next, connect the positive meter lead to the gate. Using the negative lead, measure the resistance between the gate and the drain; then measure it between the gate and the source. Both readings should show infinity. Disconnect the positive lead from the gate and connect the negative lead to the gate. Using the positive lead, measure the resistance between the gate and the drain; then measure it between the gate and the source. Both readings should indicate a low resistance and be approximately equal.

MOSFET TESTING

Another type of semiconductor you should become familiar with is the metal oxide semiconductor field-effect transistor (MOSFET), as shown in figures 2-19 and 2-20. You must be extremely careful when working with MOSFETs because of their high degree of sensitivity to static voltages. As previously mentioned in this chapter, the soldering iron should be grounded. A metal plate should be placed on the workbench and grounded to the ship's hull through a 250-kilohm to 1-megohm resistor. You should also wear a bracelet with an attached ground strap and ground yourself to the ship's hull through a 250-kilohm to 1-megohm resistor. You should not allow a MOSFET to come into contact with your clothing, plastics, or cellophane-type materials. A vacuum plunger (solder sucker) must not be used because of the high electrostatic charges it can generate. Solder removal by wicking is recommended. It is also good practice to wrap MOSFETs in metal foil when they are out of a circuit. To ensure MOSFET safety under test, use a portable volt-ohm-milliammeter (vom) to make MOSFET resistance measurements. **A vtvm must never be used in testing MOSFETs.** You must be aware that while you are testing a MOSFET, you are grounded to the ship's hull or station's ground. Use of a vtvm would cause a definite safety hazard because of the 115-volt, 60-hertz power input. When the resistance measurements are complete and the MOSFET is properly stored, unground both the plate on the workbench and yourself. You will understand MOSFET testing better if you visualize it as equivalent to a circuit using diodes and resistors, as shown in figures 2-21 and 2-22.

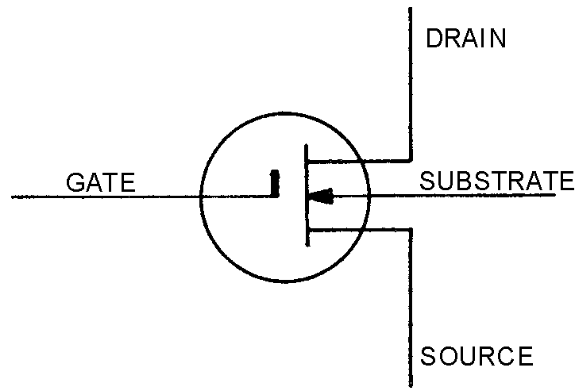

Figure 2-19.—MOSFET (depletion/enhancement type).

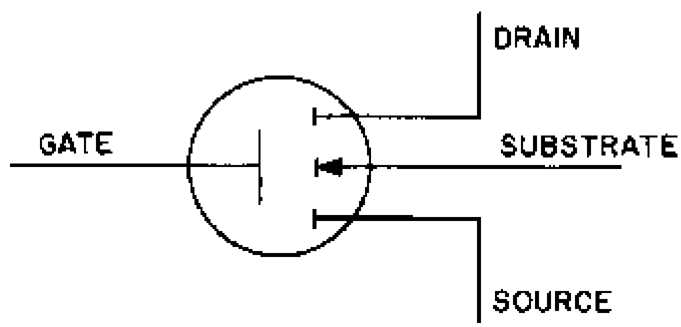

Figure 2-20.—MOSFET (enhancement type).

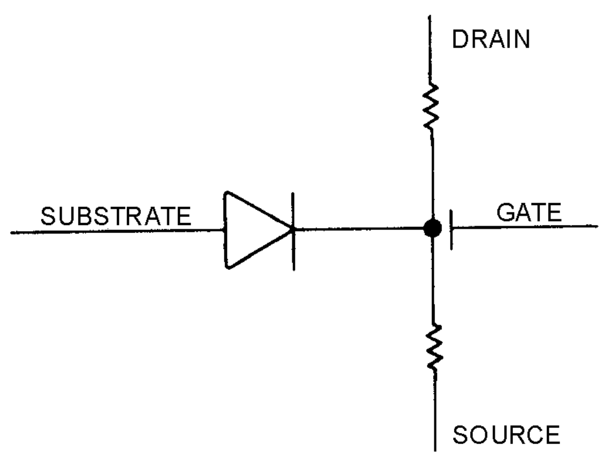

Figure 2-21.—MOSFET (depletion/enhancement type) equivalent circuit.

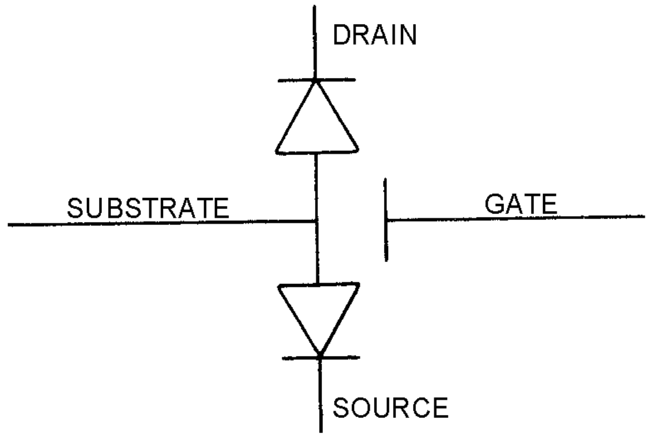

Figure 2-22.—MOSFET (enhancement type) equivalent circuit.

Q-17. Why is it not advisable to use a solder sucker when working on MOSFETs?

MOSFET (Depletion/Enhancement Type) Test

Using an ohmmeter set to the R × 100 scale, measure the resistance between the MOSFET drain and the source; then reverse the ohmmeter leads and take another reading. The readings should be equal, regardless of meter lead polarity. Connect the positive lead of the ohmmeter to the gate. Using the negative lead, measure the resistance between the gate and the drain and between the gate and the source. Both readings should show infinity. Disconnect the positive lead from the gate and connect the negative lead to the gate. Using the positive lead, measure the resistance between the gate and the drain; then measure it between the gate and the source. Both readings should show infinity. Disconnect the negative lead from the gate and connect it to the substrate. Using the positive lead, measure the resistance between the substrate and the drain and between the substrate and the source. Both of these readings should indicate infinity. Disconnect the negative lead from the substrate and connect the positive lead to the substrate. Using the negative lead, measure the resistance between the substrate and the drain and between the substrate and the source. Both readings should indicate a low resistance (about 1,000 ohms).

MOSFET (Enhancement Type) Test

Using an ohmmeter set to the R × 100 scale, measure the resistance between the drain and the source; then reverse the leads and take another reading between the drain and the source. Both readings should show infinity, regardless of meter lead polarity. Connect the positive lead of the ohmmeter to the gate. Using the negative lead, measure the resistance between the gate and the drain and then between the gate and the source. Both readings should indicate infinity. Disconnect the positive lead from the gate and connect the negative lead to the gate. Using the positive lead, measure the resistance between the gate and the drain and then between the gate and the source. Both readings should indicate infinity. Disconnect the negative lead from the gate and connect it to the substrate. Using the positive lead, measure the resistance between the substrate and the drain and between the substrate and the source. Both readings should indicate infinity. Disconnect the negative lead from the substrate and connect the positive lead to the substrate. Using the negative lead, measure the resistance between the substrate and the drain and between the substrate and the source. Both readings should indicate a low resistance (about 1,000 ohms).

INTEGRATED CIRCUIT (IC) TESTING

Integrated circuits (ICs) constitute an area of microelectronics in which many conventional electronic components are combined into high-density modules. Integrated circuits are made up of active and passive components, such as transistors, diodes, resistors, and capacitors. Because of their reduced size, use of integrated circuits can simplify otherwise complex systems by reducing the number of separate components and interconnections. Their use can also reduce power consumption, reduce the overall size of the equipment, and significantly lower the overall cost of the equipment concerned. Many types of integrated circuits are ESDS devices and should be handled accordingly.

Q-18. Name two advantages in using ICs.

Your IC testing approach needs to be somewhat different from that used in testing vacuum tubes and transistors. The physical construction of ICs is the prime reason for this different approach. The most frequently used ICs are manufactured with either 14 or 16 pins, all of which may be soldered directly into the circuit. It can be quite a job for you to unsolder all of these pins, even with the special tools designed for this purpose. After unsoldering all of the pins, you then have the tedious job of cleaning and straightening all of them.

Although there are a few IC testers on the market, their applications are limited. Just as transistors must be removed from the circuit to be tested, some ICs must also be removed to permit testing. When ICs are used in conjunction with external components, the external components should first be checked for proper operation. This is particularly important in linear applications where a change in the feedback of a circuit can adversely affect operating characteristics of the component.

Any linear (analog) IC is sensitive to its supply voltage. This is especially the case among ICs that use bias and control voltages in addition to a supply voltage. If you suspect a linear IC of being defective, all voltages coming to the IC must be checked against the manufacturer's circuit diagram of the equipment for any special notes on voltages. The manufacturer's handbook will also give you recommended voltages for any particular IC.

When troubleshooting ICs (either digital or linear), you cannot be concerned with what is going on inside the IC. You cannot take measurements or conduct repairs inside the IC. You should, therefore, consider the IC as a black box that performs a certain function. You can check the IC, however, to see that it can perform its design functions. After you check static voltages and external components associated with the IC, you can check it for dynamic operation. If it is intended to function as an amplifier, then you can measure and evaluate its input and output. If it is to function as a logic gate or combination of gates, it is relatively easy for you to determine what inputs are required to achieve a desired high or low output. Examples of different types of ICs are provided in figure 2-23.

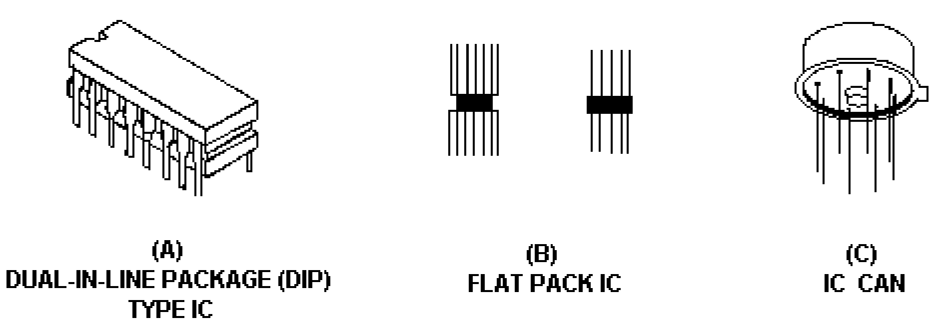

Figure 2-23.—Types of ICs.

Q-19. Why should you consider an IC as a black box?

Digital ICs are relatively easy for you to troubleshoot and test because of the limited numbers of input/output combinations involved. When using positive logic, the logic state of the inputs and outputs of a digital IC can only be represented as either a high (also referred to as a 1 state) or as a low (also referred to as a 0 state). In most digital circuitry, a high is a steady 5-vdc level, and a low is a 0-vdc level. You can readily determine the logic state of an IC by using high-input-impedence measuring devices, such as an oscilloscope. Because of the increased use of ICs in recent years, numerous pieces of test equipment have been designed specifically for testing ICs. They are described in the following paragraphs.

Q-20. What are the two logic states of an IC?

LOGIC CLIPS

Logic clips, as shown in figure 2-24, are spring-loaded devices that are designed to clip onto a dual-in-line package IC while the IC is mounted in its circuit. It is a simple device that usually has 16 light emitting diodes (LEDs) mounted at the top of the clips. The LEDs correspond to the individual pins of the IC, and any lit LED represents a high logic state. An unlit LED represents a low logic state. Logic clips require no external power connections, and they are small and lightweight. Their ability to simultaneously monitor the input and output of an IC is very helpful when you are troubleshooting a logic circuit.

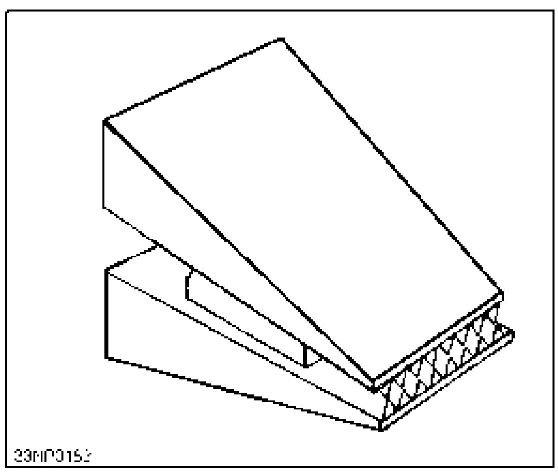

Figure 2-24.—Logic clip.

Q-21. A lighted LED on a logic clip represents what logic level?

LOGIC COMPARATORS

The logic comparator, as shown in figure 2-25, is designed to detect faulty, in-circuit-DIP ICs by comparing them with ICs that are known to be good (reference ICs). The reference IC is mounted on a small printed-circuit board and inserted into the logic comparator. You then attach the logic comparator to the IC under test by a test lead, which is connected to a spring-loaded device similar in appearance to a logic clip. The logic comparator is designed to detect differences in logic states of the reference IC and the IC being tested. If any difference in logic states does exist on any pin, an LED corresponding to the pin in question will be lit on the logic comparator. The logic comparator is powered by the IC under test.

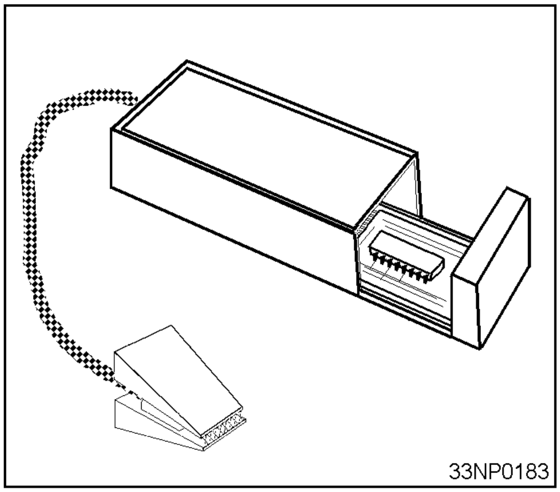

Figure 2-25.—Logic comparator.

Q-22. What does a lighted LED indicate on a logic comparator?

LOGIC PROBES

Logic probes, as shown in figure 2-26, are extremely simple and useful devices that are designed to help you detect the logic state of an IC. Logic probes can show you immediately whether a specific point in the circuit is **low, high, open,** or **pulsing**. A **high** is indicated when the light at the end of the probe is lit and a **low** is indicated when the light is extinguished. Some probes have a feature that detects and displays high-speed transient pulses as small as 5 nanoseconds wide. These probes are usually connected directly to the power supply of the device being tested, although a few also have internal batteries. Since most IC failures show up as a point in the circuit stuck either at a **high** or **low** level, these probes provide a quick, inexpensive way for you to locate the fault. They can also display that single, short-duration pulse that is so hard to catch on an oscilloscope. The ideal logic probe will have the following characteristics:

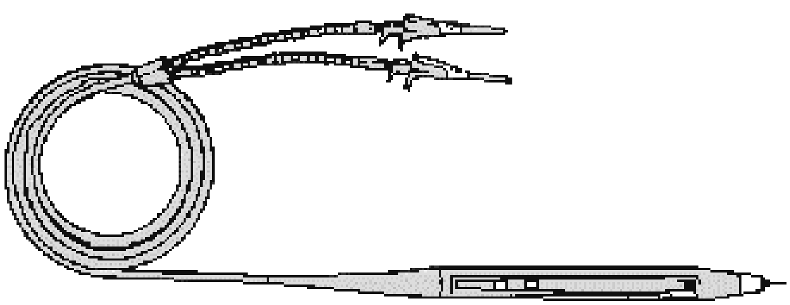

Figure 2-26.—Logic probe.

1. Be able to detect a steady logic level
2. Be able to detect a train of logic levels
3. Be able to detect an open circuit
4. Be able to detect a high-speed transient pulse

5. Have overvoltage protection

6. Be small, light, and easy to handle

7. Have a high input impedance to protect against circuit loading

Q-23. What is the purpose of a logic probe?

LOGIC PULSERS

Another extremely useful device for troubleshooting logic circuits is the logic pulser. It is similar in shape to the logic probe and is designed to inject a logic pulse into the circuit under test. Logic pursers are generally used in conjunction with a logic clip or a logic probe to help you trace the pulse through the circuit under test or verify the proper operation of an IC. Some logic pursers have a feature that allows a single pulse injection or a train of pulses. Logic pursers are usually powered by an external dc power supply but may, in some cases, be connected directly to the power supply of the device under test. View A of figure 2-27 shows a typical logic pulser. View B shows a logic pulser (right) used with a logic probe (left).

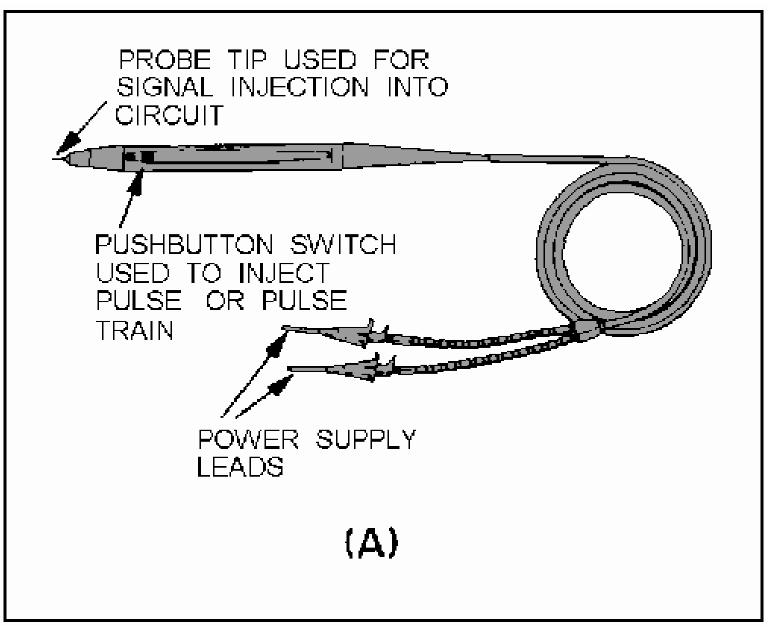

Figure 2-27A.—Logic pulser.

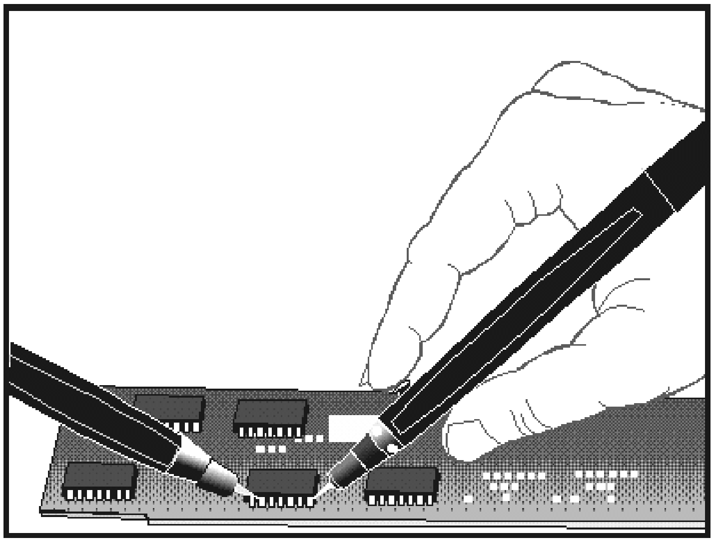

Figure 2-27B.—Logic pulser.

LOGIC ANALYZER

A relatively new device on the test equipment scene is the logic analyzer. A logic analyzer provides various functions that can assist you in maintenance, testing, and troubleshooting of equipment using digital circuitry. From your standpoint, they are extremely useful in performing timing analysis. Most logic analyzers have crt displays that can monitor up to 32 timing signals at the same time. A large percentage of today's digital equipment is designed with the logic analyzer in mind and have built-in status or bus lines for your convenience in monitoring multiple signals at the same time. When monitoring a bus line, you can readily determine, through visual displays, such things as the presence of master clock signals or sequential timing events.

BATTERY MEASUREMENTS

As a technician, you are primarily concerned with the *uses* of batteries; however, checking or testing of storage and dry cell batteries is an important part of your maintenance program. Proper preventive maintenance of batteries can significantly extend the useful life of a battery.

STORAGE BATTERIES

When you check a lead-acid type of storage battery for its condition of charge or discharge, you take a specific gravity reading of the electrolyte by using a hydrometer. A specific gravity reading between 1.275 and 1.300 indicates a full-charge condition and assures you that the battery is in good condition. A hydrometer reading of approximately 1.175 indicates a normal discharge condition, and a reading of approximately 1.250 indicates that the battery is half-discharged. Since the acids used in various batteries do not always have the same specific gravity and since electrode composition may differ, the hydrometer reading you obtain at the charged and discharged conditions will vary with the type of electrolyte and battery composition. A general rule for you to follow is not to discharge a battery more than 100 points (.100 specific gravity) before recharging.

Although readings of specific gravity are a reliable measure of the condition of a storage battery, cells that indicate normal may prove useless under load. This is usually caused by a high internal resistance. A load-voltage check of the cells with the use of a cell tester indicates the actual voltage charge held by each battery cell. Cell voltages should not differ by more than 0.15 volt for 6-volt or 12-volt batteries.

Use extreme caution whenever testing or working around lead-acid storage batteries. OPNAVINST 5100.23B emphatically states that you must wear eye protection devices at all times and that emergency eyewash facilities must be immediately adjacent to, or within 10 feet of, any eye-hazard area. Smoking and spark-producing tools or devices are also prohibited in enclosed spaces that contain lead-acid storage batteries. When charging, these batteries produce sufficient quantities of hydrogen to produce large explosions. **Lead-acid storage batteries should only be charged in well-ventilated spaces.**

Q-24. Emergency eyewash facilities must be located within what minimum number of feet of an eye-hazard area?

DRY BATTERIES

You must periodically check dry cell batteries that are used for test instruments and portable or field equipments for loss of power. For actual voltages of dry batteries, you should measure with a battery tester for a minimum acceptable voltage before installation. The TS-183/U series of battery testers incorporate a multiple-range voltmeter, battery-loading resistors, multiplier resistors, and a jack-switching arrangement that connects the load resistors across the voltmeter for a total of 32 different voltmeter-load resistor combinations. This type of tester permits you to complete a rapid and accurate measurement of battery potentials under load conditions, ranging in voltages from 1.5 to 180 volts. A data chart supplied with the battery tester provides information regarding the jack to be used and minimum acceptable voltages of various batteries used in Navy equipments.

Q-25. What is the advantage of using a battery test set versus a voltmeter to test batteries?

Table 2-2 shows general standards of tolerance for dry batteries. Whenever practical, dry cell batteries that are not in use should be stored in a refrigerated area to extend their shelf life.

Table 2-2.—Typical voltage Tolerances for Dry Cell Batteries

RATED VOLTAGE	MAX. VOLTAGE TOLERANCE
1 to 2	0.1
3 to 10	0.3
11 to 15	0.5
16 to 25	1.0
26 to 50	2.0
50 to 70	3.0
70 to 99	5.0

CARBON-ZINC AND ALKALINE BATTERIES

Carbon-zinc and alkaline cells are used primarily in portable test equipment, vom's, flashlights, some portable radios, and beacon equipment. The carbon-zinc cell provides 1.5 volts and holds its charge for approximately 1 year in normal service. The alkaline cell provides 1.2 volts and has about twice the stored energy of the carbon-zinc cell of the same size. It also has a longer life at a higher discharge rate than the carbon-zinc cell. You should discard both types of batteries at the first indication of weakness.

MERCURY CELLS

The storage life of a mercury cell varies but is generally classified as *long*. The working life of the cell is extremely long relative to other types of batteries; and it maintains its full rated voltage (1.34 volts) until just before it is ready to expire, at which point its voltage will drop off sharply. Recharging of mercury cells is possible, but is not recommended because the recharging cycle can vary from one cell to another; and, after being recharged, their operating lifetime is uncertain.

NICKEL-CADMIUM BATTERIES (NICAD)

Nickel-cadmium batteries have very high efficiency. They can be recharged hundreds of times; given the proper conditions, they may even be recharged thousands of times. They can be stored for a number of years with no significant loss of performance. After just a few charge and discharge cycles, NICAD cells can be recharged to the point that they are just as good as new batteries. Since they are sealed, they are maintenance free and can be installed in any position. There are two types of nickel-cadmium batteries — vented and nonvented. This description deals with the nonvented exclusively because a vented NICAD would have extremely limited application in a shipboard environment.

The voltage at the terminals of a NICAD will normally be between 1.25 and 1.30 volts in an open-circuit condition. This value will vary, of course, depending on the state of charge. If the charge has dropped to a low of 1.1 volts, the NICAD should be regarded as being completely discharged and should not be permitted to be discharged further. The majority of small NICADs are rated in milliampere hours; the large ones are rated in ampere hours. The small NICAD is the one the technician will almost always be concerned with.

Q-26. At what voltage is a NICAD battery considered to be fully discharged?

As a general rule, if the charging current is held to 10% of the milliampere-hour rating for the NICAD and the time of charge is held at 150% of the time required to establish its full milliampere-hour rating, you will encounter no difficulty in maintaining NICADs at their maximum charge. For example, you should charge a battery rated at 300 milliampere hours for 15 hours at 30 milliamperes. You can leave the battery on extended charge for years, provided the charge rate is lowered to less than 10% of the NICAD's milliampere rating.

You should never place a NICAD in your pocket, because metal objects (such as keys) can short the cell and cause extreme heat. Never dispose of a NICAD by fire, because it can explode. Never solder a connection directly to the cell, because the heat of an iron can damage it. Never overcharge a NICAD cell, because an accumulation of gases within its case can destroy it.

NICADs are also subject to a phenomenon commonly referred to as cell *memory*. If a NICAD is consistently discharged to a minor extent (for example, 30 minutes per day) and then recharged after each use, the useful capacity of the cell will eventually be reduced to that level. To keep this from happening, you should fully discharge (1.1 volts) NICADs on a regular basis. In fact, some maintenance requirement cards and calibration laboratory procedures require this periodic full discharge of equipment containing NICADs.

RF ATTENUATORS AND RESISTIVE LOAD TESTS

All rf attenuators, decade or step attenuators, decade resistors, and 50/75-ohm loads are clearly marked to show their attenuation factor or resistance. In the case of precision rf attenuators, they are usually marked to show their useful frequency ranges. They are all basically resistive devices and are designed for a multitude of applications. None of these devices are user-repairable; however, you should be aware of the different methods of determining whether or not they are functioning properly.

FIXED RF ATTENUATORS

Fixed rf attenuators (shown in fig. 2-28), such as the ones commonly found in power-measuring sets, are designed to provide a fixed-signal attenuation over a specific frequency range. Frequency ranges can be in excess of 30 gigahertz, and attenuation factors are typically in 1-, 3-, 6-, and 10-dB steps. Fixed attenuators can be connected in series to provide you with the desired attenuation. Most fixed rf attenuators are designed to handle only small amounts of rf power and are extremely susceptible to damage because of overloading. To test a fixed rf attenuator, you can either substitute it with a known good attenuator or perform basic measurements on the attenuator itself. With the rf substitution method, you connect an rf signal generator to a power meter and establish a suitable reference point on the meter by adjusting the power output of the signal generator. Once you establish the reference point, insert the rf attenuator between the signal generator and the power meter. You then determine the attenuation by noting the difference between the power meter reading and the initial reference point.

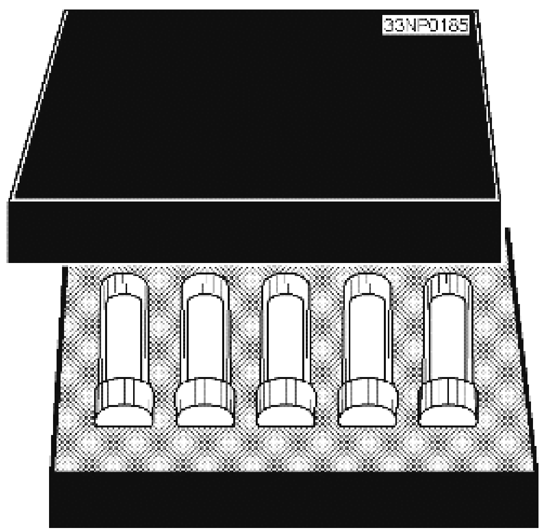

Figure 2-28.—Fixed attenuator set.

Q-27. What is the most common method of testing a fixed rf attenuator?

DECADE RESISTORS

Decade resistors (also referred to as decade boxes) typically are precision devices. Depending on the make and model of the decade resistor, it may be capable of providing you with a selection of resistors ranging in value from a small fraction of an ohm to hundreds of megohms. Decade resistors are commonly used in calibration laboratories and in engineering design applications. Like the fixed rf attenuator, most decade resistors are capable of handling only small amounts of current. They are very limited in respect to frequency capabilities and are commonly used in dc-circuit applications. You may encounter specific equipment that requires the use of a decade resistor in performing your maintenance tests or alignments. To test a decade resistor, you can connect a standard multimeter or digital multimeter directly across its resistance terminals and read its resistance on the meter. This test will only indicate gross errors in the decade resistor such as an open or a badly damaged resistor. If you are performing a precision measurement or an alignment using a decade resistor and have any doubt as to its accuracy, you should submit it to your servicing calibration laboratory. Figure 2-29 shows a typical decade resistor.

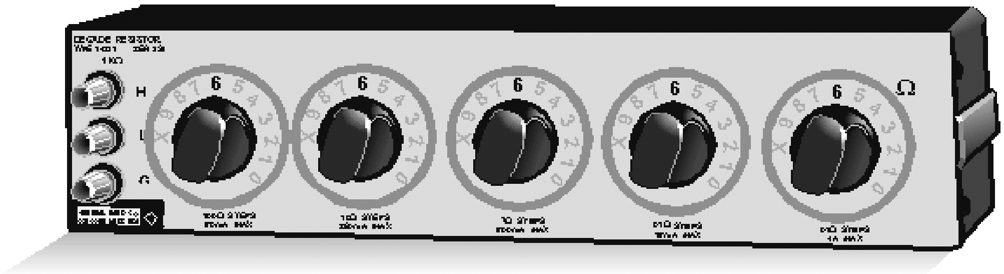

Figure 2-29.—Decade resistor.

DECADE (STEP) ATTENUATORS

Decade attenuators (also referred to as step attenuators) are common devices that may be designed as either a stand-alone piece of test equipment or as an integral part of an operational piece of electronic equipment. As the name implies, they are used to attenuate rf signals in incremental steps. Like the fixed rf attenuator, you can easily test them by using the rf substitution method, as previously described. Views A and B of figure 2-30 show two types of decade attenuators.

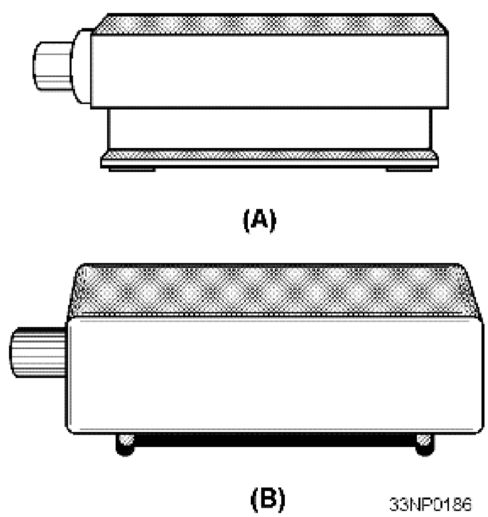

Figure 2-30.—Step attenuators.

50/75-OHM TERMINATIONS

Terminations of 50 and 75 ohms are designed as either feedthrough, impedance-matching devices, or as rf loading devices. They are precision resistors sealed in small plastic or metal enclosures and are designed to be mounted on various rf connectors. In the case of feedthrough terminations, they are designed with rf connectors at both ends, which allows the rf signal to pass through them. They are impedance-matching devices designed primarily to reduce the voltage standing-wave ratio (vswr) that is produced when two pieces of equipment with dissimilar impedances are connected together.

You can test a feedthrough termination by measuring the resistance between the center conductor and the shield of either rf connector with an ohmmeter. As mentioned above, some terminations are manufactured as loading devices that are designed to shunt an rf signal to ground. A perfectly matched termination can be compared to a transmitting antenna in that it absorbs all of the rf signal with only a small amount of power being reflected back to the transmitting device. When using a termination as a load, you should ensure that its wattage rating exceeds the power output of the equipment to which it is connected. You can also measure this type of termination by using a standard ohmmeter to read the resistance between the center conductor and the shield of the rf connector.

Q-28. What is the most common method of testing resistive terminations?

FIBER-OPTIC TESTING

Fiber optics are a relatively new type of transmission media. Figure 2-31 depicts a typical fiber-optic cable design. The core of the fiber-optic cable is the optical transmission path, which carries data from the optical transmitter to the optical receiver. The core is usually made of plastic, glass, or plastic-clad silica (PCS). Glass-core fibers are usually smaller in diameter than plastic or PCS cores. The major disadvantages of glass cores are that they have high attenuation (25 dB/km), require precision tools and connectors, and are extremely susceptible to mechanical damage. Plastic cores are typically more rugged than other types of cores, but their attenuation is high (35 dB/km). PCS cores are fairly rugged and have a relatively low attenuation (10 dB/km). A fiber-optic cable may consist of one fiber, multiples of single-optical fibers, or bundles of optical fibers. Fiber-optic cables are well suited for the transmission of high-speed data over relatively short distances. They are virtually immune to crosstalk or interference through inductance. (Interference is a characteristic of metallic cables.)

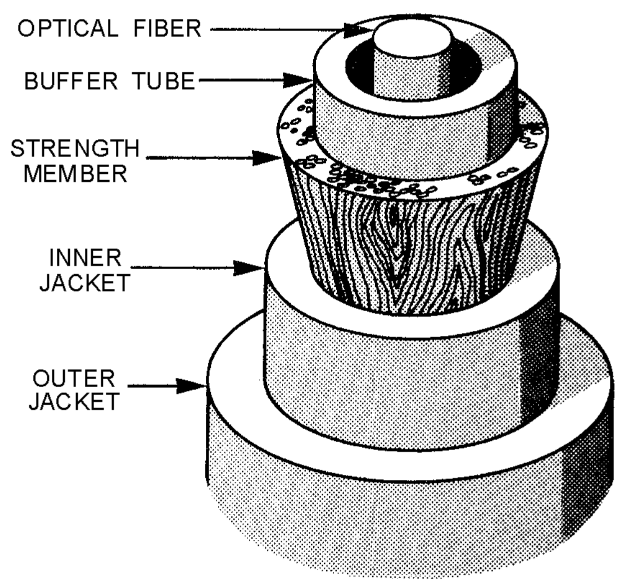

Figure 2-31.—Typical fiber-optic cable.

Testing techniques and the principles of measurement for fiber-optic and conventional cable are similar. For example, if both ends of the cable are exposed and can be used for testing, relatively unsophisticated equipment can be used to measure cable parameters, such as continuity and attenuation. This includes equipment such as optical multimeters and optical power meters (OPM). If only one cable end is available, then more sophisticated equipment such as an optical time-domain reflectometer (OTDR), is used. The following section lists and defines some common optical test equipment.

Q-29. What is the main disadvantage of using fiber-optic cables?

OPTICAL TIME-DOMAIN REFLECTOMETER (OTDR)

The portable optical time-domain reflectometer (OTDR) is used to check loss at each splice, at each connector, and of the entire system. Loss measurements are figured by using the same methods you would use for wire loss measurements. The OTDR injects a short, intense laser pulse into the fiber and monitors reflections caused by breaks, inclusions, microcracks, and discontinuities. Discontinuities appear as a spike on the OTDR display. The loss at the discontinuity point is directly related to the distance between the major pulse triggered by the laser and the spike. The manufacturer's manual provides you with conversion factors to figure actual losses and locations of the discontinuities.

OSCILLOSCOPE

An oscilloscope is used with an OTDR to provide visual evidence of fiber faults, connector and splice locations, and attenuation locations.

OPTICAL MULTIMETER

The optical multimeter measures light sources and light in cable and at the detector, fiber cable transmission loss, and connector splice loss. For cable transmission measurements, transmission through a short length of cable is compared with transmission through a known longer length.

OPTICAL OHMMETER

The optical ohmmeter measures the input versus the output of light in an optical fiber. It displays attenuation losses based on a comparison of known and unknown cable signals. It can be used in manufacturing, connecting, and installing cable. It is as simple to use as a digital voltmeter.

OPTICAL POWER METER

The optical power meter measures current by converting light power from plug-in units, such as light emitting diodes, into electrical current. In some models, the readout is in power units, watts. In other models, the readout is in absolute power levels and attenuation. Some units operate with a variety of power sensors for conventional coaxial and waveguide systems and fiber-optic systems.

RADIOMETER/PHOTOMETER

The radiometer/photometer measures light power in watts from dc to unlimited ac response. It uses plug-in sensor heads and, for low-light displays, it uses spectrometers and fiber-optic measurements.

AUTOMATIC TEST EQUIPMENT

Automatic Test Equipment (ATE) is test equipment designed to evaluate the operational performance of a piece of equipment or printed circuit board (pcb). ATE assists you in troubleshooting a fault to the defective component. Basically, ATEs are state-of-the-art, computer devices in which software programs are specifically tailored to meet the requirements of the device being tested.

The AN/USM-465 Portable Service Processor (psp), shown in figure 2-32, is the Navy's standard ATE for testing digital pcb's.

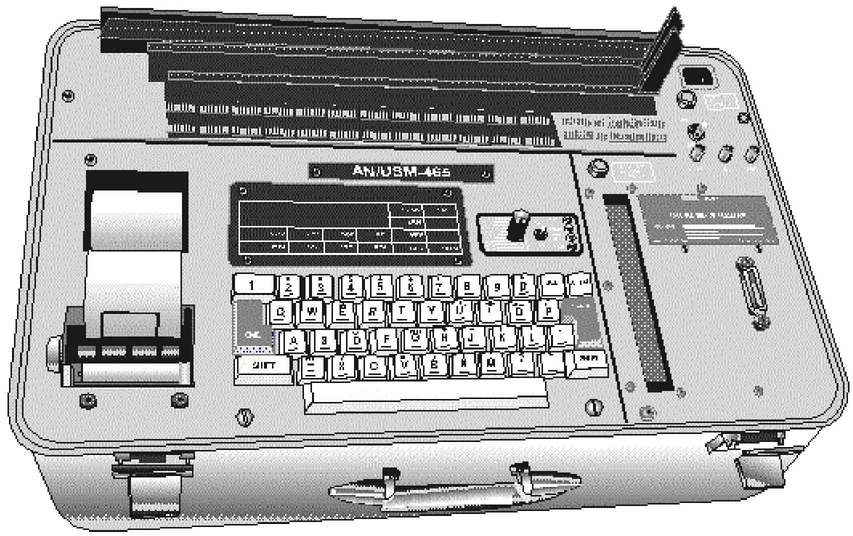

Figure 2-32.—AN/USM-465 Portable Service Processor.

The AN/USM-465 is part of the Support and Test Equipment Engineering Program (STEEP). It provides on-site screen testing and fault isolation of digital pcb's and modules. The psp is presently available on most ships and shore intermediate maintenance activities (SIMA) with Mini/Micro maintenance stations (2M). Psp's come with maintenance-assist modules (spare parts kit) and diagnostic kits.

The psp is easy to use. You have a choice of three pcb connectors (located on the top panel of the test set) into which you insert the pcb being tested. The software program, which is provided on magnetic tape cartridges, is then loaded into the test set. The test set automatically tests the pcb by applying input signals to the appropriate pins while monitoring the output signal for a correct indication. An LED display will give you a pass or fail indication. If a pcb fails the operational test, the psp tells you (via LED display) what troubleshooting steps must be taken. The psp uses a *guided probe* fault isolation technique that tells you what test points to check on the faulty pcb. The software program guides you from the faulty output backwards toward the input until the fault is located. The probe is a standard 10 megohm, 10 to 1 oscilloscope probe. The guided probe circuitry and software is also unique because it is capable of locating faults within feedback loops and can sense when you have placed the probe at an incorrect test point.

An interesting advantage is that if the psp itself fails, the faulty board inside the psp can be identified by the test set's own capability. After you replace the faulty pcb with a good one from the spare parts kit, you can use the psp to identify the faulty component on its own pcb.

HUNTRON TRACKER 2000

The Huntron Tracker 2000, shown in figure 2-33, is a versatile troubleshooting tool used to statically test resistors, capacitors, inductors, diodes, transistors, multiple-component circuits, and integrated circuits. Its built-in features eliminate the use of multiple pieces of test equipment. These features and its lightweight portability make the 2000 a widely used tool for troubleshooting.

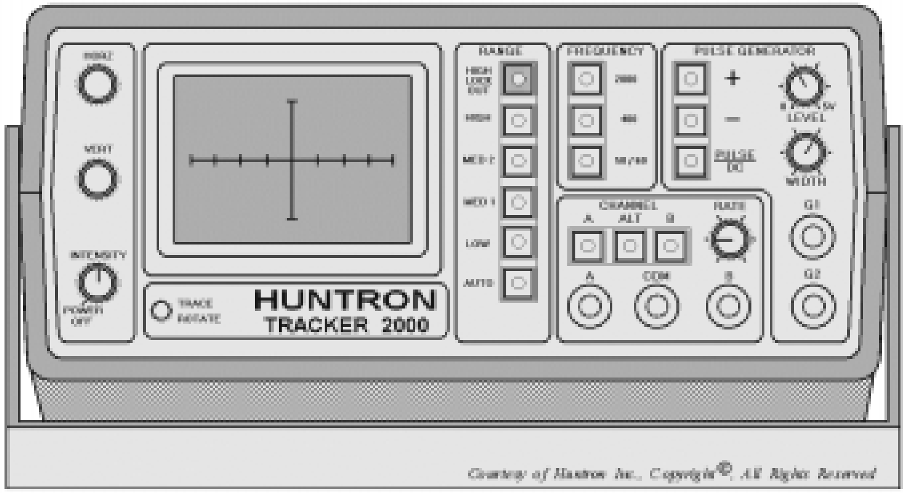

Figure 2-33.—Huntron Tracker 2000.

We recommend you review setup and operating procedures discussed in NEETS Module 16, *Introduction to Test Equipment*, NAVEDTRA B72-16-00-95, before continuing with this chapter. Since the 2000 was covered in depth in module 16, we will cover only the most common troubleshooting procedures and provide a few troubleshooting tips.

Q-30. What two features make the Huntron Tracker 2000 a widely used troubleshooting tool?

The Huntron Tracker 2000 has the following features:

- Multiple-test signal frequencies (2000 Hz, 400 Hz, and 50/60 Hz).
- Four impedance ranges (low, medium 1, medium 2, high).
- Automatic range scanning.
- Range control: High Lockout.
- Rate-of-channel alteration and/or range scanning is/are adjustable.
- Dual-polarity pulse generator for dynamic testing of three terminal devices.
- LED indicators for all functions.
- Dual-channel capability for easy comparison.
- Large CRT display with easy-to-operate controls.

CAUTION

The device to be tested must have all power turned off, and have all high voltage capacitors discharged before connecting the Tracker 2000 to the device.

Testing Components by Comparison

Testing components by comparison is the most preferred method for troubleshooting. The ALT (alternate) mode setup is the most commonly used mode for this method. This mode allows the technician to compare a known good component to a suspect component. This is accomplished by connecting channel A to a known good device, channel B to the device under test, and a common test lead to COM as illustrated in figure 2-34. Select the ALT button, and the 2000 will alternately display the signature of the known good device and the device under test. By examining the signature differences, you can detect a defective component. Figure 2-35 is a typical example of the CRT display on the 2000 while testing the base to emitter on a good transistor. Figure 2-36 illustrates a defective transistor under the same test setup. Note that in the low range, the transistor appears to be good. Sometimes component defects are more obvious in one range than another, so is a suspect device appears normal for one range, try the other ranges.

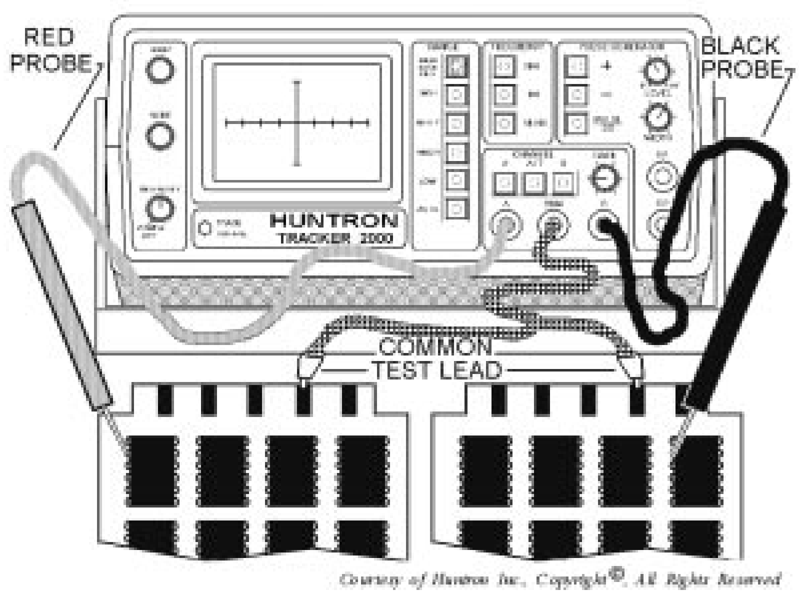

Figure 2-34.—Alternate mode setup.

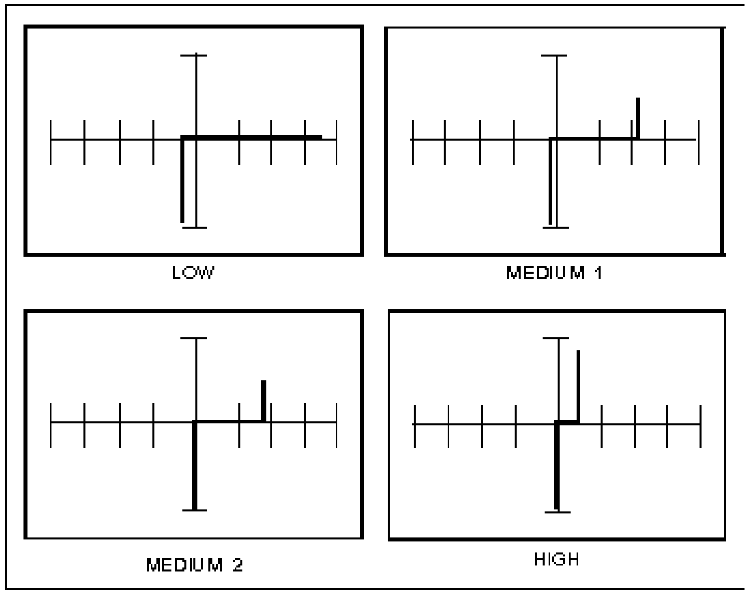

Figure 2-35.—Signatures between base-emitter of a good transistor.

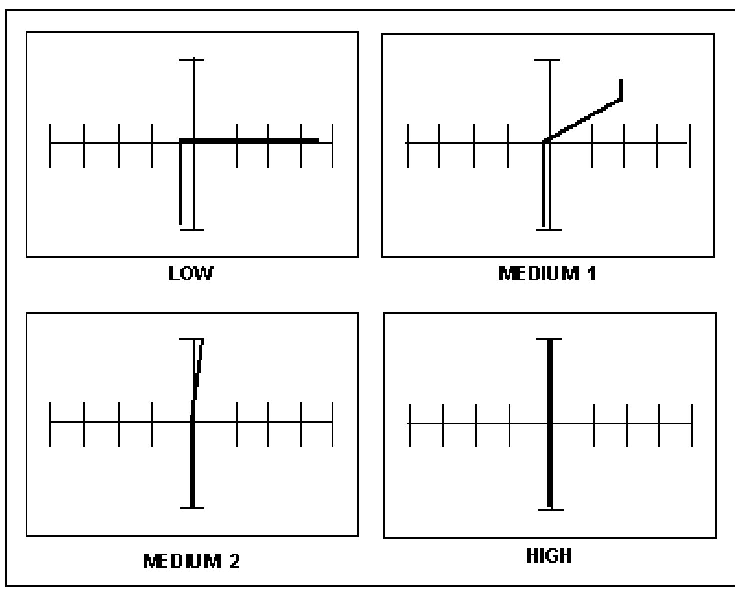

Figure 2-36.—Signatures between base-emitter of a defective transistor.

Q-31. What is the most preferred method of troubleshooting?

Q-32. Why is it recommended to use more than one range while troubleshooting a device?

Troubleshooting Tips

When you are testing individual components in a circuit, a parallel resistor or diode of similar value may cause a defective component to appear good. Therefore, you should, in most cases, electrically isolate the suspected component from the circuit while testing individual components. The best way to do this is to desolder all but one lead on the suspected component.

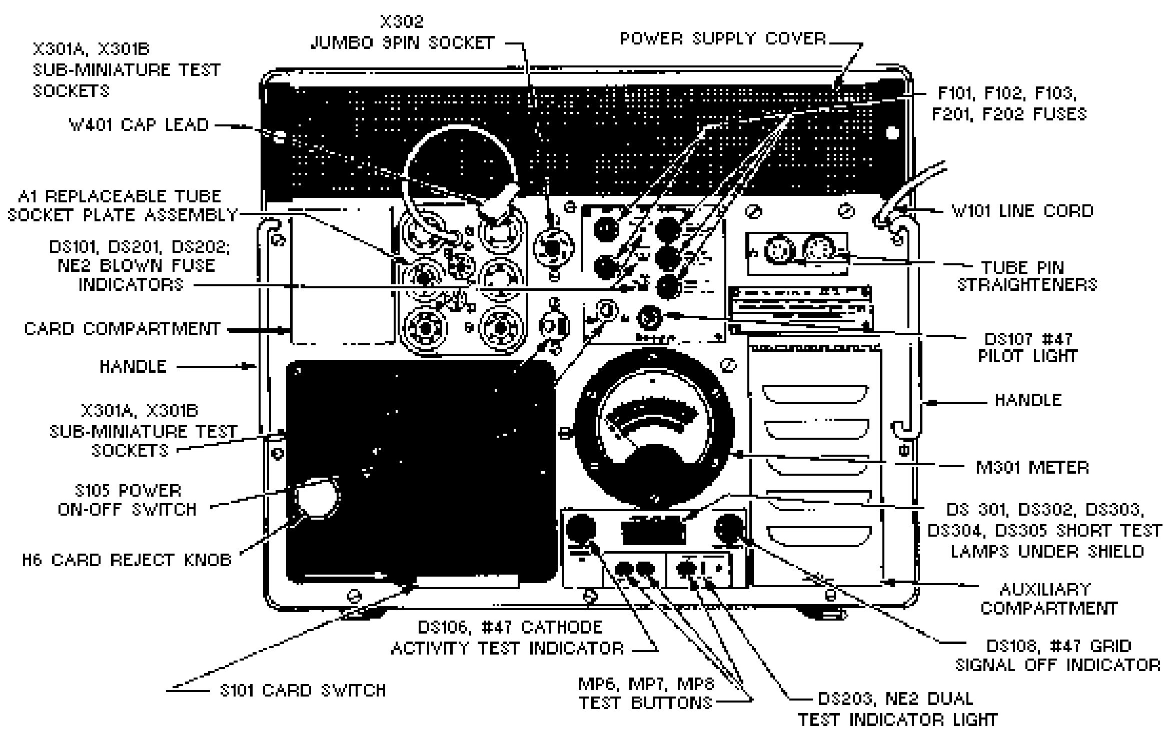
Q-33. When you are testing individual components in a circuit, what may cause a defective component to appear good?

You should be aware that devices made by different manufacturers may appear to have slightly different signatures. This is normal, especially with digital integrated circuits, and does not necessarily indicate a failed device. When this occurs, the best way to verify this is to compare the outputs of the device under test with the equipment specifications to ensure the signals are adequate for proper equipment operation.

SUMMARY

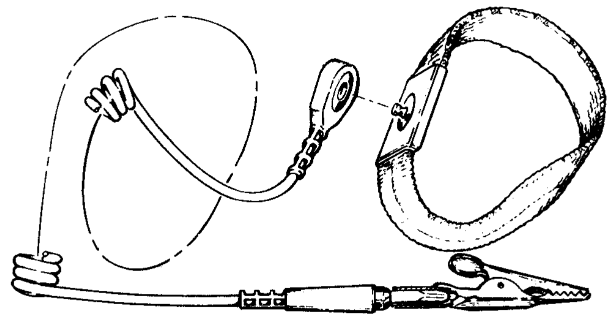
The information that follows summarizes the important points of this chapter.

ELECTRON TUBES are usually tested for **SHORTS, TRANSCONDUCTANCE**, and the presence of GAS. Several different types of tubes (i.e., twt's, magnetrons, and klystrons) are normally tested in-circuit.



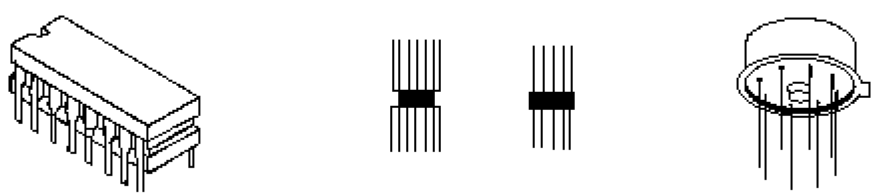
Most **TRANSISTORS** can be tested by measuring the forward-to-back resistance of their junctions using a standard ohmmeter. The resistance scale of the ohmmeter must be carefully selected to ensure that the current rating of the transistor is not exceeded.

ESD-SENSITIVE DEVICES are components that require special handling. Some of the more sensitive devices can be damaged by static charges as small as 35 volts.



Most **DIODES** and **MOSFETs** can be tested by measuring the forward-to-back resistance of their junctions using a standard ohmmeter. MOSFETS, however, are classed as ESD-sensitive devices; and care should be exercised when handling or testing them.

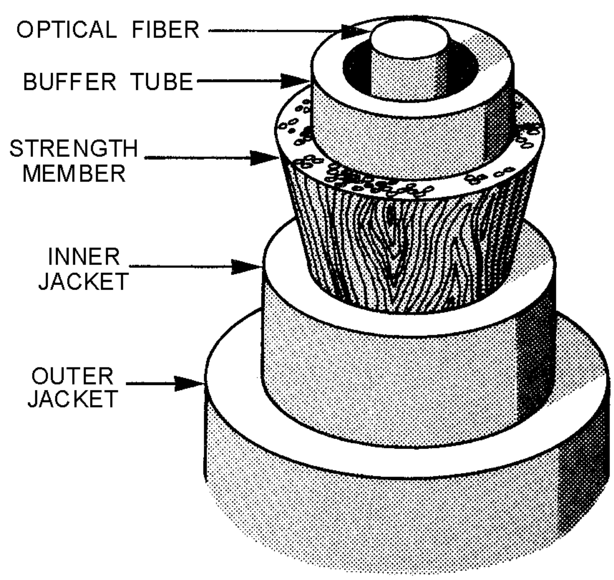
INTEGRATED CIRCUITS (ICs) have revolutionized the electronics industry. They are rugged, compact, and inexpensive. There is a wide assortment of equipment on the market designed for testing ICs.



BATTERIES are common to a large number of both electronic test equipment and operational equipment. You should be familiar with the different types of batteries, their test requirements, and the safety precautions to be followed.

RF ATTENUATORS and **RESISTIVE LOADS** are common devices that are widely used for attenuating rf signals and impedance matching. Resistive loads can be tested with a standard ohmmeter, and rf attenuators are normally tested through the rf substitution method.

FIBER-OPTIC CABLES are used primarily for the transmission of high-speed data over short distances. Their construction and theory of operation require that they be tested with a light source, usually a laser beam. There is a wide assortment of test equipment designed specifically for testing fiber-optic cables.



AUTOMATIC TEST EQUIPMENT (ATE) is test equipment designed to evaluate the operational performance of a piece of equipment or printed circuit board (pcb).

The **HUNTRON TRACKER 2000** is a versatile troubleshooting tool commonly used for statically testing resistors, capacitors, inductors, diodes, transistors, multiple-component circuits, and integrated circuits.

ANSWERS TO QUESTIONS Q1. THROUGH Q33.

A-1. Lack of adequate storage space.

A-2. Open filaments.

A-3. Testing the tube in its circuit.

A-4. In their circuit.

A-5. Restore it to serviceable condition by operating it temporarily at reduced beam voltage.

A-6. Correct gain figure.

A-7. Rugged design.

A-8. Sensitive to heat and minor overloads.

A-9. Any range setting that produces a current flow through the transistor that exceeds 1 milliamp (usually R x 1 range).

A-10. 3,500 to 4,000 volts.

A-11. 35 volts.

A-12. For your own safety.

A-13. Voltages and resistances.

A-14. Greater than 10 to 1.

A-15. Gate and anode.

A-16. Current is allowed to flow in either direction.

A-17. Solder suckers create an electrostatic charge capable of damaging a MOSFET.

A-18. Low power consumption, compact size, and lower cost.

A-19. ICs cannot be repaired. All you need to test is output versus input.

A-20. A "1" or "0."

A-21. A "1" state.

A-22. A difference in logic states between the reference IC and the IC under test.

A-23. They provide you with a visual indication of the logic state at any point you choose in the circuit.

A-24. 10 feet.

A-25. A battery test set will test batteries under load conditions.

A-26. At 1.1 volts.

A-27. Rf substitution method.

A-28. Reading their resistances with a standard ohmmeter.

A-29. High attenuation.

A-30. It eliminates the need for multiple pieces of test equipment and it is lightweight and portable.

A-31. Testing components by comparison.

A-32. Some defective devices may appear to be good in certain ranges.

A-33. A parallel resistor or diode of similar value.

CHAPTER 3

QUANTITATIVE MEASUREMENTS

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to do the following:

1. Explain the purposes and benefits of performing quantitative measurements.
2. Identify the various methods of performing impedance measurements.
3. Identify the various methods of performing power measurements.
4. Identify the various methods of performing frequency measurements.

INTRODUCTION TO QUANTITATIVE MEASUREMENTS

You have already studied the basics of performing electronics measurements and how to determine if a component is or is not functioning properly. This chapter will cover techniques used in measurements of specific impedance, frequency, and power. These measurements are extremely important to you in evaluating the performance of a piece of electronic equipment.

IMPEDANCE MEASUREMENTS

Impedance measurements are often used during routine test procedures. Impedance-measuring equipment, such as impedance bridges, are mainly used in determining the capacitance and inductance of component parts. However, the values of combined circuit constants also may be obtained and used in direct calculations of impedance. An impedance measurement effectively totals the inductive and capacitive reactance together with the resistance in a circuit. In addition, impedance measurements are useful in testing and analyzing antenna and transmission line performance and for determining the figure of merit (Q) of electrical parts and resonant circuits.

Q meters are impedance-measuring instruments that determine the ratio of reactance to resistance of capacitors or inductors and resistors. Details of Q meters and impedance bridges as well as a number of other methods of measuring circuit impedance are described in the following paragraphs. Also discussed are methods of measuring the impedance of antennas and transmission lines.

BRIDGE METHODS

Bridges are among the most accurate types of measuring devices used in the measurement of impedance. In addition, bridges are also used to measure dc resistance, capacitance, and inductance. Certain types of bridges are more suitable for measuring a specific characteristic, such as capacitance or inductance. Basic schematics for the various bridge circuits are shown in figure 3-1. The bridge circuits shown are similar in that they usually contain two branches in the measuring circuit, two branches in the comparing circuit, a detector circuit, and a power circuit, as shown in figure 3-2. The bridge shown in figure 3-2 is actually the dc Wheatstone bridge; however, the general principles of circuit operation for ac remain the same.

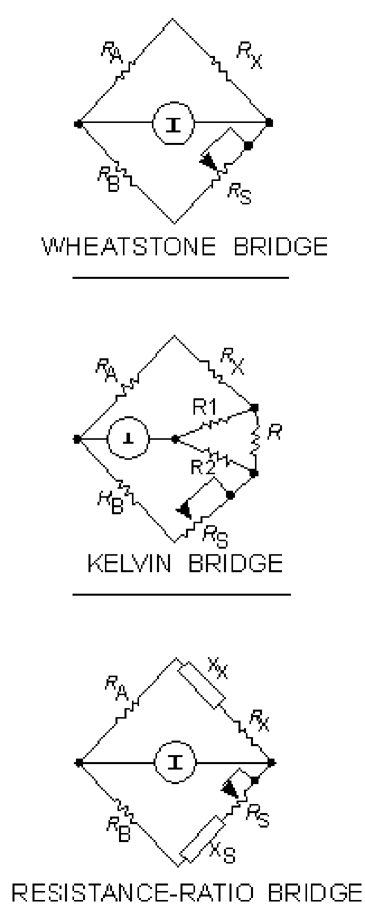

Figure 3-1.—Basic bridge circuits.

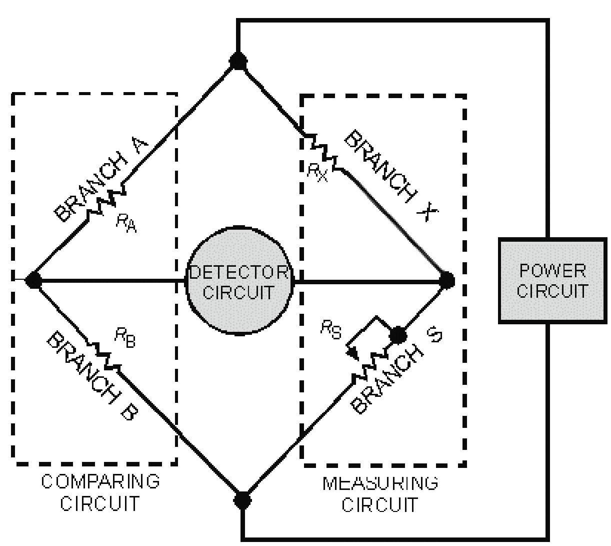

Figure 3-2.—Typical bridge circuit configuration.

The comparing circuit contains branches A and B and has provisions for changing the ratios of the branches with respect to each other, which enables various measuring ranges to be obtained. Comparison of figures 3-1 and 3-2 shows that either or both branches of the comparing circuit do not necessarily contain resistors alone. Branch B of the Hay bridge, containing C_B and R_B in series connection, provides a striking contrast with the parallel connection of C_B and R_B of the Maxwell bridge.

The measuring circuit in figure 3-2 also contains two branches. The resistance, capacitance, or inductance to be measured is connected to branch X of the bridge-measuring circuit. The subscript X is also used in figure 3-1 to designate the circuit parameters involved in computing the values of various electronic parts. Branch S contains the variable control used to bring the bridge into a balanced condition. A potentiometer is used for this purpose in most bridge equipment, because it offers a wide range of smoothly variable current changes within the measuring circuit.

The third arm of the bridge is the detector circuit. The detector circuit may use a galvanometer for sensitive measurements that require high accuracy. In the case of bridges using ac as the power source, the galvanometer must be adapted for use in an ac circuit. In many practical bridge circuits using ac to operate the bridge, an electron-ray indicating tube is used to indicate the balanced condition by opening and closing the shadow area of the tube. Headsets are also used for audible balance detection, but this method reduces the accuracy obtainable with the bridge.

Switches are used in bridge circuits to control the application of operating power to the bridge and to complete the detector circuit. Frequently, the two switching functions are combined into a single key, called a bridge key, so that the operating power is applied to the bridge prior to the detector circuit. This sequence reduces the effects of inductance and capacitance during the process of measurement.

The most unfavorable condition for making a measurement occurs when the resistance, capacitance, or inductance to be measured is completely unknown. In these cases, the galvanometer cannot be protected by setting the bridge arms for approximate balance. To reduce the possibility of damage to the galvanometer, you should use an adjustable shunt circuit across the meter terminals. As the bridge is brought closer to the balanced condition, the resistance of the shunt can be increased; when the bridge is in balance, the meter shunt can be removed to obtain maximum detector sensitivity.

Bridges designed specifically for capacitance measurements provide a dc source of potential for electrolytic capacitors. The electrolytic capacitors often require the application of dc polarizing voltages in order for them to exhibit the same capacitance values and dissipation factors that would be obtained in actual circuit operation. The dc power supply and meter circuits used for this purpose are connected so that there is no interference with the normal operation of the capacitance-measuring bridge circuit. The dissipation factor of the capacitor may be obtained while the capacitor is polarized. In figure 3-2, the signal voltage in the A and B branches of the bridge will be divided in proportion to the resistance ratios of its component members, R_A and R_B, for the range of values selected. The same signal voltage is impressed across the branches S and X of the bridge. The variable control, R_S, is rotated to change the current flowing through the S and X branches of the bridge. When the voltage drop across branch S is equal to the voltage drop across branch A, the voltage drop across branch X is equal to the voltage drop across branch B. At this time the potentials across the detector circuit are the same, resulting in no current flow through the detector circuit and an indication of zero-current flow. The bridge is balanced at these settings of its operating controls, and they cannot be placed at any other setting and still maintain this balanced condition.

The ability of the bridge circuit to detect a *balanced* condition is not impaired by the length or the leads connecting the bridge to the electronic part to be measured. However, the *accuracy* of the measurement is not always acceptable, because the connecting leads exhibit capacitive and inductive characteristics, which must be subtracted from the total measurement. Hence, the most serious errors affecting accuracy of a measurement are because of the connecting leads.

Stray wiring capacitance and inductance, called residuals, that exist between the branches of the bridge also cause errors. The resistance-ratio bridge, for example, is redrawn in figure 3-3 to show the interfering residuals that must be eliminated or taken into consideration. Fortunately, these residuals can be reduced to negligible proportions by shielding and grounding. A method of shielding and grounding a bridge circuit to reduce the effects of interfering residuals is through the use of a Wagner ground, as shown in figure 3-4. Observe that with switch S in position Y, the balanced condition can be obtained by adjusting Z^1 and Z^2. With switch S in position X, the normal method of balancing the bridge applies. You should be able to reach a point where there is no deflection of the meter movement for either switch position (X or Y) by alternately adjusting Z^1 and Z^2 when the switch is at position Y and by adjusting R_S when the switch is at position X. Under these conditions, point 1 is at ground potential; and the residuals at points 2, 3, and 4 are effectively eliminated from the bridge. The main disadvantage of the Wagner ground is that two balances must be made for each measurement. One is to balance the bridge, and the other is to balance the Wagner ground. Both adjustments are interacting because R_A and R_B are common to both switch positions X and Y.

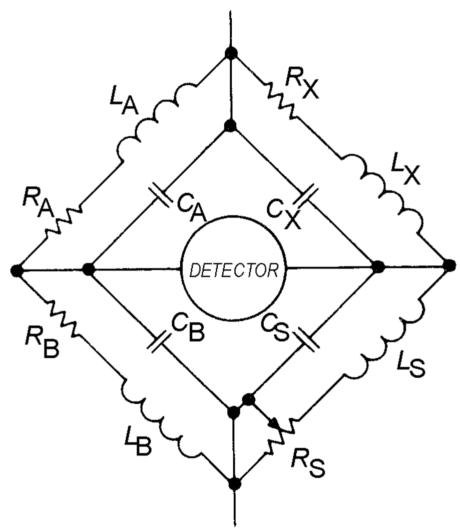

Figure 3-3.—Resistance-ratio bridge residual elements.

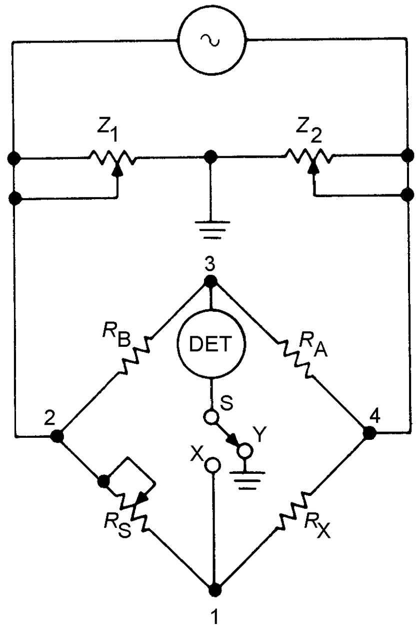

Figure 3-4.—Wagner ground.

Many bridge instruments provide terminals for external excitation potentials; however, do not use a voltage in excess of that needed to obtain reliable indicator deflection because the resistivity of electronic parts varies with heat, which is a function of the power applied.

Q-1. What conditions must be met in order to balance a bridge circuit?

Q-2. When you are measuring a component using a bridge, what is the most common cause of inaccurate measurements?

Wheatstone Bridge

The Wheatstone bridge, shown in figure 3-1, is often used to measure resistance. These instruments are usually portable because they require only a small, dc source to power the bridge, which is easily obtained from flashlight batteries. In those cases where an external supply voltage is desirable for the operation of the bridge, use the minimum voltage that will give a reliable indication by the galvanometer. Increasing the supply voltage any further results in uncompensated thermal variations and decreased bridge accuracy. If greater bridge sensitivity is needed, use a galvanometer with greater sensitivity.

A number of other considerations are involved in the choice of a galvanometer. For example, the galvanometer should not be subjected to false or erratic indications because of external magnetic fields. This requirement dictates the choice of a shielded meter mechanism. It is also desirable to use a critically dampened meter movement to ensure decisive movement of the meter pointer during conditions of bridge unbalance. Thermal agitation sometimes produces voltages that interfere with the balancing of the bridge. For this reason, the Wheatstone bridge usually includes a polarity-reversing switch in the detector circuit. When a measurement is required, note the reading for both positive and negative indications, and figure the average of both readings. With the exception of inaccuracies introduced by thermal variations (caused by excessive supply voltages), the accuracy of the Wheatstone bridge is, otherwise, independent of the value of supply voltages. The units used in calibrating the galvanometer are unimportant to the accuracy of the bridge, since a 0 indication is desired at the balanced condition.

Resistance values ranging from 1 ohm to 1 megohm can be measured with an accuracy of approximately 0.1%. However, difficulties are encountered when very high and very low resistances are measured. Resistances less than 1 ohm are difficult to measure accurately because of uncertainty arising from the contact resistance present between the resistor to be measured and the binding posts of the bridge. Measurement of resistances greater than 1 megohm becomes difficult because of two factors: (1) The ratio of standard resistances R_A and R_B involve a ratio on the order of 1,000 to 1, and (2) the voltage applied to the bridge must be substantially increased to obtain definite galvanometer action. The result is that an increase in the supply voltage increases the power dissipation (heat) of the bridge resistors. The change in resistance R_B, because of the heat, is sufficient to produce an appreciable error. A Kelvin bridge is recommended for measuring resistances lower than 1 ohm. An electronic multimeter is recommended for the indicating device in bridges used for the measurement of very high resistances.

One of the most elementary precautions concerning the use of a bridge, when measuring low resistance, is to tighten the binding posts securely so that the contact resistance between the binding posts and the resistance to be measured is minimum. Leakage paths between the resistor leads along the outside surface of the resistor body must be avoided when resistances greater than 0.1 megohm are measured. Search for defective solder joints or broken strands in stranded wire leads; these defects can cause erratic galvanometer indications. In those cases where wire leads must be used to reach from the resistance under test to the bridge terminals, measure the ohmic value of those leads prior to further measurements.

Q-3. How does the supply voltage affect the accuracy of Wheatstone bridge measurements?

Kelvin Bridge

It is often necessary to make rapid measurements of low resistances, such as samples of wire or low values of meter shunt resistors. A frequently used instrument that is capable of good precision is the Kelvin bridge, shown in figure 3-1. Note the similarity between this and the Wheatstone bridge. Two additional resistances, R1 and R2, are connected in series and shunted across resistance R, which is the circuit resistance existing between the standard and unknown resistances, R_S and R_X, respectively. In performing the adjustment for balance, you must make the ratio of R1 to R2 equal to the ratio of R_A to R_B. When this is done, the unknown resistance can be computed in the same manner as that for the Wheatstone bridge, because resistance R is effectively eliminated.

In using a Kelvin bridge, you must follow precautions similar to those given for the Wheatstone bridge. A rheostat is usually placed in series with the battery so that bridge current can be conveniently limited to the maximum current allowable. This value of current, which affects the sensitivity of the bridge, is determined by the largest amount of heat that can be sustained by the bridge resistances without causing a change in their values. All connections must be firm and electrically perfect so that contact resistances are held to a minimum. The use of point and knife-edge clamps is recommended. Commercially manufactured Kelvin bridges have accuracies of approximately 2% for resistance ranges from 0.001 ohm to 25 ohms.

Q-4. Kelvin bridges are well suited for what type of measurements?

Resistance-Ratio Bridge

The resistance-ratio bridge, shown in figure 3-1, may be used to measure capacitance, inductance, or resistance so long as the electronic part to be measured is compared with a similar standard. The measurement of the value of a capacitor must be made in terms of another capacitor of known characteristics, termed the STANDARD CAPACITOR. The same requirement is necessary for an inductance measurement. The standard of comparison is designated as X_X, and the losses of the standard are represented as R_X. If you experience difficulty in obtaining a balanced bridge condition, insert additional resistance in series with branch S of the bridge. This adjustment becomes necessary because the *Q* of the unknown capacitor or inductor in branch X is higher than the comparable *Q* of the standard in branch S.

Schering Bridge

The Schering bridge, shown in figure 3-1, is a commonly used type of bridge for the measurement of capacitors and dielectric losses. The *Q* of a capacitor is defined as the reciprocal of the dissipation factor, which is the ratio of the capacitor's dielectric constant to its conductivity at a given frequency. Accordingly, capacitor *Q* is determined by the frequency used to conduct the measurement and the value of the capacitor, C_B, required to obtain bridge balance. The accuracy of this type of bridge is excellent, about 2% for dissipation factors ranging from 0.00002 to 0.6. Typical accuracies for capacitive reactances in the range of 100 picofarads to 1 microfarad are 0.2%.

Hay Bridge

The Hay bridge, shown in figure 3-1, is used for the measurement of inductance and the *Q* of the inductor. It is interesting to note that this type of bridge measures inductance by comparing it with a standard capacitor of known characteristics. This arrangement provides the advantage of a wide measurement range with the minimum use of electronic parts as comparison standards. A typical range of values that can be measured with the Hay bridge is from 1 microhenry to 100 henries. The accuracy of the measurements made with this bridge is about 2%. The frequency used in conducting the inductance measurement must be taken into account because of the series reactance of capacitor C_B. The loss factor of the inductor under test is balanced in terms of the *Q* of the inductor. The Hay bridge, then, is used for measurement of inductances having a *Q* greater than 10. For instance, a *Q* of 10 gives a calibration error of 1%, whereas a *Q* of 30 gives a calibration error of 0.1%.

Q-5. When you are testing an inductor with a Hay bridge, the characteristics of the inductor are compared with what type of device?

Maxwell Bridge

The Maxwell bridge, shown in figure 3-1, is used for the measurement of inductance and inductive *Q*. This bridge is similar to the Hay bridge because it also measures inductance by comparison with a standard capacitor of known characteristics. Notice, in particular, that capacitor C_B is connected in parallel with resistor R_B. In connection with this difference, the requirement of an accurately known frequency is removed. This bridge circuit is employed for measuring the inductance of inductors having large losses; i.e., low *Q*. The range of this type of instrument is much greater than that of the Hay bridge; values ranging from 1 microhenry to 1,000 henries are measurable, with an error of only 2%.

VECTOR BRIDGES

The basic bridges described up to now determined the resistive and reactive components of the unknown impedance; however, the vector bridge indicates the magnitude and phase angle. Typically, vector bridges require two null readings. Consider the basic bridge circuit of figure 3-5. The magnitude of the unknown impedance (Z_X) is determined by the voltages applied across *R* and Z_X and to the bases of emitter followers Q1 and Q2, which bias the balanced rectifiers, CR1 and CR2. Resistors *A* and *B* are equal in value. When *R* is adjusted to equal Z_X, the voltages between points 1 and 2 and between points 1 and 4 are equal in magnitude, and the vtvm will indicate 0 volts.

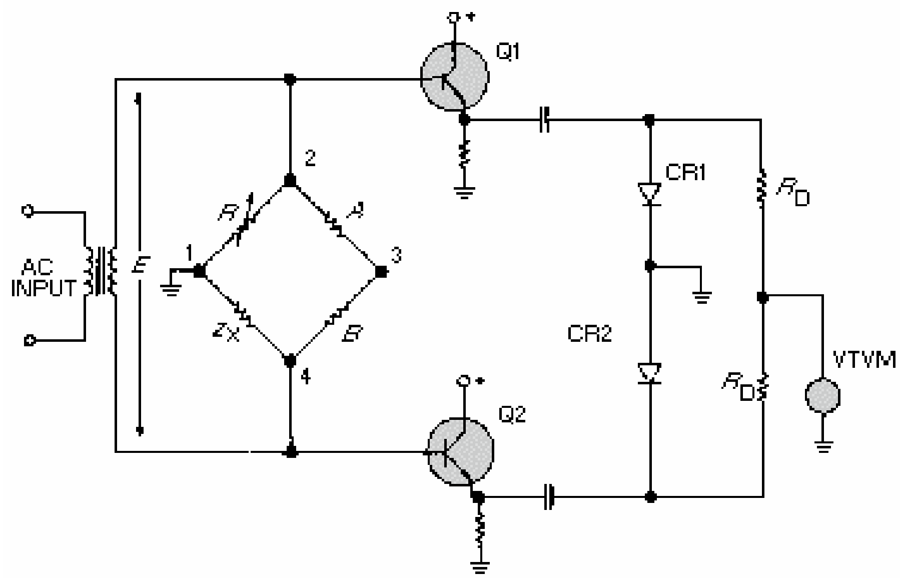

Figure 3-5.—Typical vector-bridge configuration (amplitude).

The absolute value of Z_X is determined from the dial calibration of *R*. Without altering the amplitude balance, you reconnect the external circuits as shown in figure 3-6. Note that the voltage between points 1 and 3 is being compared to the voltage between points 1 and 2. Potentiometer *R*, calibrated in degrees, is adjusted for a null indication on the vtvm; and the phase angle is read directly. If Z_X is purely resistive, the voltage between points *1* and *3* will be zero and the setting of *R* will be 0 volts. If Z_X is purely reactive (capacitive or inductive), the setting of *R* will be at maximum voltage. For phase angles between 0º and 90º, the scale of *R* may be calibrated directly in degrees. The sign of the phase angle can be determined by changing the signal frequency slightly and observing the change in impedance. The presence of harmonics in the signal input will severely hamper the measurements. If a pure frequency source is not available, suitable low-pass filters will have to be employed in the output leads from the bridge.

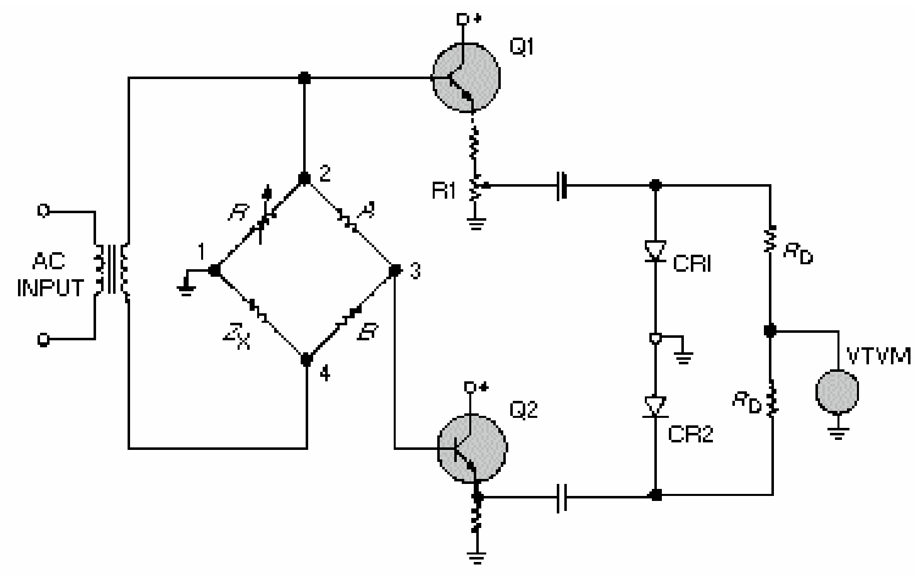

Figure 3-6.—Typical vector-bridge configuration (phase).

CONSTANT-CURRENT, IMPEDANCE-MEASURING TECHNIQUE

This technique employs an oscillator circuit and a vtvm, as shown in figure 3-7.

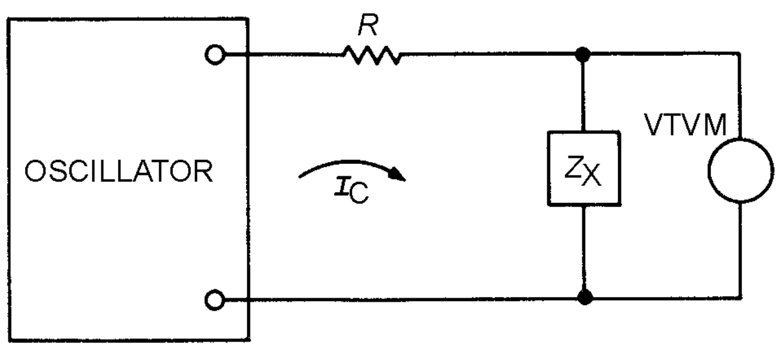

Figure 3-7.—Constant-current, impedance-measuring method.

A large value of resistance, R, is selected so that I_C is virtually independent of the range of Z_X to be measured. Thus, $I_C Z_X$ represents the value of voltage measured by the vtvm. If R is chosen so that the voltage drop across Z_X corresponds to a full-scale reading on the vtvm, a direct reading impedance meter is realized. For example, assume that the audio oscillator open-circuit voltage is 10 volts (rms) and that the full-scale reading of the vtvm is 0.05 volt. If you want to measure Z_X values ranging up to a maximum of 5,000 ohms, you should use a 1-megohm resistor for R. This will result in a full-scale, 0.05-volt deflection. An oscillator that does not produce harmonics should be used.

IMPEDANCE-ANGLE METER

Like vector bridges, impedance-angle meters determine an unknown impedance in terms of magnitude and phase angle. However, a non-bridge technique is used. The simplified circuit of a commercial instrument is shown in figure 3-8. With switches S1 and S2 at the BAL position, the variable standard resistor, *R*, is adjusted until the balanced rectifier outputs of Q1 and Q2 are equal (indicated by a null in the deflection of the voltmeter connected between the emitters of Q3 and Q4). The dial setting of *R* gives the value of Z_X. For phase angle determination, the circuit is switched to CAL and the input voltage is adjusted for full-scale voltmeter deflection. The circuit is then switched to PHASE; thus, the paralleled outputs of Q1 and Q2 are applied to rectifier CR1 only. With S2 in the phase position, there is no input to the base of Q4. If *Z* is purely resistive, the outputs of Q1 and Q2 cancel, and the voltmeter indicates zero deflection. For a complex impedance, the base of Q3 will be unbalanced with respect to the base of Q4; and the voltmeter deflection, calibrated in degrees, determines the phase angle of the unknown impedance. Typical commercial impedance angle meters, operating at 2 MHz, are accurate to within 4% for impedances of from 10 to 500 ohms.

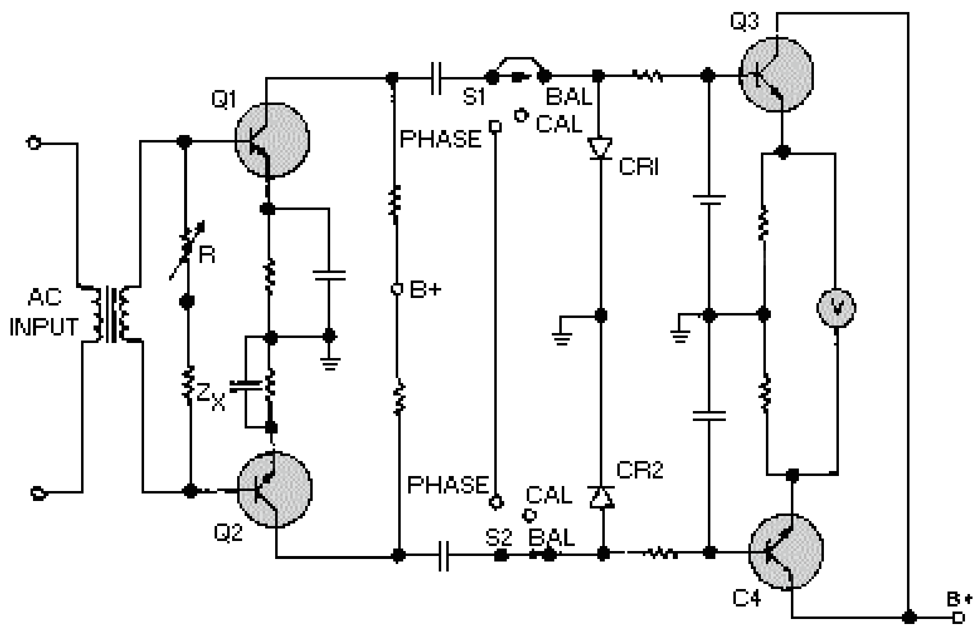

Figure 3-8.—Impedance-angle meter.

Q-6. What do impedance-angle meters and vector bridges have in common?

IMPEDANCE TESTING OF ANTENNAS AND TRANSMISSION LINES

The amount of current that flows in an antenna is one of the most important factors affecting the performance of transmitter equipment. As much of the rf energy generated as possible must be efficiently transferred to the antennas to secure the maximum radiated power from a transmitter. Also, for best reception, maximum transfer of energy from the antenna to the receiver must occur. Efficient transmission and reception conditions prevail whenever the transmitter (or receiver) is properly matched to the transmission line and the transmission line is properly matched to the antenna. Normally, performance tests concerning impedance match consist primarily of taking standing-wave measurements. In certain instances, it may be found that a change in antenna impedance has resulted in an undesirably high standing-wave ratio. This could be the result of a new antenna installation or an interfering structure near the antenna that influences antenna characteristics.

In practice, the antenna-matching network is varied to match the new antenna characteristics, since the transmission line is designed to match equipment impedance. This can best be done by making a series of standing-wave-ratio checks and antenna-matching adjustments until an acceptable standing-wave ratio is reached. It must be understood, however, that the antenna does have a specific impedance at a given frequency and that, when necessary, this impedance may be determined by use of an rf impedance bridge.

A typical rf impedance bridge circuit is shown in figure 3-9. Rf impedance bridge measurements require an rf signal generator, a detector, and a calibrated rf bridge to determine transmission-line impedance. The bridge compares the parallel resistive-reactive combination with the series combination and can typically measure impedance over a frequency range of 500 kHz to 60 MHz.

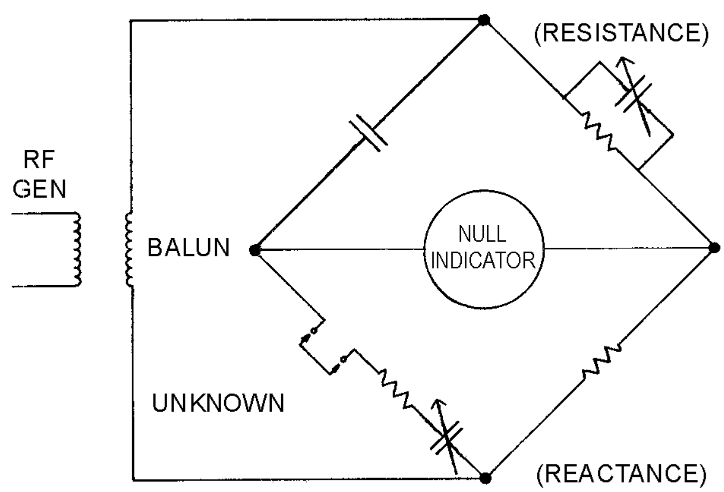

Figure 3-9.—Typical rf bridge.

Basically, the bridge is balanced with a known capacitance under short-circuit conditions. The unknown impedance is then inserted in lieu of the short bus, and the bridge is rebalanced. The difference between the known impedance under short-circuit conditions and the balance measurements obtained with the unknown impedance inserted in lieu of the short is the value of the unknown impedance.

Q-7. What is the result of an impedance mismatch between a receiver or transmitter and its transmission line or antenna?

POWER MEASUREMENTS

It is often necessary to check the input and output signal power levels of electronic equipment. The determination of dc power is computed by using a derivative of Ohm's law ($P = IE = I^2R = E^2/R$). However, the presence of a reactive component in ac circuits means that apparent power is being measured or calculated unless the rms voltage-current value is multiplied by a power factor to obtain true lower. The measurement of ac power is further complicated by the frequency limitations of various power meters. If there is no phase difference, ac power may be computed in the same manner as dc power by determining the average value of the product of the voltage and current. In practical ac circuits, the apparent power must be multiplied by the cosine of the phase angle between the voltage and current in order to compute true power.

In the repeated measurement of audio-frequency (af) power, you may use a normal power meter calibrated directly in watts. However, when reactive components of dissipative impedance introduce a phase angle, a device that is proportional to both the power factor and the apparent power must be used. Because power-level measurements are concerned with decibel units, a working knowledge of decibels is required for proper interpretation of power tests. The decibel is used to determine the ratio of power changes or to indicate the power level in a circuit with respect to either 0 or a standard reference level.

AF POWER

In the electrical transmission of speech or music, rapidly fluctuating amplitudes and frequencies are involved. The average power-level measurement and its variation rate depend on the signal characteristics and time interval over which this average is taken. Power measurements for af circuits are usually indicated in terms of decibels (dB), decibels referenced to 1 milliwatt (dBm), or volume units (vu). For example, the power gain of an amplifier can be expressed in dB; the power level of a sinusoidal signal compared to a 1-milliwatt reference is indicated in dBm; and the power level of a complex signal, such as voice, music, or multiplexed information, compared to a reference level of 1 milliwatt, is indicated in vu.

Q-8. What are the three units of measure most commonly used when referring to af power measurements?

DECIBEL METERS

A dB meter is a form of ac electronic voltmeter calibrated in dB's. These meters are useful for making measurements where direct indication in decibels is desired. However, remember that these are voltmeters, and power measurements are not meaningful unless the circuit impedance is known. When the dB meter is calibrated, a reference point, based on a specific power or value of voltage across a specified resistance, is selected to represent 0 dB. Many electronic voltmeters use a single dB scale based on 1 milliwatt into a 600-ohm load to represent 0 dBm. Based on this reference point, various voltage readings could be made on the low ac-voltage scale. The +dB numbers corresponding to voltage ratios that exist between successive ranges and the low ac range have been computed for each range. These numbers, shown on the front panel of the instrument, are added algebraically to each successive range reading to produce the correct value for the range. The term decibel does not, in itself, indicate power. It indicates a ratio or comparison between two power levels that permits you to calculate the power. Often, it is more desirable to express performance measurements in terms of decibels using a fixed power level as a reference. The original standard reference level was 6 milliwatts, but to simplify calculations a standard reference level of 1 milliwatt has been adopted.

Q-9. In reference to dB meters, 0 dBm represents 1 milliwatt into what value of load?

VOLUME UNIT METERS

The volume unit (vu) meter is used in audio equipment to indicate input power to a transmitter or to a transmission line. This type of meter has special characteristics, such as a standardized speed of pointer movement, speed of return, and calibration. The measurement of the average power level and its rate of variation with respect to time depends not only on the signal characteristics, but also on the time interval over which the average is being taken. Accordingly, the speed of response of the instrument used to measure average power is of particular concern. The unit of measurement is the volume unit (vu), which is numerically equal to the number of dB above or below the reference level of 1 milliwatt into a 600-ohm load (provided the standard instrument was calibrated under constant-amplitude, sine-wave conditions). A change of one vu is the same as a change of one decibel. Therefore, the vu value obtained represents averages of instantaneous power of speech or music obtained by an instrument having particular dynamic characteristics. The vu readings are equivalent to the power level in decibels only if the sinusoidal waveform is of constant amplitude.

Q-10. What is the main difference between a vu and a dB meter?

ELECTRODYNAMIC WATTMETER

The electrodynamic wattmeter is used to measure power taken from ac or dc power sources. The electrodynamic wattmeter, shown in figure 3-10, uses the reaction between the magnetic fields of two current-carrying coils (or sets of coils), one fixed and the other movable. When the current through the fixed-position field winding(s) is the same as current through the load and the current through the moving coil is proportional to the load voltage, then the instantaneous pointer deflection is proportional to the instantaneous power. Since the moving pointer cannot follow the rapid variations in torque because of its momentum, it assumes a deflection proportional to the average power. The dynamometer-type wattmeter automatically compensates for the power factor error of the circuit under test. It indicates only the instantaneous power resulting from in-phase values of current and voltage. With out-of-phase relationships, a current peak through the moving coil never occurs at the same instant as the voltage peak across the load, resulting in less pointer deflection than when the current and voltage are in phase. The simple meter shown in figure 3-10 is not compensated. When the load is disconnected, this meter will still indicate that power is being consumed in the circuit. This difficulty can be eliminated by incorporating two compensating windings, mounted with the primary fixed-coil current windings, as shown in figure 3-11. These stationary windings are used to produce a magnetic flux proportional to the current through the movable coil. As shown by the arrows, the currents through the primary movable coil and the compensating coil flow in opposite directions, producing a torque caused by the opposing magnetic fields. These opposing fields cancel. Hence, with the load removed from the circuit, the meter will indicate zero power through the load.

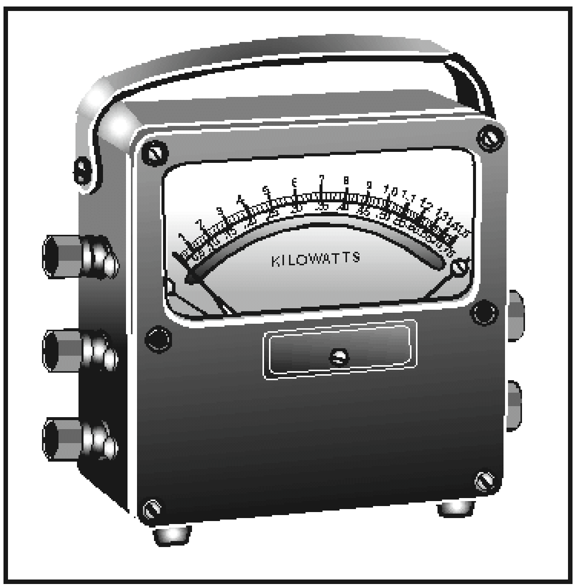

Figure 3-10.—Typical electrodynamic wattmeter.

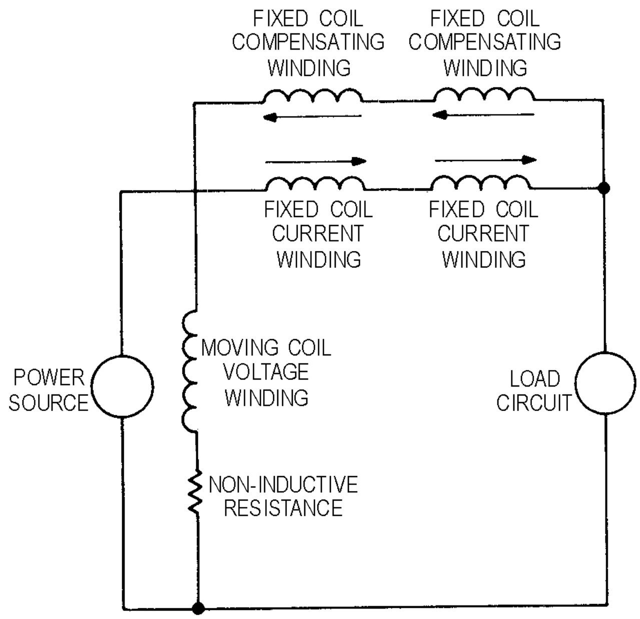

Figure 3-11.—Electrical equivalent of the compensated electrodynamic wattmeter.

Electrodynamic wattmeters are subject to errors arising from various factors, such as temperature and frequency characteristics and vibration. Heat through the control mechanism can cause the springs to lengthen and lose tension; as a result, deflection errors are produced. Figure 3-12 illustrates the mechanical equivalent of the electrodynamic wattmeter. Large currents within the circuit will also produce errors. Therefore, the maximum current range of electrodynamic wattmeters is normally restricted to about 20 amperes. When larger load currents are involved, a current transformer of suitable range is used in conjunction with the wattmeter. However, a current transformer cannot be used if the ac circuit under test contains a dc component.

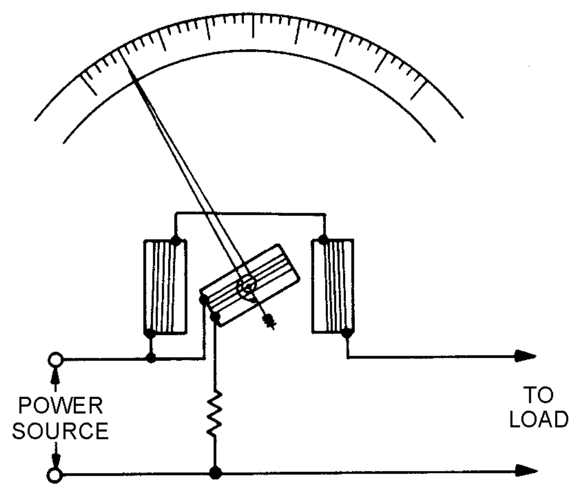

Figure 3-12.—Mechanical equivalent of the electrodynamic wattmeter.

The voltage range of wattmeters is generally limited to several hundred volts because of heat dissipation within the voltage circuit. However, the voltage range can be extended by using external voltage dividers. Wattmeters used as laboratory standards have an accuracy of 0.1%, high-grade portable wattmeters an accuracy of 0.2% to 0.25%, and high-grade switchboard wattmeters an accuracy of 1% of full-scale value. Because electrodynamic wattmeter errors increase with frequency, they are used primarily for measuring 60-hertz line power. Unshielded electrodynamic wattmeters should not be placed in the vicinity of stray magnetic fields. A wattmeter has current, voltage, and power ratings; therefore, damage may result when any of these ratings is exceeded.

The electrodynamic wattmeter may be converted into an instrument for measuring reactive power by replacing the resistance normally in series with the voltage coil with a large inductance. A 90-degree current lag within the voltage coil provides a direct reading proportional to the reactive power in the circuit. Compensating networks must be used to cause the phase shift to be exactly 90º.

Q-11. What type of device is used to extend the current-measuring capability of electrodynamic wattmeters?

IRON-CORE, COMPOSITE-COIL, AND TORSION-HEAD WATTMETERS

Iron-core wattmeters are primarily used as switchboard instruments and employ the induction principle. Voltage and current coils are wound around a laminated iron core shaped to produce a mutually perpendicular magnetic field across an air gap. Eddy currents induced in a thin metal cylinder rotating in this air gap interact with the magnetic field to produce a torque proportional to the instantaneous power. This type of construction provides the advantages of increased operating torque, larger angles of rotation, ruggedness, compactness, and freedom from errors caused by stray fields. It has the disadvantage of a very narrow frequency range.

The composite-coil wattmeter uses the upscale torque, produced by the ac power being measured, in opposition to the torque produced by an adjustable dc current in a set of windings intermingled or wound within the ac windings. Greater reading precision is obtained with this method than is possible with straightforward wattmeters, and errors caused by elasticity of the spring suspension carrying the moving-coil system are avoided. The torsion-head wattmeter is used to restore the movable coil to its original position after deflection and to remove the mutual inductance error.

ELECTRONIC WATTMETER

Electronic wattmeters are used for direct, small power measurements or for power measurements at frequencies beyond the range of electrodynamometer-type instruments. A simplified electronic wattmeter circuit is shown in figure 3-13. The matched triodes are operated in the nonlinear portion of their characteristic grid-voltage, plate-current curves. The symmetrical resistive T network between the generator and load will provide V1 and V2 voltages proportional to, and in phase with, the load current and voltage, respectively. A source of ac power is connected to the load through the series resistors R1 and R2. These two resistors are of equal value and are made small to prevent the voltage drop across them from reducing the load voltage appreciably. R3 is made large enough to have negligible power consumption. Therefore, the R3 voltage is equal to the load voltage, and the voltage across either series resistor is proportional to the difference in the output currents of the tubes. The average value of the difference could be measured by a dc meter connected to read the voltage potential between the grids of V1 and V2. This method is adequate only at low frequencies. As the frequency increases, the stray capacitances and inductances also increase. The frequency range of the electronic wattmeter can be extended up to 20 megahertz by using pentodes instead of triode tubes. The operating conditions in a pentode are adjusted so that plate current is proportional to the product of a linear function of plate voltage and an exponential function of grid voltage.

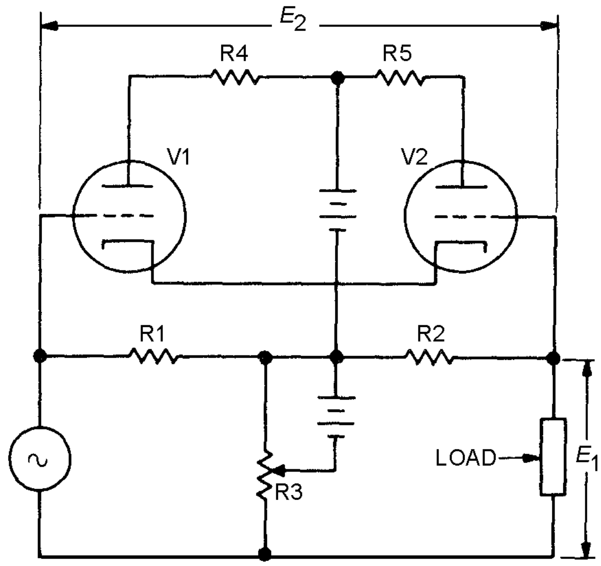

Figure 3-13.—Simple electronic wattmeter circuit.

Q-12. For power measurements, what advantage does an electronic wattmeter have over an electrodynamic wattmeter?

ABSORPTION POWER METERS

Absorption power meters absorb either all or part of the source power. They require means of dissipating the absorbed power, sensing the power thus dissipated, and indicating the amount of power absorbed by the sensing network. Output power meters, in-line wattmeters, and meters employing bolometers are examples of absorption power meters used by the Navy.

Output Power Meters

Figure 3-14 shows a common output power meter used in vhf-uhf applications. It has a 0- to 150-watt range covered in two steps: 0-50 watts and 0-150 watts. Attenuator AT1 provides a 50-ohm nominal resistive (dummy) load and uses metal film on glass construction. This dummy load is tapped to provide the proper operating voltage to the meter. Resistors R3 and R5 form a calibration network at 50 watts; R7 and R8 form a calibration network at 150 watts. Accuracy, at approximately 20º C, is ±5% for frequencies between 30 MHz and 600 MHz, ±10% for frequencies between 0.6 GHz and 0.8 GHz, and ±20% for frequencies between 0.8 and 1.0 GHz. When radio-frequency (rf) power is applied to AT1, this attenuator minimizes the effects of power factors generated by any reactive components. The rf energy is then detected and filtered by CR1 and C1, respectively. The resultant dc voltage, which is proportional to the input power, is applied to a sensitive microammeter via one of the calibration networks. This meter has a scale provided with two ranges: 0-50 watts and 0-150 watts. To protect the meter, you should always try the higher range first. If the value proves to be under 50 watts, a shift to the lower scale would provide improved accuracy.

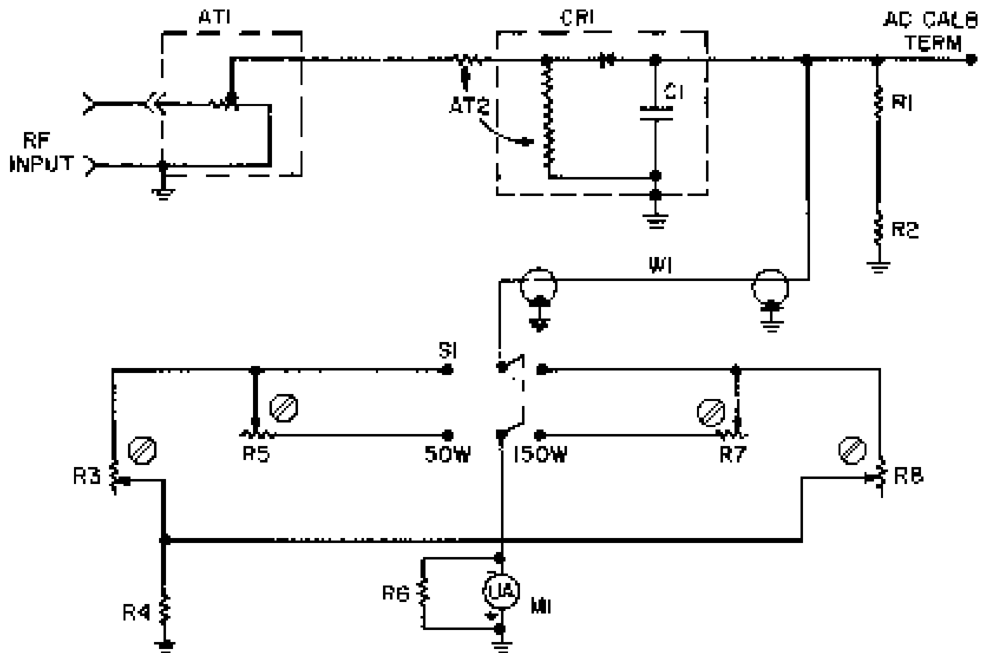

Figure 3-14.—Vhf-uhf wattmeter.

In-Line Wattmeters

The AN/URM-120 in-line wattmeter, shown in figure 3-15, measures power applied to a 50-ohm impedance load and the power reflected from that load. The internal directional coupler is oriented such that it responds only to a wave traveling in one direction on the transmission line. The coupler can be rotated to accommodate either incidental or reflected power. The rf is then rectified, filtered, and applied to the meter, which is scaled in watts. The rf power of 50 to 1,000 watts can be measured between the frequencies of 2 MHz to 30 MHz; and 10 to 500 watts, between the frequencies of 30 MHz to 1,000 MHz.

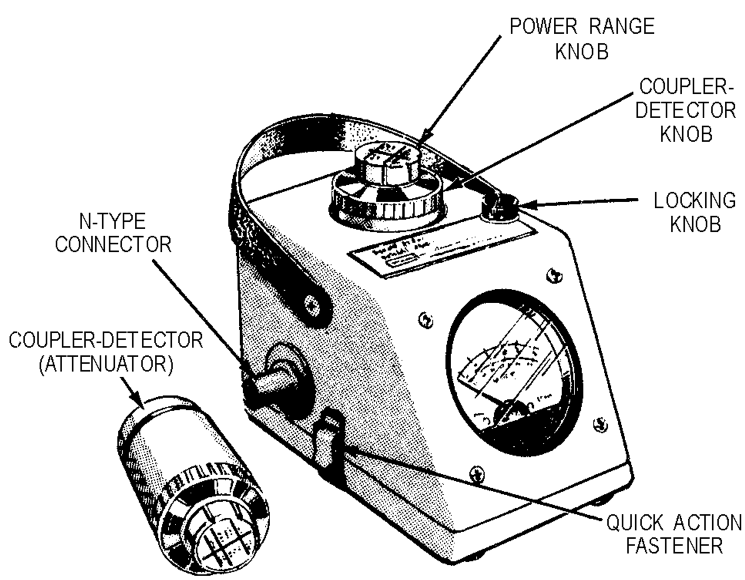

Figure 3-15.—Typical in-line wattmeter.

Q-13. What is the advantage of using in-line wattmeters over output power meters?

Bolometer

A bolometer features a specially constructed element of temperature-sensitive material. The active material is a semiconductor bead supported between two pigtail leads. When rf power is applied to a bolometer element, the power absorption by the element heats the element and causes a change in its electrical resistance. Thus, a bolometer can be used in a bridge circuit so that small resistance changes can be easily detected and power measurement can be accomplished by the substitution method (that is, substitution of dc or low-frequency power to produce an equivalent heating effect). A D'Arsonval meter movement is usually employed as the null indicator.

According to one principle of measurement (the principle used in the balanced bridge), the bridge is initially balanced with low-frequency bias power. Rf power is then applied to the bolometer and the bias power is gradually removed until the bridge is again balanced. The actual rf power is then equal to the bias power removed.

According to another principle of measurement (the principle used in the unbalanced bridge), the bridge is not rebalanced after the rf power is applied. Rather, the indicator reading is converted directly into power by calibration previously performed.

Figure 3-16 illustrates the basic bolometer bridge circuit. The bolometer element must be physically small to be highly sensitive; it must be equally responsive to low-frequency and rf power; and it must be matched to the rf-input power line. The cross-sectional dimension of the bolometer element is approximately equal to the skin depth of rf current penetration at the highest frequency of operation. This condition permits the dc and rf resistivities to be essentially equal with the reactive component of the bolometer impedance at a minimum. Thermistors, which are a type of bolometer, use semiconductor material shaped like a bead, with a thicker skin depth and shorter length to minimize standing-wave effects. These physical properties assure correspondence between lengthwise low-frequency and rf power distribution to provide the necessary inherent accuracy of the bolometer.

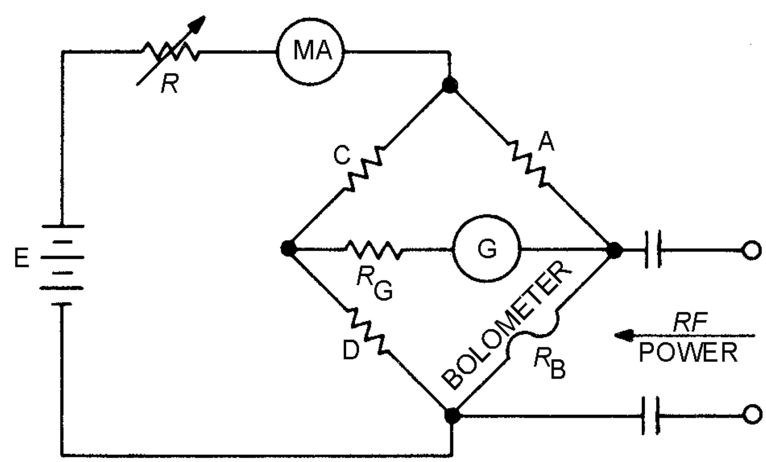

Figure 3-16.—Basic bolometer bridge circuit.

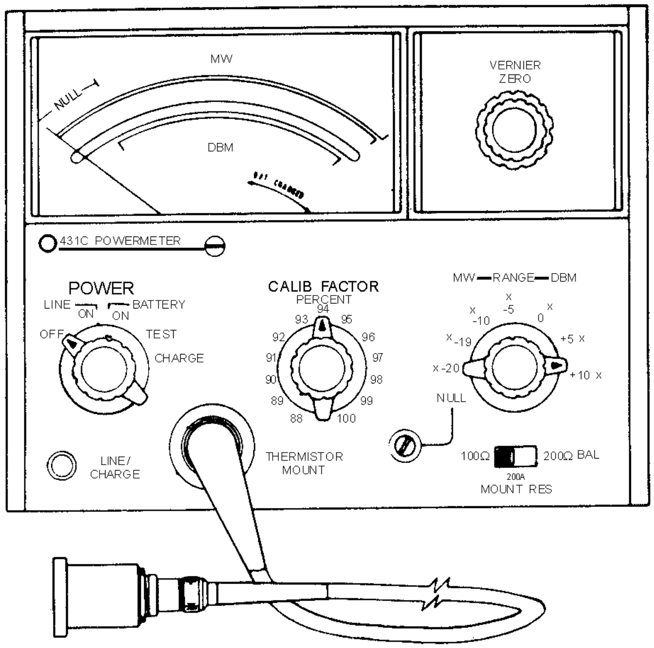
An air-mounted bolometer provides a power sensitivity 100 or more times greater than that provided by static calorimetric devices. Additional sensitivity may be obtained by mounting the element within an evacuated envelope to eliminate convective heat loss. The small size of bolometer elements is associated with small thermal mass and short thermal time constants. The thermal time constant varies directly with the volume-to-area ratio of the element for a particular shape and composition. Typical time is up to 0.1

second for thermistor beads. The thermistor type of bolometer element is usually composed of a ceramic-like mixture of metallic oxides having a large negative temperature coefficient of resistance. Two fine platinum-alloy wires are embedded in the bead, after which the bead is heated and coated with a glass film. Typical dimensions of a thermistor bead used for microwave measurements are 0.015 inch along its major axis and 0.010 inch along its minor axis. The thermistor bead may be operated at high temperatures; it is rugged, both electrically and mechanically; it has high resistance-power sensitivity; and it has a good temperature-power sensitivity. In addition, it can endure large pulse energies; it has a sluggish thermal response; and it has negligible pulsed-power measurement errors. The more sensitive thermistor requires thermal shielding or heat compensation for best operation.

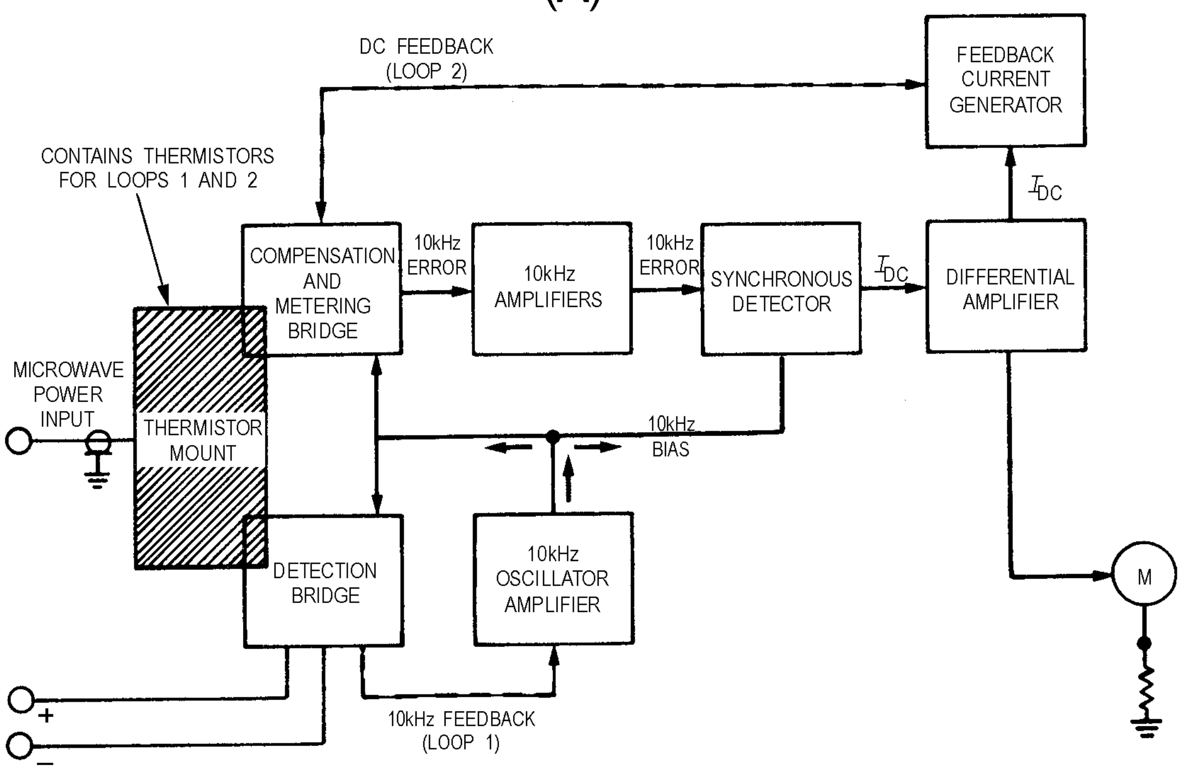
Q-14. What type of material is used in the construction of bolometers and thermistors?

Bolometer Power Meter

The standard power meter used in the Navy (Hewlett-Packard 431 C) is an automatic self-balancing instrument employing dual-bridge circuits. It is designed to operate with temperature-compensated thermistor mounts that enable you to measure power in a 50-ohm coaxial system from 10 MHz to 18 GHz and in a waveguide system from 2.6 GHz to 40 GHz. This power meter can be operated from either an ac or a dc primary power source. The ac source can be either 115 or 230 volts at 50 to 400 hertz. The dc source is a 24-volt rechargeable battery. A seven-position range switch allows full-scale power measurements of 10 microwatts to 10 milliwatts or of −20 dBm to +10 dBm. These ranges can be further extended with the aid of attenuators. The thermistor mount (as shown in fig. 3-17) contains two thermistors: one in the detection bridge, which absorbs the microwave power to be measured, and the other in the compensation and metering bridge, which supplies temperature compensation and converts the measured rf power to a meter indication. Each bridge includes its respective thermistor element as a bridge arm.



(A)



(B)

Figure 3-17.—Power meter.

Basically, the power meter circuit consists of two bridges; each bridge includes one of the thermistor elements as a bridge arm. The bridges are made self-balancing through the use of feedback loops. Positive or regenerative feedback is used in feedback loop 1; degenerative (negative) feedback is used in feedback loop 2. Both bridges are excited by a common 10-kHz source. The 10-kHz amplifier-oscillator supplies 10-kHz power to bias the thermistor in feedback loop 1 to produce the resistance required to balance the rf bridge. An equal amount of 10-kHz power is supplied by the same oscillator to the second thermistor in feedback loop 2 through two series-connected transformers. Feedback loop 2 balances the meter bridge. When rf is applied to the thermistor in the detection bridge (but not to the compensation and metering bridge), an amount of 10-kHz power is present, equal to the rf power being removed from the detection bridge by the self-balancing action of the bridge. Since the rf power replaced the 10-kHz power, the detection bridge is in balance; however, the metering bridge must be balanced by its separate feedback loop. Sufficient dc power to equal the 10-kHz power lost by the metering bridge is automatically replaced, balancing this loop. Hence the dc power applied to the metering bridge thermistor is equal to the microwave power applied to the detection bridge. The meter circuit senses the magnitude of the feedback current. The resultant meter current passes through a differential amplifier to the indicating meter. The two thermistors are matched with respect to their temperature characteristics; therefore, there is only a very small amount of drift of the zero point with ambient temperature changes. When there is a change in temperature, there is a change in the electrical power needed by the thermistors to maintain constant operating resistances. This change is automatically performed by feedback loop 1, which changes the amount of 10-kHz power for both thermistors by the proper amount. The dc power in feedback loop 2 is not changed; and since it is this dc power that is metered, the temperature change has not affected the meter indication.

CALORIMETERS

The calorimeters are the most accurate of all instruments for measuring high power. Calorimeters depend on the complete conversion of the input electromagnetic energy into heat. Direct heating requires the measurement of the heating effect on the medium, or load, terminating the line. Indirect heating requires the measurement of the heating effect on a medium or body other than the original power-absorbing material. Power measurement with true calorimeter methods is based solely on temperature, mass, and time. *Substitution* methods use a known, low-frequency power to produce the same physical effect as an unknown rf power being measured. Calorimeters are classified as STATIC (nonflow) types and CIRCULATING (flow) types.

Q-15. Power measurements performed with calorimeters are based on what three variables?

Static Calorimeters

The static calorimeter uses a thermally shielded body. Since an isolated body loses little heat to a surrounding medium, the temperature increase of the body is in direct proportion to the *time* of applied power. The product of the rate of temperature rise in the calorimetric body and its heat capacity equals applied power. Figure 3-18 illustrates a static-type calorimeter.

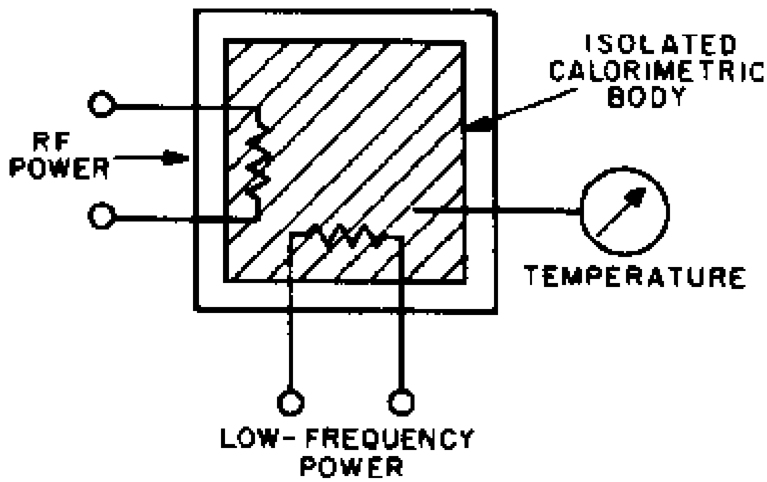


Figure 3-18.—Static calorimeter using low-frequency power substitution.

The most common type of static calorimeter is the ADIABATIC calorimeter. In the adiabatic meter, power is applied directly to a thermally isolated body; and the rate of temperature rise is determined from a temperature change measurement during a sufficiently long, known time interval. Figure 3-19 illustrates an adiabatic calorimeter using water as the body contained in a covered Dewar flask. A tapered-wall, open-ended waveguide contains a sealed, inclined glass partition to create a wedge-shaped water load of low-reflection coefficient. Thorough mixing of the water is accomplished with a stirrer, and a sensitive thermometer measures the temperature rise. A heating coil is wound around the waveguide inside the calorimeter and is used for calibrating purposes when low-frequency power is applied. This type of meter can be used for accurate measurement of several hundred watts of average power and can withstand 50 kilowatts of peak power.

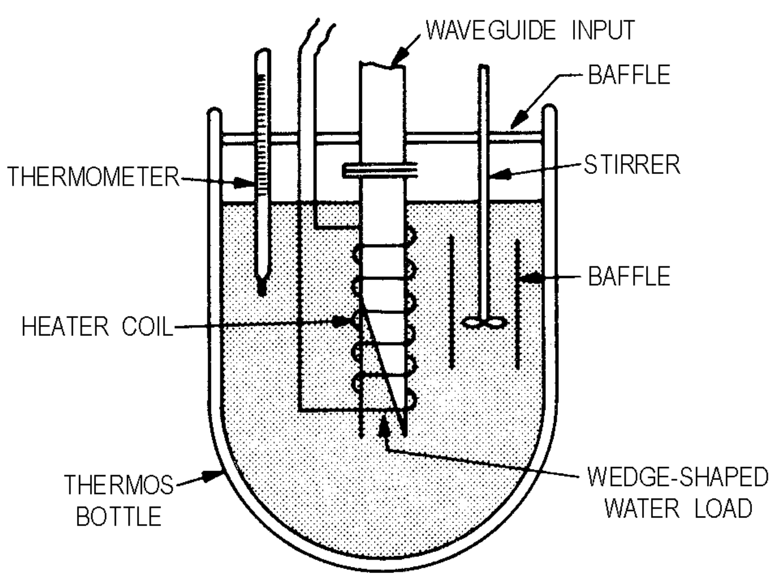

Figure 3-19.—Adiabatic calorimeter.

The NONADIABATIC calorimeter uses an rf termination with a resistive film strip or LOSSY dielectric materials (solids or liquids that are designed to efficiently dissipate the applied power) as a load. Temperature indication can be accomplished with thermocouples, thermopiles, thermistors, thermometers, bimetallic strips, and manometers. Calibration is against a power standard or known low-frequency power.

Based on the above principle, a coaxial calorimeter of good sensitivity with a short, 50-ohm resistive film on a lava (dielectric) center conductor, enclosed within a tapered, thin-walled outer conductor, is used for frequencies between 0 and 1.2 GHz. The rf termination is electrically connected to, but thermally isolated from, a massive mounting plate by a short section of silvered-lava coaxial line with a high thermal resistance. The steady-state temperature rise of the outer casing of the load with respect to the mounting plate is measured by a differential platinum-resistance thermometer in a Wheatstone bridge. Low-frequency power applied to the termination provides a method of calibration. Power in the range of 0 to 2.5 watts may be measured. A 70-second time constant and steady-state temperatures are attained in about 6 minutes. The small physical size of termination (to keep convective and radiative heat losses low) provides high sensitivity. Calibration with lower frequency power is extremely accurate, because the termination is broadband and should exhibit the same power distribution from dc to 10 gigahertz.

A twin calorimeter provides a method of using two calorimetric bodies thermally shielded against ambient temperature variations and improves sensitivity. Figure 3-20 illustrates this type of calorimetric device. The power to be measured is applied to one calorimetric body; the other calorimetric body acts as a temperature reference. The steady-state temperature difference between the two calorimeters is used as a measure of rf power. Calibration is performed by applying low-frequency power. A differential-air, thermometer-type temperature difference indicator, shown in figure 3-21, is used with a twin calorimeter to measure microwave power in the 0.1-mW range. This instrument consists of two similar glass cells connected by a capillary tube containing a liquid pellet. Each glass cell contains a tapered, carbon-coated strip; and the entire assembly is mounted in a rectangular waveguide. Balancing dc power heats one strip; the other strip is heated by rf power. The liquid pellet, which indicates the differential expansion of the air within the two cells, is viewed through an aperture in the waveguide wall, preferably with a microscopy for highest sensitivity. This procedure permits a 2% accuracy at 10 mW.

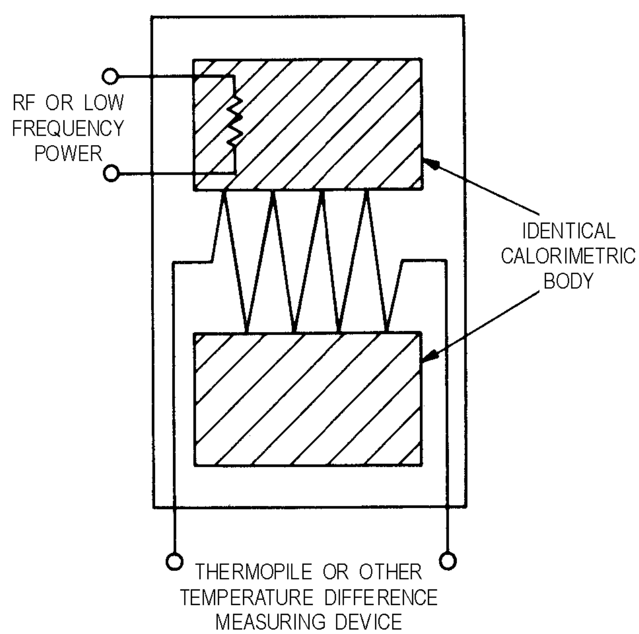

Figure 3-20.—Twin calorimetric system.

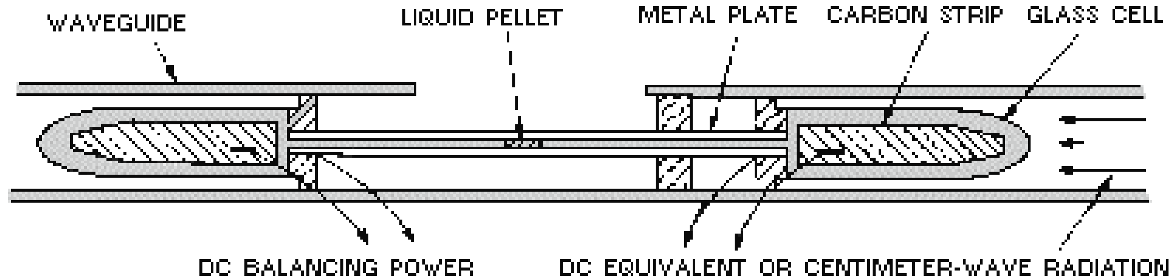

Figure 3-21.—Differential-air, thermometer-type calorimeter.

Flow Calorimeters

Flow calorimeters are classified by the type of circulating method used (open or closed), the type of heating used (direct or indirect), and the type of measurement performed (true calorimetric or substitution). Water or other calorimetric fluid is used only once in an open system. An overflow system is used to maintain a constant rate of flow. Closed systems recirculate the fluid continuously by means of a pump, and a cooling system restores the fluid to ambient temperatures prior to its return to the calorimeter. Closed systems are more elaborate and permit the use of fluids other than water.

Flow calorimeters provide the primary standards for the measurement of high power levels; and, in conjunction with calibrated directional couplers, attenuators, power dividers, or other similar devices serve to standardize medium- and low-power measuring instruments. The measurement time depends on the required time for the entering fluid to reach the outlet, where the rise in temperature is measured. The circulating fluid may serve in a dual capacity as the dissipative medium and coolant, using the direct heating method, or solely as a coolant, using the indirect heating method. Because of its excellent thermal properties and high dielectric losses at 1 GHz or higher, water is normally used in both heating methods. Water is rarely used as the fluid at frequencies lower than 100 MHz, because of insufficient dielectric losses. The indirect heating method offers a wider frequency and power-range coverage and can be used in substitution-type measurements.

True calorimetric measurements contain appreciable error, because of nonuniformity of flow rate, air bubbles, flow-rate measurement inaccuracies, and temperature rise. Flow regulators, bubble traps, and good thermal insulation are required to eliminate the majority of these errors. Substitution methods do not involve direct heat dissipation measurement of moving fluid. Greater accuracy is obtained because known low-frequency power is substituted for the unknown rf power, with all other measurement parameters remaining constant. The accuracy depends on the exactness of the low-frequency power determination and the degree to which factors remain fixed during the substitution of one type of power with another.

Figure 3-22 illustrates a flow calorimeter using low-frequency power substitution. Two different measurement techniques are possible with this type of meter: the calibration technique and the balance technique. The CALIBRATION TECHNIQUE uses an adjustable known power to exactly reproduce the same temperature indication originally obtained by the unknown rf power measurement. The BALANCE TECHNIQUE uses an initial low-frequency power (P_1) to provide a steady-state temperature rise in the calorimetric fluid. When unknown rf power is applied, the original power (P_1) is reduced to a new power (P_2) to maintain the same temperature indication. Therefore, the actual power equals P_1 minus P_2. Figure 3-23 illustrates a widely used method of power measurement using a balanced-flow calorimeter. Temperature-sensitive resistors are bridge-connected as the thermometric elements and are balanced at ambient temperature prior to the application of power. Low-frequency balancing power and the unknown rf power are applied to maintain the bridge at null. This occurs when the temperature rise caused by the unknown rf power equals the temperature rise caused by the known low-frequency power.

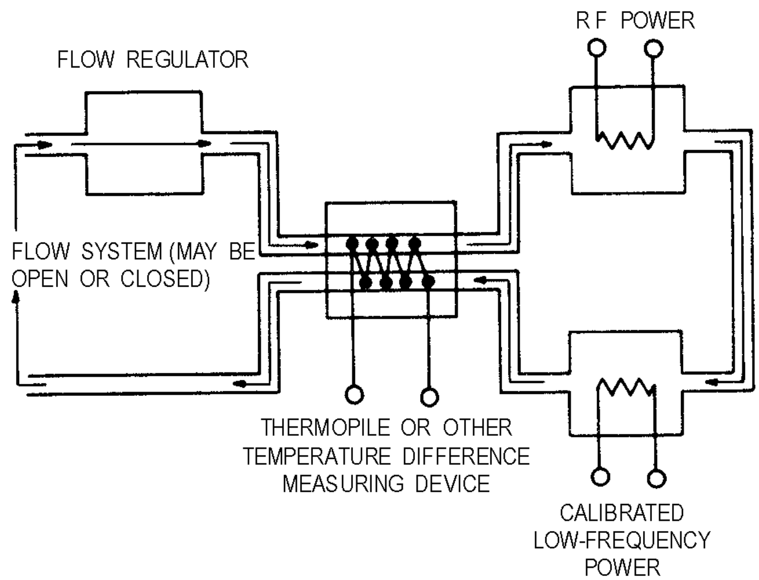

Figure 3-22.—Flow calorimetric system using substitution at low-frequency power.

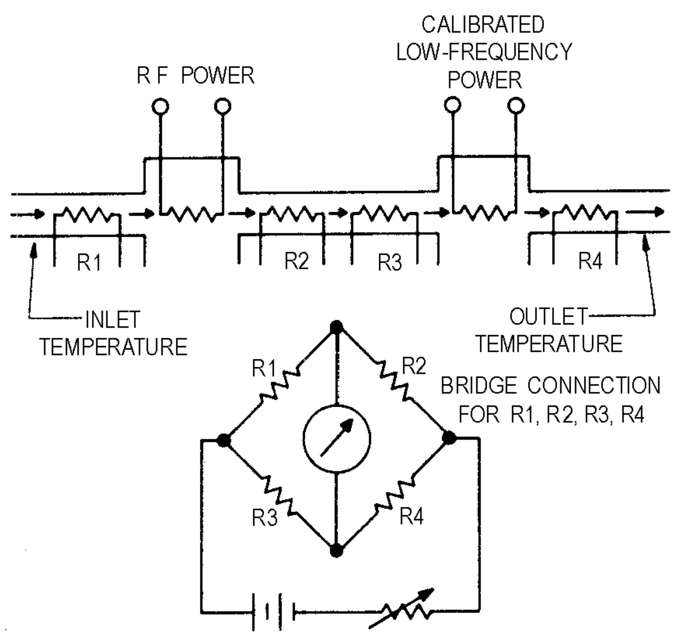

Figure 3-23.—Balanced-flow calorimeter.

Q-16. What is the result of applying power to a calorimeter?

FREQUENCY MEASUREMENTS

Frequency measurements are an essential part of preventive and corrective maintenance for communication and electronic equipment. Rotation frequencies of some mechanical devices must be determined; the output frequency of electric power generators is checked when the engine is started and during preventive maintenance routines; carrier equipment that operates in the audio-frequency range must be adjusted to operate at the correct frequencies; and radio transmitters must be accurately tuned to the assigned frequencies to provide reliable communications and to avoid interfering with radio circuits operating on other frequencies. These are only a few of the applications for making frequency measurements.

FREQUENCY-MEASUREMENT METHODS

Frequency-measuring equipment and devices, particularly those used to determine radio frequencies, constitute a distinct class of test equipment, because of the important and critical nature of such measurements. The requirement of precise calibration is extremely important in all frequency-measuring work. To provide accurate measurements, every type of frequency-measuring device must be calibrated against some frequency standard.

FREQUENCY STANDARDS

Of considerable importance in the measurements of frequency or wavelength are the standards against which frequency-measuring devices are compared and calibrated. Frequency standards belong to two general categories: primary and secondary standards. The PRIMARY FREQUENCY STANDARD maintained by the U.S. National Bureau of Standards has long-term stability and an accuracy of 1 part in 10^{12}, using an atomic clock. A SECONDARY FREQUENCY STANDARD is a highly stable and accurate standard that has been calibrated against the primary standard. Secondary standards are maintained by calibration laboratories that service your test equipment.

The National Bureau of Standards provides time and frequency standards from station WWV at Fort Collins, Colorado, and from station WWVH at Kekaha, Kauai, Hawaii. The following technical radio services are given continuously by these stations:

- Standard radio frequencies
- Standard audio frequencies
- Standard time intervals
- Standard musical pitch
- Time signals
- Radio propagation notices (WWV only)
- Geophysical alerts
- Universal Time Coordinated (UTC)
- + UT^1 Corrections

The UTC scale uses the ATOMIC SECOND as a time interval. UT^1 is based on the earth's uniform rate of rotation. Since the earth's rotation is not precisely uniform, UT^1 is an adjustable interval.

To ensure reliable coverage of the United States and extensive coverage of other parts of the world, radio stations WWV and WWVH provide the primary standard radio frequencies listed in table 3-1. The transmission of WWV and WWVH are interrupted for 5 minutes of each hour. The silent period begins at 15 minutes past the hour for station WWVH and 45 minutes past the hour for station WWV. These silent periods are provided to eliminate errors caused by interference.

Table 3-1.—NBS Frequency Standards and Time Transmission

TRANSMISSION	WWV	WWVH
RF Signal Frequency MHz	5, 10, and 15	5, 10, and 15
Frequency Stability	1 part in 1011	1 part in 1011
Frequency Deviation	1 part in 1012 per day	1 part in 1012 per day
Seconds Frequency and Duration	5 cycles of 1000Hz for .005 seconds	6 cycles of 1200Hz for .005 seconds
Audio Tones	600Hz and 500Hz with 440Hz to mark the hour	600Hz and 500Hz with 440Hz to mark the hour
Frequency Accuracy	1 part in 1012	1 part in 1012
Propagation Forecast	14 min. past the hour (in voice)	None

Two primary standard audio-frequency tones (440 Hz and 600 Hz) are broadcast on all WWV and WWVH carrier frequencies. In the absence of a message, a 500-Hz tone is broadcast during the message interval. The 440-Hz signal that denotes the 1-hour mark is the standard musical pitch, A above middle C. The 600-Hz tone provides a frequency standard for checking the 60-Hz power-line frequency.

The standard time pulse marking interval of 1 second consists of five cycles of a 1,000-Hz tone at WWV and six cycles of a 1,200-Hz tone at WWVH. These marker pulses are heard as clock ticks. Intervals of 1 minute are marked by a 0.8-second, 100-Hz tone for WWV and a 0.8-second, 1,200-Hz tone for WWVH. Each hour is marked by a 0.8-second, 1,500-Hz tone on both stations. Universal Time Coordinated (UTC) is announced on WWVH between the 45 and 52.5 seconds of each minute and on WWV between the 52.5 and 60 seconds of each minute.

An announcement of radio propagation conditions (geophysical alert) for the North Atlantic area is broadcast by station WWV in voice at 18 minutes after each hour. For example, these short-term announcements might state, "The radio propagation quality forecast at ... (normal, unsettled, disturbed)." The propagation format is repeated phonetically and in numerical code to ensure clarity. The letter designations N, U, and W, signifying "normal," unsettled," and "disturbed," respectively, classify the radio propagation conditions at the time of the broadcast. The digits from 1 to 9 indicate the expected radio propagation conditions during the next 6 hours; refer to table 3-2 for code interpretations. The National Bureau of Standards forecasts are based on information obtained from a worldwide network of geophysical and solar observations.

Table 3-2.—NBS Radio Propagation Coding

PHONETIC	PROPAGATION CONDITION
Whiskey	Disturbed
Uniform	Unsettled
Normal	Normal
NUMERAL	
1	Useless
2	Very poor
3	Poor
4	Poor to fair
5	Fair
6	Fair to good
7	Good
8	Very good
9	Excellent

Q-17. What government agency is responsible for monitoring our primary frequency standards?

MECHANICAL ROTATION AND VIBRATION METHODS

There are many instances when you are very much concerned with the question of rotational or vibratory speeds. Knowledge of rotational speeds is necessary where the output of a direct current generator has fallen below a minimum desired output or where the speed of a motor (such as the motor in a teletypewriter or radar antenna) must be maintained at a constant value. There are many instruments that you can use for this purpose, such as tuning forks, stroboscopes, vibrating-reed meters, and electromechanical counters. The oscilloscope and the frequency counter are two of the other devices which may be used, but their use may require the employment of accessory equipment.

Tuning Fork Methods

A tuning fork is generally used in conjunction with the measurement of the rotational speed of a teletypewriter or facsimile motor but is not limited to this application. However, you must remember that the tuning fork can be used at only one frequency, the frequency of vibration for which it was manufactured, and therefore cannot be used on variable-speed motors. To use the tuning fork, you direct a source of light upon the point to be observed. In the case of a teletypewriter, a black-and-white segmented target is painted on the outer circumference of the motor governor. Radial spokes in a flywheel could be used equally well. Permit the motor to reach operational speed under normal load conditions; otherwise, the motor will slow down considerably when the normal load is applied. Strike the tuning fork against the side of your hand to set it into vibration. Then observe the target through the slots in the plates attached to the tines of the fork. The correct speed is obtained when the segments of the target appear to be stationary. If the segments seem to move backward, apparently against the known motor rotational direction, the speed is too low. If the segments seem to move forward, the speed is too high. There is also the possibility that the target segments will appear to jump back and forth or to disappear suddenly. Such erratic action is often because of governor malfunctioning. The correct speed adjustment is reached when the targets appear to be stationary.

Q-18. What is the primary measurement application for tuning forks?

Stroboscope Methods

When using a stroboscope to measure the speed of rotating or reciprocating mechanisms, hold the instrument so that the light from the stroboscope lamp falls directly on the part to be observed. If the part is uniform, or symmetrical, place an identification mark with chalk or a grease pencil on the portion to be observed. This method provides a positive means of identification, because if only one reference mark is observed during measurement, you can be sure that either the fundamental synchronization or a submultiple thereof has been obtained. If the approximate speed of rotation is known, the stroboscope controls may be set to the appropriate positions prior to actual measurement. The main frequency control that determines the rate of the flashing light is then varied until the reference mark on the moving part appears to be standing still. The calibrated scale of the stroboscope will then show the speed directly in revolutions per minute (rpm).

If you have no idea of the speed of the moving part, it is best to start the measurement procedure at the highest frequency that the stroboscope can deliver. The flashing rate of the stroboscope can then be gradually reduced until a single stationary image of the reference mark is obtained. This is the point of fundamental synchronism that corresponds to the speed of the moving part. Do not continue to reduce the flashing rate of the instrument beyond this point without a valid reason for doing so. If you do continue the reduction, a stationary image will still be observed, but the stroboscope will indicate a submultiple of the true rotational speed; thus, a measurement error will be introduced.

Stroboscopes generally have a high- and low-range switch. The typical low range is from 600 to 3,600 rpm, and the upper range is from 3,600 to 15,000 rpm; there is a slight overlap in ranges to ensure reliable frequency coverage. In view of the limitation imposed by flasher tube life, the stroboscope should always be operated at a flashing rate that is as low as possible, consistent with the rotational speed of the observed part. If you should be required to operate this instrument over a long period of time, use a submultiple of the fundamental synchronous speed. The pattern will remain just as stationary, and the tube life will be greatly extended. In addition, the quality of the light is better at the lower ranges than at the upper end of the scale. Sometimes you will encounter a rotating or vibrating device that is moving faster (or slower) than the measuring range of the stroboscope will accommodate. Although such speeds can still be measured, you must use the multiple or submultiple synchronism points.

There are two methods of measuring high speeds. The first method is to obtain a single stationary image of the rotating object at a subharmonic speed relationship and to record that value as *A*. Then obtain a second single stationary image at the next lower subharmonic speed relationship, and record this value as *B*. The unknown speed may then be computed from the following formula:

$$\text{unknown speed} = \frac{A \times B}{A - B}$$

For example, assume reading *A* was 4,000 rpm and reading *B* was 3,500 rpm. The computation would be as follows:

$$\text{unknown speed} = \frac{(4 \times 10^3)(3.5 \times 10^3)}{(4 \times 10^3) - (3.5 \times 10^3)}$$

$$\text{unknown speed} = \frac{14 \times 10^6}{5 \times 10^2}$$

$$\text{unknown speed} = 28,000 \text{ rpm}$$

The second method is used where the value of $A \times B$ becomes progressively smaller. The A reading is obtained as in the previous example (for the sake of easier computation, suppose that the A reading is still 4,000 rpm). Then obtain another submultiple reading for B, keeping in mind the number of times a stationary single image was observed. If a stationary single image was observed seven different times and the final B reading was 2,000 rpm, the calculation would become as follows:

$$\text{unknown speed} = (N_x)\frac{AB}{A - B}$$

$$\text{unknown speed} = (7_x)\frac{(4 \times 10^2)(2 \times 10^2)}{(4 \times 10^2) - (2 \times 10^2)}$$

$$\text{unknown speed} = (7_x)\frac{8 \times 10^6}{2 \times 10^3}$$

$$\text{unknown speed} = 28,000 \text{ rpm}$$

At speeds lower than the lowest range of the stroboscope, multiple images will be observed. For example, assume a dial reading of 900 rpm was obtained when two stationary images were observed. Then dividing the rpm by the number of images will give the unknown shaft speed, as shown below:

$$\text{unknown speed} = \frac{900}{2} = 450 \text{ rpm}$$

WARNING

Exercise caution in using a stroboscope. The *illusion* of stopped motion is very convincing. Do not attempt to touch the moving equipment.

Q-19. If you are required to monitor the speed of a device with a stroboscope over an extended period of time, what step should be taken to prolong the life of the flasher tube?

Frequency Counter Methods

Various frequency counters have found application as an ELECTRONIC TACHOMETER to obtain accurate measurements of high-speed rotating machinery. A tachometer pickup may be used to produce signals that are fed directly to the frequency counter. If the tachometer pickup is designed to generate 1 signal per revolution, the counter will indicate directly in revolutions per second; if the pickup is designed to produce 60 signals per revolution, the counter will indicate directly in revolutions per minute.

AUDIO-FREQUENCY MEASUREMENTS

Audio-frequencies can be measured with a variety of nonelectronic and electronic devices.

Examples of nonelectronic measuring devices are the vibrating-reed meter and the moving-disk frequency meter. (Both of these devices were discussed in NEETS, module 3.) They are used primarily to measure the frequency of ac power, 60 Hz. However, such instruments do not have a wide frequency range. The most common instruments available for the measurement of audio frequencies are oscilloscopes and frequency counters.

OSCILLOSCOPE METHOD

The frequency of a waveform can readily be determined by using an oscilloscope. The most common oscilloscope method of measuring a frequency is accomplished by first measuring the time duration of the waveform. Frequency is the reciprocal of time

$$f = \frac{1}{t}$$

and may be easily computed, as shown in figure 3-24.

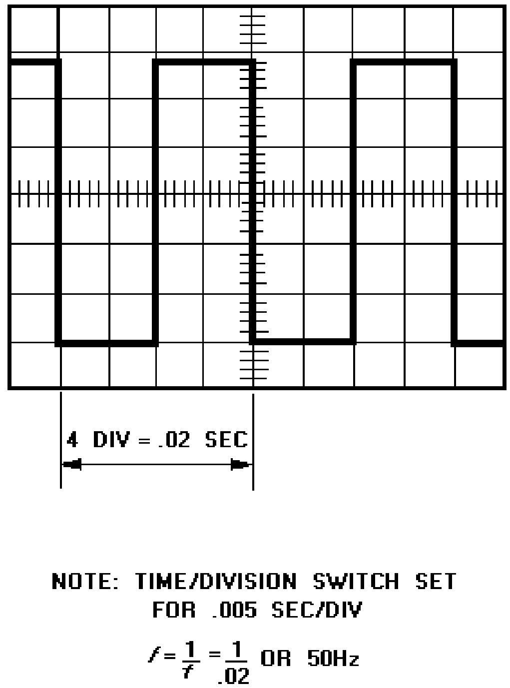

Figure 3-24.—Oscilloscope method of determining frequency.

Another common method of determining the frequency of a waveform is by using Lissajous patterns. This method was discussed in NEETS, module 19.

FREQUENCY COUNTER METHOD

While oscilloscopes can be used to compare rectangular waveforms for the purpose of measuring the frequency of a signal, frequency counters, as shown in figure 3-25, are much more useful for this purpose. The fundamental measurement of frequency is accomplished by totaling the number of cycles into the counter for a precise period of time. The result is then displayed as an exact digital readout. The audio-frequency signal must be of sufficient amplitude to trigger the counter. The AUTO-MANUAL switch provides two methods of frequency counter operation. One method is to initiate the count simultaneously with the initiation of the signal to be measured. With this method, the AUTO-MANUAL switch should be set to the MANUAL position. The second method assumes that the signal to be measured has been operating over some indefinite period of time and that it will continue to do so after a measurement has been taken (hence, only that segment of the signal required to make the frequency measurement is important). With this method, the AUTO-MANUAL switch is to be set to the AUTO position.

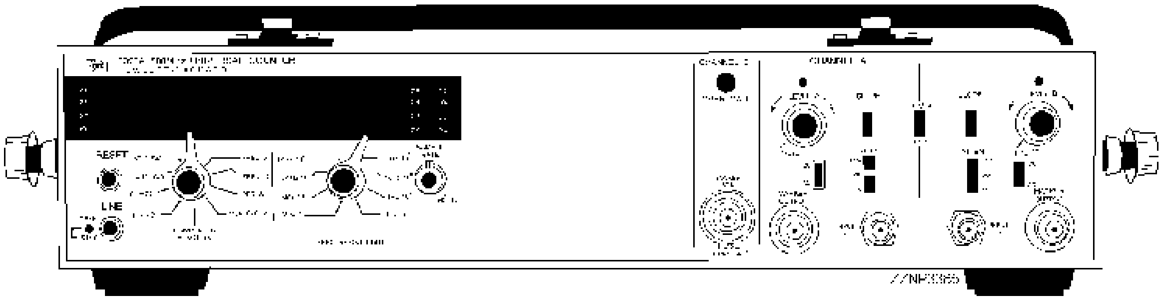

Figure 3-25.—Frequency counter.

RADIO-FREQUENCY (RF) MEASUREMENTS

Radio-frequency measurements are primarily made with frequency counters. Most oscilloscopes are limited in use to approximately 100 MHz. Frequency meters, such as the Hewlett-Packard 530 series, are widely used but lack the accuracy of frequency counters.

Frequency Meters

Prior to the invention of the frequency counter, most frequency measurements above the af range were made primarily with frequency meters.

This process involved heterodyning the frequency to be measured against the calibrated output of the frequency meter to obtain a zero beat from which the measured frequency was then read. This method proved inaccurate because of reading errors.

Frequency meters as we know them today are entirely different from their predecessors. Today's frequency meters (fig. 3-26) contain waveguide or coaxial lines coupled to quarter-wavelength resonant cavities. The meter is adjusted until the cavity is tuned to the resonant frequency of the signal being measured. At resonance, power is absorbed by the cavity and produces a dip in the output-power level, as measured at the frequency meter's output connector. The resonant frequency is read directly from the frequency meter dial and is accurate, in most cases, to approximately ±0.2%. Frequency meters are capable of measuring frequencies in the range of 1 to 40 gigahertz, far exceeding the frequency limitations of the average frequency counter.

Q-20. What happens when a frequency meter is adjusted to the frequency of the signal being measured?

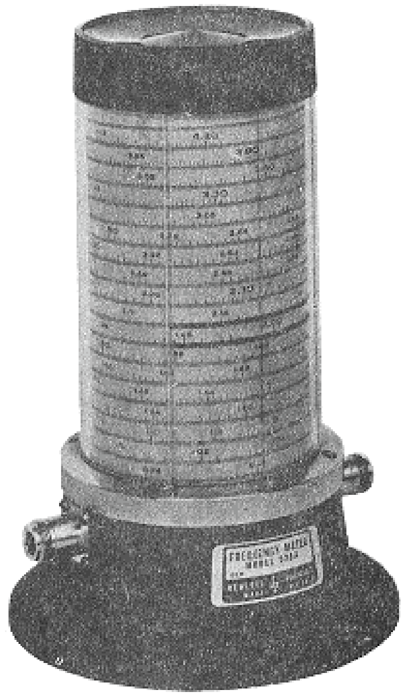

Figure 3-26.—Frequency counter.

Frequency Counters

In the early 1950s, the frequency counter was developed. The device could measure and accurately indicate frequencies up to 10 MHz. Present-day frequency counters can accurately read frequencies as high as 40 GHz. In addition to direct frequency measurement indication, some types of frequency counters can measure the WAVE PERIOD, which is the inverse of frequency; RATIO, which compares one frequency against another; and TIME INTERVAL, the time between two events or the time between two functions of an event. In addition, frequency counters can totalize event indications. This is similar to measuring the frequency except that a manual or an electronic start-stop gate controls the time over which the measurement is taken. Frequency counters can also provide scaling in the form of a digital output signal from the frequency counter that represents a frequency-related division of the input frequency.

All of the above functions have useful applications. For pulse timing, the period function is used; totalizing is used in digital applications; and ratio is used in comparing harmonic-related signals. Scaling is used for triggering other test equipment used in conjunction with the frequency counter; and time-interval capability is used in measuring the interval between two pulses or between two sets of pulses. Because of the wide variety of frequency counters in use, the technical manual for a specific frequency counter should be consulted to determine the instrument's full capabilities.

Frequency Counter Accuracy

All frequency counter measurements are measured with 1 part in 10^8 of accuracy. However, frequency counters have provisions for input from external frequency standards. This extends the accuracy of the frequency to that of the standard. A frequency self-check capability is provided to determine if the counting and lighting circuits are operating properly.

Wavemeters

Wavemeters are calibrated resonant circuits used to measure frequency. Although the accuracy of wavemeters is not as high as that of heterodyne frequency meters, they have the advantage of being comparatively simple and can be easily carried about.

Any type of resonant circuit may be used in wavemeter applications. The exact kind of circuit employed depends on the frequency range for which the meter is intended. Resonant circuits consisting of coils and capacitors are used for low-frequency wavemeters. Butterfly circuits, adjustable transmission line sections, and resonant cavities are used in vhf and microwave instruments.

There are three basic kinds of wavemeters: the absorption, the reaction, and the transmission types. Absorption wavemeters are composed of the basic resonant circuit, a rectifier, and a meter for indicating the amount of current induced into the wavemeter. In use, this type of wavemeter is loosely coupled to the circuit to be measured. The resonant circuit of the wavemeter is then adjusted until the current meter shows a maximum deflection. The frequency of the circuit under test is then determined from the calibrated dial of the wavemeter.

The reaction type derives its name from the fact that it is adjusted until a marked reaction occurs in the circuit being measured. For example, the wavemeter is loosely coupled to an oscillator, and the resonant circuit of the meter is adjusted until it is in resonance with the oscillator frequency. The setting of the wavemeter dial is made by observing the output current of the oscillator. At resonance, the wavemeter circuit takes energy from the oscillator, causing the current to dip sharply. The frequency of the oscillator is then determined from the calibrated dial of the wavemeter.

The transmission wavemeter is an adjustable coupling link. When it is inserted between a source of rf energy and an indicator, energy is transmitted to the indicator only when the wavemeter is tuned to the frequency of the source. Transmission wavemeters are widely used in measuring microwave frequencies.

In figure 3-27, a typical cavity wavemeter is illustrated.

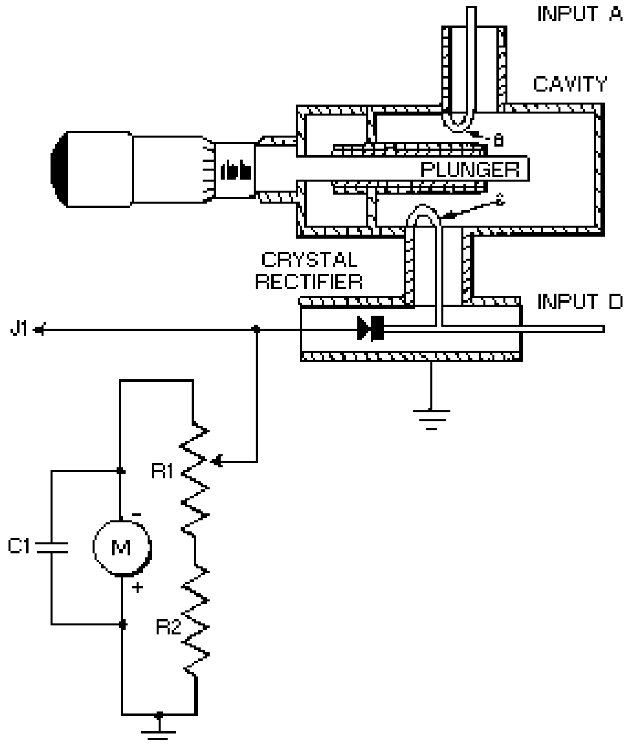

Figure 3-27.—Typical cavity wavemeter.

The wavemeter illustrated is of the type commonly used for the measurement of microwave frequencies. The device employs a resonant cavity, which effectively acts as a high-Q LC tank circuit. The resonant frequency of the cavity is varied by means of a plunger that is mechanically connected to a micrometer mechanism. Movement of the plunger into the cavity reduces the cavity size and increases the resonant frequency. Conversely, an increase in the size of the cavity (made by withdrawing the plunger) lowers the resonant frequency. The microwave energy from the equipment under test is fed into the wavemeter through one of two inputs, A or D. A crystal rectifier then detects or rectifies the signal, and the rectified current is indicated on the current meter, M.

The instrument can be used as either a transmission type or an absorption type of wavemeter. When used as a transmission wavemeter, the unknown signal is coupled into the circuit by means of input A. When the cavity is tuned to the resonant frequency of the signal, energy is coupled through coupling loop B into the cavity and out through loop C to the crystal rectifier where it is rectified and indicated on the meter. At frequencies off resonance little or no current flows in the detector and the meter reading is small. Therefore, the micrometer and attached plunger are varied until a maximum meter reading is obtained. The micrometer setting is then compared with a calibration chart supplied with the wavemeter to determine the unknown frequency.

When the unknown signal is relatively weak, such as the signal from a klystron oscillator, the wavemeter is usually used as an absorption type of device. Connection is made to the instrument at input D. Rf loop C then acts as an injection loop to the cavity. When the cavity is tuned to the resonant frequency of the klystron, maximum energy is absorbed by the cavity, and the current indicated on the meter dips. When the cavity is not tuned to the frequency of the klystron, high current is indicated on the current meter. Therefore, the cavity is tuned for a minimum reading, or dip, in the meter; and the resonant frequency is determined from the micrometer setting and the calibration chart.

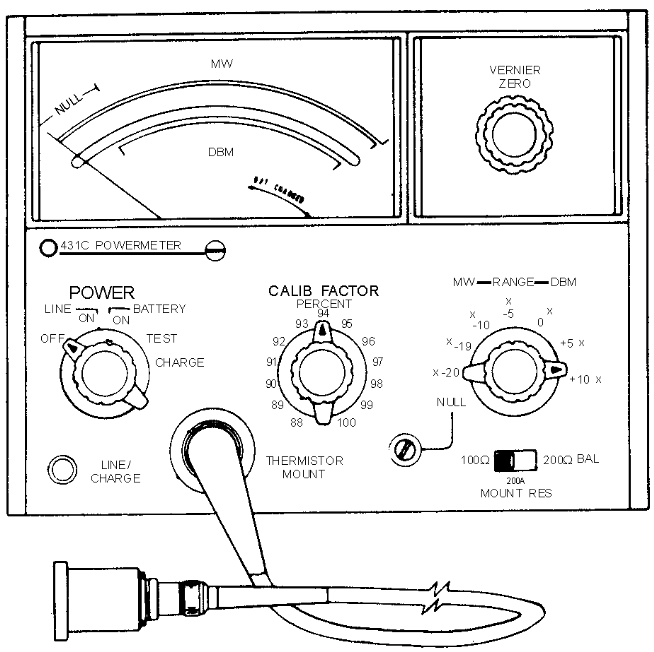
The potentiometer, R1, is used to adjust the sensitivity of the meter from the front panel of the instrument. J1 is a video jack and is provided for observing video waveforms with a test oscilloscope.

SUMMARY

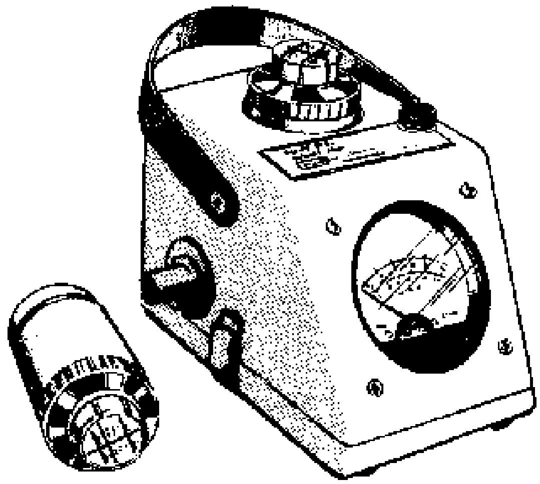
The following is a brief summary of the important points of this chapter.

All **IMPEDANCE BRIDGES** have several things in common. Each type of bridge has a comparing circuit and a measuring circuit. They measure an unknown impedance by comparing the characteristics of the device under test with the characteristics of components within the test set.

POWER METERS that are designed to measure af power can be separated into two distinct groups. Power meters that are designed for measuring sine waves are basically electronic voltmeters calibrated in dB or dBm. VU METERS are designed to measure the average value of complex waveforms, such as a voice.



The most common type of test equipment used to measure rf power is the **ABSORPTION POWER** METER. Absorption power meters are designed to absorb all or part of the signal being measured. Examples of absorption power meters are output power meters, in-line wattmeters, and meters employing bolometers.



CALORIMETERS are the most accurate type of test equipment used for measuring high power. As power is applied to a calorimeter, its medium (either liquid or solid) is heated. The heat that is produced is directly proportional to the amount of applied power. The amount of applied power is determined by measuring the change in temperature of the medium.

Today's **ELECTRONIC FREQUENCY COUNTERS** are capable of measuring frequencies from dc to 40 GHz. Most have added features that enable period averaging, time-interval measurements, and scaling. Frequency counter accuracy can be extended by using an external frequency standard in lieu of its internal frequency standard.

CHAPTER 4

QUALITATIVE MEASUREMENTS

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to do the following:

1. Identify the various methods of measuring standing-wave ratios.
2. Identify the various methods of determining electrical losses caused by deterioration of transmission lines.
3. Identify the methods of measuring intermodulation distortion.

INTRODUCTION TO QUALITATIVE MEASUREMENTS

As a technician, you are responsible for repairing and maintaining complex electronic systems. The basic ability to repair a specific piece of equipment is only the first step in becoming a qualified technician. Your ultimate goal should be to become proficient at *systems* fault isolation — in other words, to know the entire system like the back of your hand. To reach this goal you will need to be familiar with all parts of the system and know how they are interconnected and interact with each other. There are numerous shortcuts or tricks of the trade that can only be learned through experience on any system, but the most practical thing for you to remember is to approach all problems in a logical manner.

Various combinations of electronic equipment are interconnected to form a system capable of performing specific functions. You must be able to apply general test methods and practices to installation, tuning, maintenance, and repair of the system. This requires you to have a thorough knowledge of many types of electronic equipment. When radar, communication, and digital computers are interconnected, they require different maintenance procedures than when they are operated separately. Revised test procedures may be necessary. Detrimental interactions between equipment or facilities must be corrected and effective preventive maintenance procedures must be planned for all equipment within the system. System quality figures, such as sensitivity and coverage, must be determined and measured during equipment preventive maintenance checks to assure efficient operation. System monitoring at specific test points is often used to help localize a problem.

System testing and monitoring are frequently accomplished by using an external piece of electronic equipment, which is designed specifically for testing a particular system. Some computers and computer systems build in their own monitoring and testing devices and will inform the operator when and where failure has occurred. You must realize that any equipment designed to test, monitor, or repair another system is itself subject to malfunction and will require periodic checks and preventive maintenance. This chapter will cover some of the basic test methods and practices associated with system-level troubleshooting.

STANDING-WAVE RATIO (SWR) MEASUREMENTS

Standing-wave ratio (swr) is the ratio of the maximum voltage or current to the minimum voltage or current at any point along a transmission line. Swr measurements are used to determine the matching quality of the termination of the line.

A variety of methods and test equipments may be used to measure the voltage or current distribution along a transmission line. An open transmission line is accessible for coupling to many types of voltage-measuring devices, such as a wavemeter or a grid-dip meter. However, at higher frequencies where coaxial cables or waveguides are used to minimize skin effect losses, (discussed in NEETS, module 10) access is more complicated. Access to the interior of the waveguide or center conductor of the coaxial cable must be gained by using a unidirectional or bidirectional coupler, which is inserted into the transmission line. The coupler contains a slot into which an rf probe is inserted and positioned with respect to directivity.

The conditions that produce standing waves and their adverse effects are discussed in detail in NEETS, module 10. The different methods of detecting and measuring standing waves are discussed in the following paragraphs.

PROBES

A magnetic or electric probe can be used to observe the standing wave on a short-circuited, terminated line. The wavelength is obtained by measuring the distance between alternate maximum or minimum current points along the line. A typical setup operating at 300 megahertz might use two 10-foot lengths of number 14 phosphor-bronze wires, which are spaced 1 inch apart and supported parallel to a set of probe guide rails. The line should be partially matched to the source generator by means of a parallel-wire shorting stub connected in parallel with the transmission line and the oscillator output line. Figure 4-1, view A and view B, illustrates the types of probes required for this method of measurement.

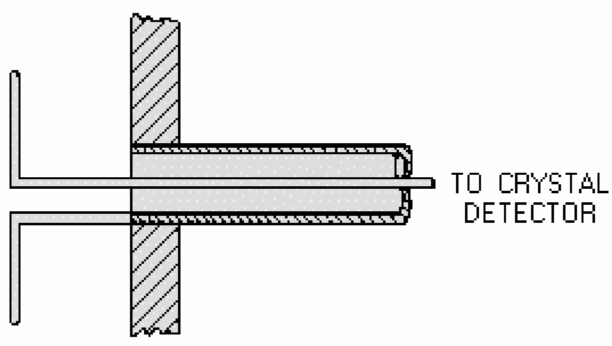

Figure 4-1A.—Typical electromagnetic probe.

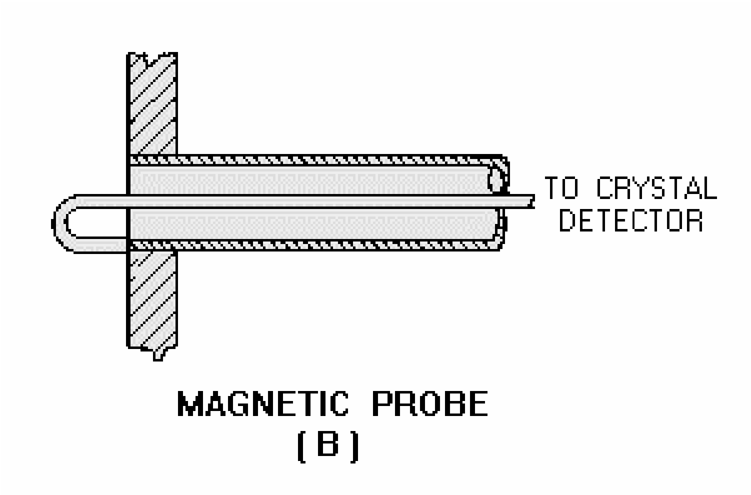

Figure 4-1B.—Typical electromagnetic probe.

NEON-LAMP AND MILLIAMMETER METHODS

In this method of measurement, a neon bulb or milliammeter is moved along the two-wire parallel transmission line. Points of maximum voltage (standing-wave voltage peaks) with the lamp or points of maximum current (standing-wave current peaks) with the indicator will have maximum brilliance or indication, respectively.

Q-1. At what points along a transmission line will a neon lamp glow the brightest?

BRIDGE METHODS

The bridge method permits measurement of the standing-wave ratio without actually measuring the standing waves. The bridge method is applicable because the input impedance of a line terminated in its characteristic impedance is a pure resistance equal to the characteristic impedance. A line terminated in this way can be used as the unknown resistance in a bridge circuit and a null can be obtained in the indicating device when the other resistance arms of the bridge are properly adjusted.

Many types of bridges can be used. For example, an ac bridge that is independent of the applied frequency can be used. The bridge will become unbalanced when the line is no longer properly terminated. Improper termination will produce a reactive component as well as a resistive component in the input impedance of the line and result in a standing wave. The reading of the indicating device depends on the degree of imbalance, which becomes more severe as the mismatch caused by the termination becomes worse. The indicating device can be calibrated directly to indicate the standing-wave ratio. The most common indicator consists of a crystal rectifier, a filtering circuit, and a sensitive dc meter movement in series with a high resistance.

RESISTANCE-CAPACITANCE BRIDGE

A resistance-capacitance bridge circuit is shown in view A of figure 4-2. The bridge is theoretically independent of the applied frequency.

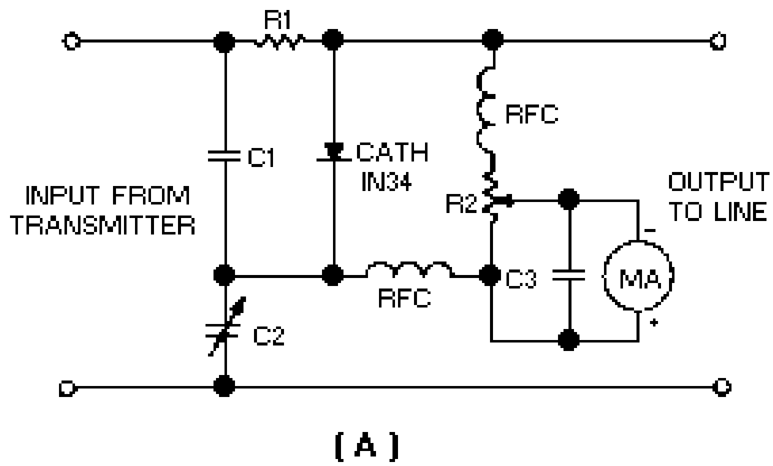

Figure 4-2A.—Resistance-capacitance bridge circuit for measuring standing-wave ratio.

However, the applied frequency must be low enough to avoid skin effect, stray inductance, capacitance, and coupling between circuit elements and wiring. The leads must be kept short to eliminate stray reactance, which causes bridge imbalance. The rectifier circuit wiring must be isolated from other bridge component fields so that induced voltages do not cause an erroneous indication. You should only use resistors having negligible capacitance and inductance effects.

Before you calibrate a newly constructed bridge, the following procedure must be followed if residual readings caused by stray effects are to be held to a minimum:

1. Connect a noninductive resistor (R_L in view B) that is equal to the characteristic impedance of the line to the output terminals of the bridge.

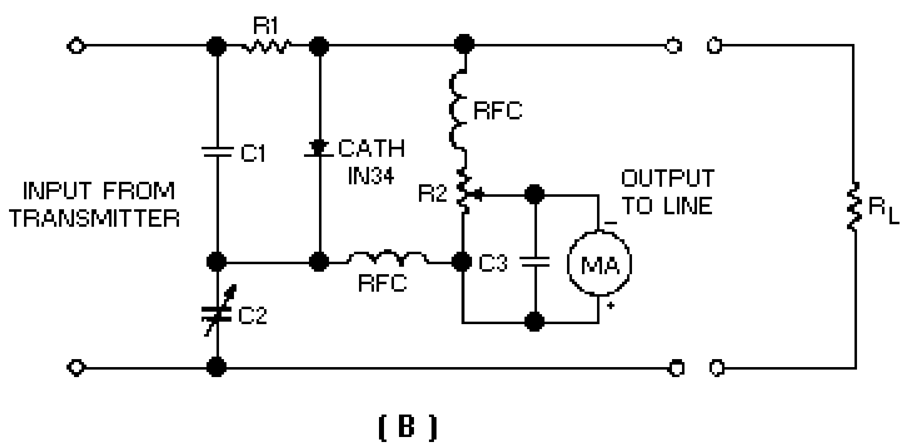

Figure 4-2B.—Resistance-capacitance bridge circuit for measuring standing-wave ratio.

2. Apply an rf voltage to the input terminals and adjust the variable capacitor for a minimum reading on the meter.

3. Reconnect the resistor (R_L) to the input terminals and connect the rf power source to the output terminals.

4. Adjust the rf voltage amplitude applied to the bridge until a full-scale meter reading is obtained.
5. Reconnect the bridge in the normal manner (resistor R_L to the output terminals, etc.). If the meter reading is now more than 1% or 2% of the full-scale reading, different arrangements (lead dress) of the internal wiring must be tried until the null is reduced to 0 or as close as possible to the 0 point.

The bridge can be calibrated after completion of the preceding check. Connect the transmission line under investigation to the output terminals of the bridge and connect a succession of noninductive resistors (R_O in view C) to the load end of the transmission line until the bridge is balanced. Assuming that the bridge was originally balanced for the characteristic impedance of the line, the standing-wave ratio can be computed from the following equation:

$$SWR = \frac{R_L}{R_0} \text{ or } \frac{R_0}{R_L}$$

Where:

R_0 = line impedance

R_L = load resistance

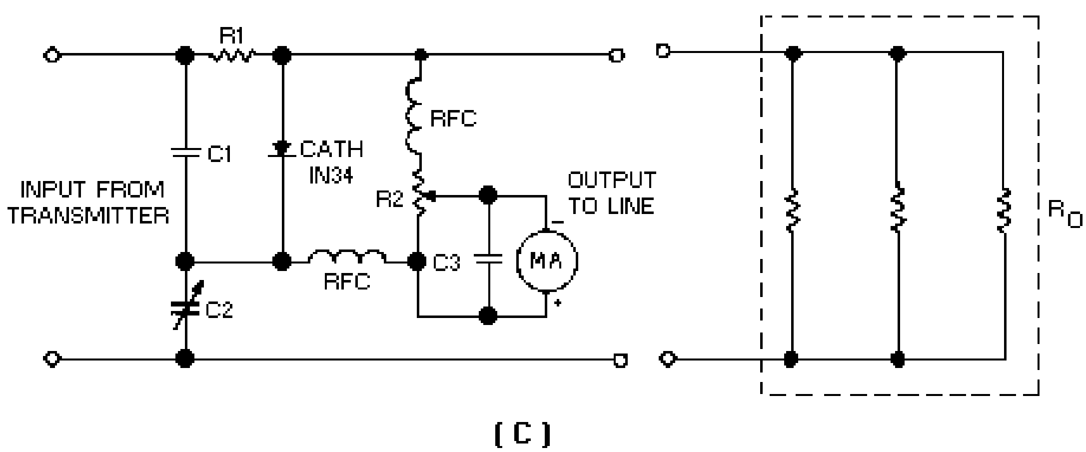

Figure 4-2C.—Resistance-capacitance bridge circuit for measuring standing-wave ratio.

Select the formula that yields a ratio greater than unity. The swr calibration can be recorded on the meter scale directly, recorded on a chart in terms of the meter deflection, or plotted on a graph against the meter deflection. The variable capacitor, in turn, can be calibrated for various characteristic impedances. This is accomplished by applying suitable resistors (R_O) across the output terminals and noting the capacitor settings at the respective balance points. A range of 50 to 300 ohms should prove attainable.

ACCURACY OF BRIDGE MEASUREMENTS

To assure accurate measurements, the rf signal applied to the bridge must be properly adjusted each time a calibrated instrument is used. Essentially, this adjustment is a repetition of the previously described reversed-bridge procedure. The following steps are to be performed:

1. Connect the line to the input terminals of the bridge and connect the transmitter to the output terminals.

2. Adjust the transmitter coupling until full-scale deflection is obtained. From this point on, the coupling must be left untouched.

3. Reconnect the bridge in the usual way and proceed with the measurement.

POWER OUTPUT VERSUS IMPEDANCE MATCHING

For maximum transfer of the power out of an rf source, with minimum heating from reflected power, the total output impedance sensed by the rf source must be equal to the internal impedance of that source. A perfect impedance match between transmitter and load would exist if the swr were 1 to 1. As discussed in NEETS, module 10, test equipment designed to measure the instantaneous voltage of a standing wave will give you a voltage standing-wave ratio (vswr). Test equipment designed to measure the instantaneous current component of a standing wave will give you the current standing-wave ratio (iswr). Regardless of the type of test equipment selected, both ratios will be the same.

Q-2. What vswr is a perfect match between a transmitter and its load?

SWR METERS

The Hewlett-Packard Model 415E swr meter, shown in figure 4-3, is a commonly used swr meter. It is extremely accurate, sensitive, lightweight, easy to use, and portable. It is essentially a high-gain, tuned audio amplifier with a square-law meter that is calibrated to read swr directly. The meter is designed to be operated at a mean center frequency of 1,000 hertz.

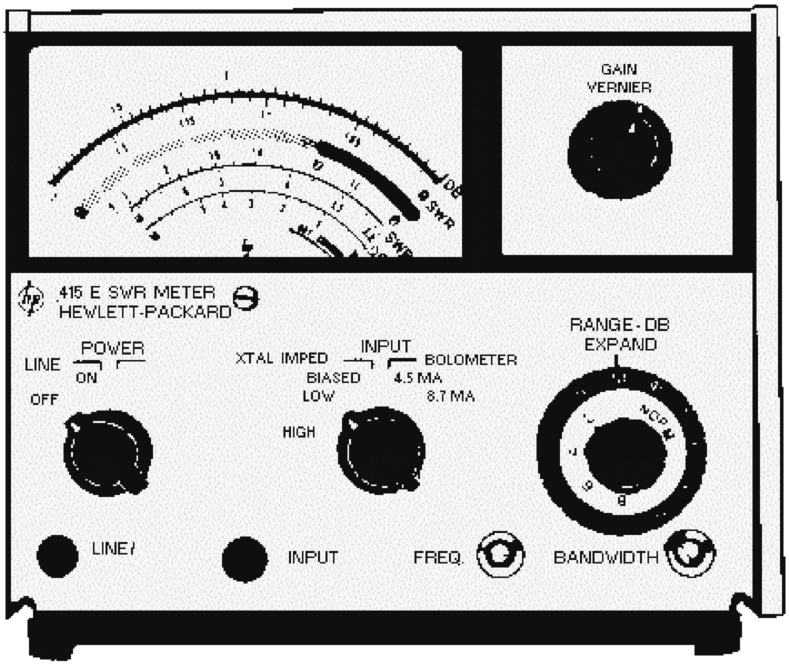

Figure 4-3.—Typical swr meter.

Figure 4-4 shows a typical swr measurement setup using the swr meter. The signal source is usually a sinusoidal wave that is square-wave modulated at 1,000 hertz.

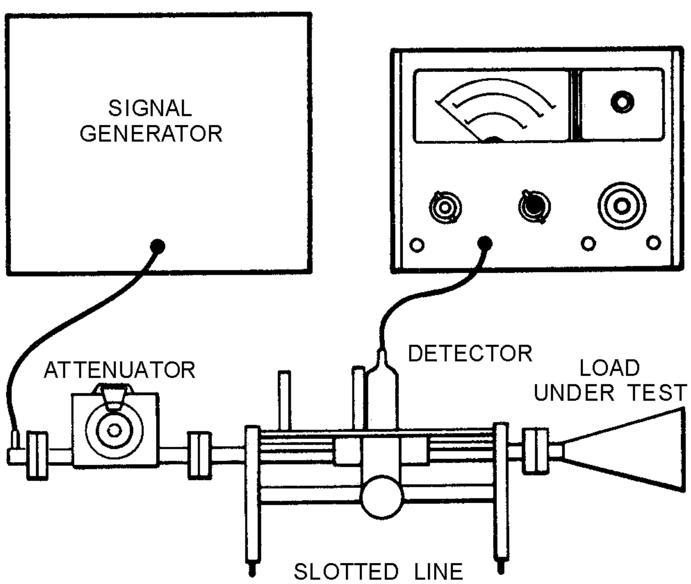

Figure 4-4.—Typical setup for measuring swr.

The swr meter usually gets its input from a detector, either a barretter or a crystal diode. This detector must be a square-law device (its output voltage is proportional to the applied rf power) to ensure the accuracy of the meter. The input is amplified and applied directly to the meter. To perform the measurement as shown in figure 4-4, you move the detector along the slotted line so that its probe is at a voltage maximum and adjust the gain of the meter with the RANGE-DB, GAIN, and VERNIER controls (EXPAND switch to NORM) for full-scale deflection (1.0 on the 1.0 to 4 SWR scale). Then move the probe toward a minimum. If the meter drops below 3.2, rotate the RANGE-DB switch one position clockwise and read on the 3.2 to 10 SWR scale. If the pointer drops below this scale, rotate the RANGE-DB switch one more position clockwise and read on the 1.0 to 4 scale and multiply by 10. This pattern continues for still higher swr readings.

The dB scales can be used for a standing-wave-ratio measurement by setting the meter to full scale at a voltage maximum, then turning the RANGE-DB switch clockwise for an on-scale reading at a voltage minimum and noting the difference in dB reading at the maximum and minimum. A dB reading is obtained by adding the RANGE-DB switch setting and meter indication. The swr meter may also be used for high resolution insertion loss measurements.

The setup for performing insertion loss or attenuation measurements is shown in figure 4-5. It requires that you initially establish a convenient reference on the DB scale of the meter. This is accomplished by connecting the signal source directly to the detector and using the GAIN and VERNIER controls to adjust the meter pointer to a convenient reference. Then you can insert the device to be measured between the signal source and the detector and note the change in dB, as shown on the meter.

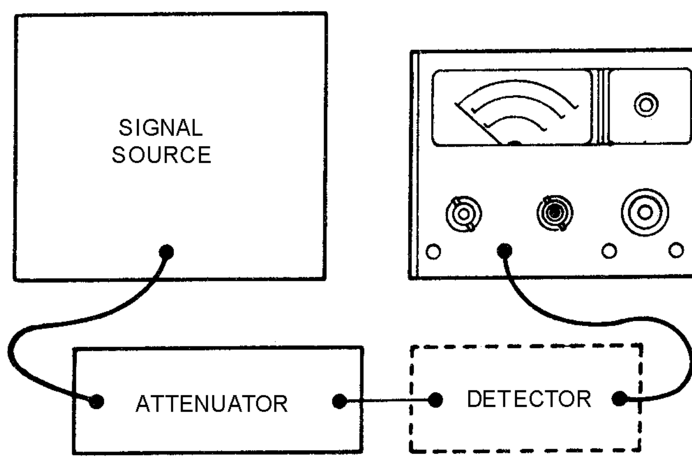

Figure 4-5.—Typical setup for measuring attenuation or insertion loss.

ATTENUATION AND INSERTION LOSS MEASUREMENTS OF TRANSMISSION LINES

Transmission lines are sometimes subjected to extremes of weather and the corrosive effects of salt water. You should be aware of the adverse effects of this environment on transmission lines and how to determine electrical losses caused by transmission-line deterioration.

Q-3. What are the two common causes of transmission-line deterioration?

LOSS MEASUREMENT

Insertion loss measurement of transmission lines requires the use of a good signal generator and an accurate power meter. The method is identical to the insertion loss measurements used on most couplers. When a known frequency, at a predetermined level of power, is inserted into one end of a transmission line, then the same frequency and the same level of power should be transmitted to the other end of a transmission line. Because all transmission lines contain some degree of resistance, some loss of power will occur during the test.

Exposure to the elements over a period of time causes transmission-line deterioration. To determine the accuracy of this test, you should use the power meter to measure the output of the signal generator at the end of the test cable to be attached to the transmission line. Any power loss associated with the test cables should be recorded and subtracted from the measurement taken with the transmission line connected.

You should note that transmission lines, like all other electronic components, are designed to operate over a specific range of frequencies. It is not uncommon for a transmission line to operate improperly at one frequency, yet operate properly over the remainder of its frequency spectrum. You should check transmission-line losses over their entire frequency range. Insertion loss measurements are normally taken when a system is first installed or the transmission line is replaced. Periodic measurements should be performed to enable you to determine if system performance is being degraded by transmission-line deterioration.

Q-4. Is it possible for a transmission line to operate improperly at certain frequencies and properly at others?

TRANSMISSION-LINE FORMULAS

Transmission lines are engineered and manufactured to meet certain specifications. The most important of these specifications relates to frequency, power-handling capabilities, and characteristic impedance. The dielectric constant (K) of the insulating material is probably the manufacturer's most important consideration and is the primary factor that affects the size of the coaxial cable. The formulas in the following sections discuss some aspects of coaxial transmission-line engineering.

A cross section of a coaxial line is shown in figure 4-6. The characteristic impedance of a coaxial line can be determined by the following formula:

$$Z_O = \frac{138}{\sqrt{K}} \left(\log \frac{D}{d}\right)$$

Where:

D = the inside diameter of the outer conductor

d = the outside diameter of the inner conductor and must be expressed in the same units as D

K = the dielectric constant of the insulating material (See table 4-1.)

Z_O = the characteristic impedance

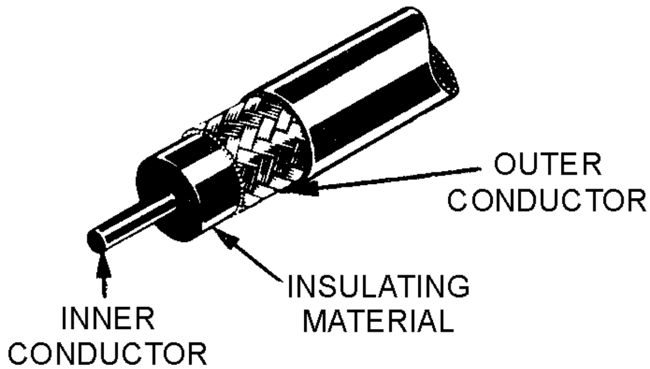

Figure 4-6.—Coaxial line.

Table 4-1.—Dielectric Constants of Materials

Material	Dielectric constant (Approx.)	Material	Dielectric constant (Approx.)
Air	1.0	Lucite	2.5
Amber	2.6-2.7	Mica (electrical)	4.0-9.0
Asbestos Fiber	3.1-4.8	Mica (clear India)	7.5
Bakelite (asbestos base)	5.0-22	Mica (filled phenolic)	4.2-5.2
Bakelite (mica filled)	4.5-4.8	Micaglass (titanium dioxide)	9.0-9.3
Barium Titanate	100-1250	Micarta	3.2-5.5
Beeswax	2.4-2.8	Mycalex	7.3-9.3
Cambric (varnished)	4.0	Neoprene	4.0-6.7
Carbon Tetrachloride	2.17	Nylon	3.4-22.4
Celluloid	4.0	Paper (dry)	1.5-3.0
Cellulose Acetate	2.9-4.5	Paper (coated)	2.5-4.0
Durite	4.7-5.1	Paraffin (solid)	2.0-3.0
Ebonite	2.7	Plexiglas	2.6-3.5
Epoxy Resin	3.4-3.7	Polycarbonate	2.9-3.2
Ethyl Alcohol (absolute)	6.5-25	Polyethylene	2.5
Fiber	5.0	Polyimide	3.4-3.5
Formica	3.6-6.0	Polystyrene	2.4-3.0
Glass (electrical)	3.8-14.5	Porcelain (dry process)	5.0-6.5
Glass (photographic)	7.5	Porcelain (wet process)	5.8-6.5
Glass (Pyrex)	4.6-5.0	Quartz	5.0
Glass (window)	7.6	Quartz (fused)	3.78
Gutta Percha	2.4-2.6	Rubber (hard)	2.0-4.0
Isolantite	6.1	Ruby Mica	5.4
Selenium (amorphous)	6.0	Styrofoam	1.03
Shellac (natural)	2.9-3.9	Teflon	2.1
Silicone (glass) (molding)	3.2-4.7	Titanium Dioxide	100
Silicone (glass) (laminate)	3.7-4.3	Vaseline	2.16
Slate	7.0	Vinylite	2.7-7.5
Soil (dry)	2.4-2.9	Water (distilled)	34-78
Steatite (ceramic)	5.2-6.3	Waxes, mineral	2.2-2.3
Stearite (low loss)	4.4	Wood (dry)	1.4-2.9

Attenuation in a coaxial line in terms of decibels per foot can be determined by the following formula:

$$a = \frac{4.6\sqrt{f}\,(D + d)}{D \times d\,(\log\frac{D}{d})}$$

Where:

D = the inside diameter of the outer conductor (in inches)

d = the outside diameter of the inner conductor (in inches)

f = the frequency (in megahertz)

a = the attenuation (in decibels per foot of line)

As a technician, you need not be concerned with designing coaxial transmission lines. It is, however, our feeling that you should be familiar with the parameters that go into making a transmission line. It can readily be seen by the above formulas that transmission lines cannot be randomly selected without consideration of system requirements. NAVSHIPS 0967-000-0140, EIMB, *Reference Data*, section 3, lists the characteristics of most common transmission lines.

Q-5. What factor has the greatest effect on the physical size of a coaxial cable?

Q-6. Is the attenuation of a coaxial cable independent of frequency?

INTERMODULATION DISTORTION MEASUREMENTS

Intermodulation distortion occurs when two or more frequencies become mixed across a nonlinear device. The resultants are the difference frequency and the sum frequency, both components of the originals. Undesirable frequencies can be generated by a mixing of two discrete frequencies. Spurious radiation, arising from close spacing of transmitter and receiver, is a prime source of an undesirable frequency that can cause intermodulation distortion in an electronic circuit. This is particularly the case when antenna couplers are employed. Cross modulation and parasitic generation (described in the next section) are two other sources of undesirable frequencies that may cause intermodulation distortion.

Q-7. What is the main cause of intermodulation distortion?

CROSS MODULATION AND PARASITIC GENERATION

CROSS MODULATION occurs when a signal from an adjacent channel crosses over into a second channel and modulates the frequency of the second channel. PARASITIC GENERATION occurs when regenerative feedback is sufficient to cause a circuit to oscillate, even though it is not designed to oscillate. Both types of distortion are common to systems that are misaligned.

INTERMODULATION DISTORTION DETECTION

The presence of intermodulation distortion is determined by a two-tone test method. Two sinusoidal frequencies of equal amplitude are introduced into the system under test. The two frequencies are spaced close together with reference to the unit under test. The output of the system under test (an amplifier, receiver, or transmitter) is monitored on a spectrum analyzer that is comparable in characteristics to the suspect system. The resultant display should be an exact reproduction of the input frequencies. If not, some form of intermodulation distortion is present. To determine if external sources are causing the intermodulation distortion, you can use a single-frequency signal. If the display on the spectrum analyzer does not show the single frequency, then intermodulation distortion is present.

Intermodulation distortion cannot be entirely suppressed, but it can be minimized by shielding components and circuitry, parasitic suppression circuitry, and antenna spacing. These factors are incorporated in the design of the system and are tested during production. Any shields or parasitic suppressors that are removed by the technician must be replaced before troubleshooting and/or repair can be effective. Antenna locations also pose a consideration when installing a new system. Ship alteration specifications must be observed when new antenna systems are being installed.

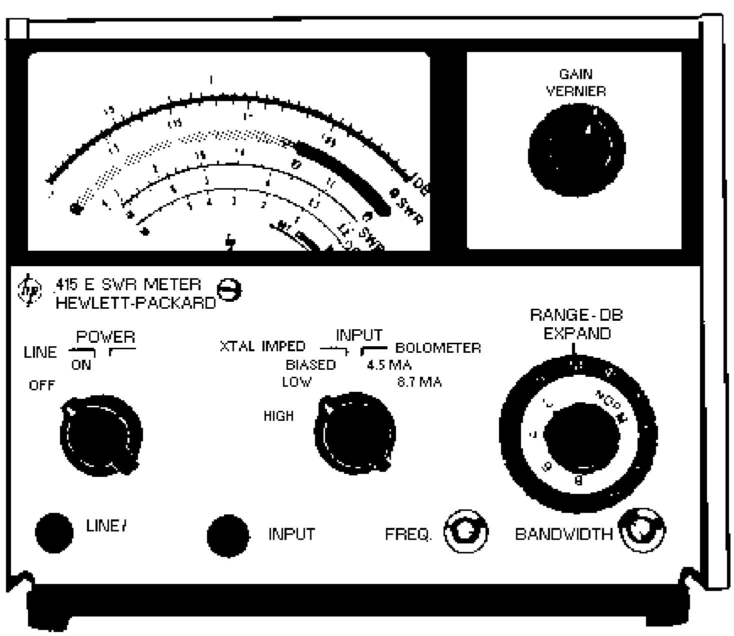
Q-8. When you are testing a piece of equipment for intermodulation distortion, what should the output of the equipment look like?

SUMMARY

The important points of this chapter are summarized in the following paragraphs:

STANDING WAVES are the result of an impedance mismatch between a transmission line and its load. If a transmission line is not properly terminated, it will cause a percentage of the transmitter power to be reflected back to the source. The reflected wave or standing wave will increase in magnitude as the mismatch becomes greater.

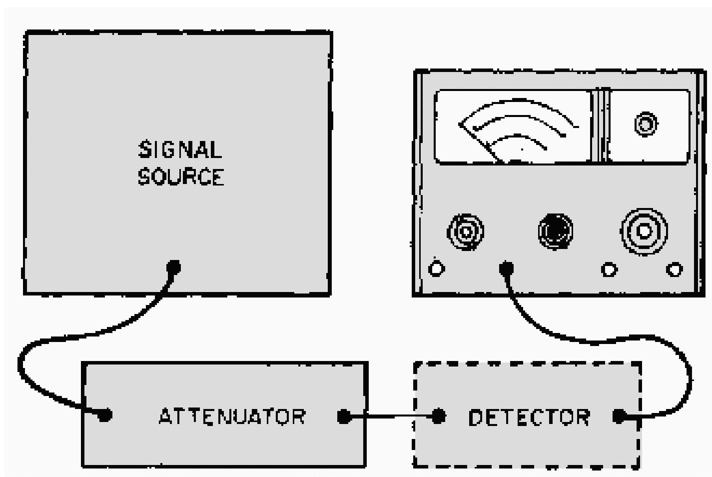
VSWR refers to the voltage ratio of the incident wave (that which is transmitted to the load) and the reflected wave (that which is reflected by the load back to the transmitter). An ideal vswr is considered to be 1 to 1.



Standing waves that are present on a transmission line can be used to determine the **TRANSMITTER FREQUENCY**. Voltage or current peaks are present at half-wavelength intervals. By measuring the distance between peaks, you can compute frequency mathematically.

TWO-WIRE, PARALLEL TRANSMISSION LINES are usually tested for standing waves with test devices that are inductively coupled to the line. These test devices vary greatly in their complexity, ranging from bridge circuits to simple neon lamps.

INSERTION LOSS MEASUREMENTS are performed by injecting a signal of a known amplitude into a transmission line and then monitoring the signal at the far end of the cable with a power meter. Loss measurements must be taken at various frequencies to determine if the transmission line is good across its frequency range.



The most common cause of **INTERMODULATION DISTORTION** is improper spacing of transmitters and receivers. CROSS MODULATION is common to equipment that is misaligned. Intermodulation distortion can be tested by injecting two signals (different frequencies) into a piece of equipment and then monitoring its output for distortion using a spectrum analyzer. Intermodulation distortion is usually caused by improper antenna spacing or by poorly shielded components or circuits.

A-6. No.

A-7. Close spacing of transmitters and receivers.

A-8. An exact reproduction of the input.

CHAPTER 5

INTRODUCTION TO WAVEFORM INTERPRETATION

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to do the following:

1. Explain the use of waveform interpretation in testing applications.
2. Identify the different types of modulation and methods of measuring modulation.
3. Explain the various uses of spectrum analyzers.
4. Explain the various uses of time-domain reflectometers.
5. Identify the various tests that can be performed with the swept-frequency technique.

INTRODUCTION TO WAVEFORM INTERPRETATION

Measurements performed with oscilloscopes, time-domain reflectometers, and spectrum analyzers enable you to view the signal produced by the equipment or circuit under test. However, a visual display is of no value unless you are able to interpret the signal characteristics.

A displayed waveform is a representation of a varying signal related to time. You can graphically plot an unknown waveform by using a system of coordinates in which the amplitude of the unknown signal is plotted linearly against time. An analysis of the resultant waveform provides you with valuable information in determining the characteristics of many electronic (and some mechanical) devices. For example, the waveform of a signal may indicate the presence of harmonics or parasitic oscillations, or it may indicate how closely a device is following a desired cycle of operation. As the parts in an amplifier begin to shift in value or deteriorate, waveform distortion often occurs and indicates abnormal operation of a circuit and often precedes circuit breakdown. Malfunctioning of electrical or electronic circuits within equipment can usually be traced, by waveform inspection, to a specific part or parts of the circuit responsible for the distorted signal. On the basis of these facts, it is apparent that there is an important need for test equipment that can provide a visual presentation of a waveform at the instant of its occurrence in a circuit.

DISTORTION is a term used by technicians and engineers alike that generally signifies dissatisfaction with the shape of the wave processed by an amplifier. Distortion of a waveform is the undesired change or deviation in the shape of the observed signal with respect to a reference waveform. Classifying any waveform as a *distorted* wave without reference to the electronic circuitry involved is meaningless. A waveform that can be validly termed distorted with respect to a specific amplifier circuit may be the normal waveform to be expected from another amplifier circuit. One of the most important steps in waveform analysis, the one that usually proves the most difficult for the maintenance personnel, is the interpretation of patterns viewed on the test equipment.

This chapter will cover some of the basic test methods and practices associated with waveform interpretation.

MODULATION MEASUREMENTS

Modulation measurements are sometimes required during tuning procedures to adjust transmitting equipment for the proper amount of modulation. During maintenance tests of modulated transmitter equipment, you should determine the amount of distortion in the output signal and the modulation level or index. The modulation level in multiplexing equipment is usually set at the factory or during corrective maintenance procedures. Proper adjustment of the input signal level and automatic signal-level regulation circuits provides the correct amount of modulation. Defects in modulation circuits of a transmitter can be detected by measurements of the quality of the received signals at the receiver. Corrective maintenance analysis of multiplex equipment modulation circuits can usually be made by signal-level measurements.

Some radio transmitters, when operating in the AM mode, must be adjusted for correct modulation during normal tuning procedures. If the modulation level is low, the transmitter is not operating at its maximum efficiency. On the other hand, modulation in excess of 100% produces serious distortion. Since neither of these conditions is desirable, amplitude modulation should be maintained between 60% and 95% when possible. The modulation level or index of AM and fm radio transmitters that operate in the vhf range is initially adjusted by the manufacturer or during corrective maintenance. The amplifier gain of the modulator can be initially adjusted by reference to the modulation meter provided on the front panel of the equipment.

Pulse modulation of radar and radio beacon signals can be measured by waveform displays presented on a standard oscilloscope. The amount of usable energy in a pulsed waveform, as measured by a spectrum analyzer, is also an indication of the pulse modulation quality.

Attaining 100% amplitude modulation of an rf carrier with a sine wave requires a modulating power equal to one-half of the rf carrier power. Under this condition, the average power of the modulated carrier is equal to 1.5 times the average unmodulated carrier power. The added power is divided equally between the upper and lower sidebands. During the peaks of 100% modulation, the amplitude of the carrier is doubled. This will cause the instantaneous peak power to be four times the instantaneous unmodulated peak power $P = E^2/R$. When voice modulation is employed, only the highest amplitude peaks can be allowed to modulate the carrier 100%. Since many speech components do not modulate the carrier 100%, the average power required for voice modulation is less than that required for modulation with a sine wave. Voice peaks usually modulate a carrier 100% when the modulation increases the average carrier output power 25% over its normal value.

Q-1. What is the result of overmodulating an AM signal?

Q-2. For AM transmissions, the carrier is normally modulated within what range?

AMPLITUDE-MODULATION MEASUREMENTS

An increase in the power output of an AM transmitter is indicated by an increase in antenna current. The increase can be taken as a measure of the degree of modulation and can be expressed as a percentage, as shown in figure 5-1. The graph for this figure was developed from the relationship existing between the carrier power and the increased power resulting from the added modulation power. The formula for calculating the PERCENTAGE of MODULATION is as follows:

$$\text{Percentage of modulation} = \frac{100\ (E_{max} - E_0}{E_0}$$

Where:

E_{max} = the highest peak voltage

E_0 = the unmodulated carrier voltage

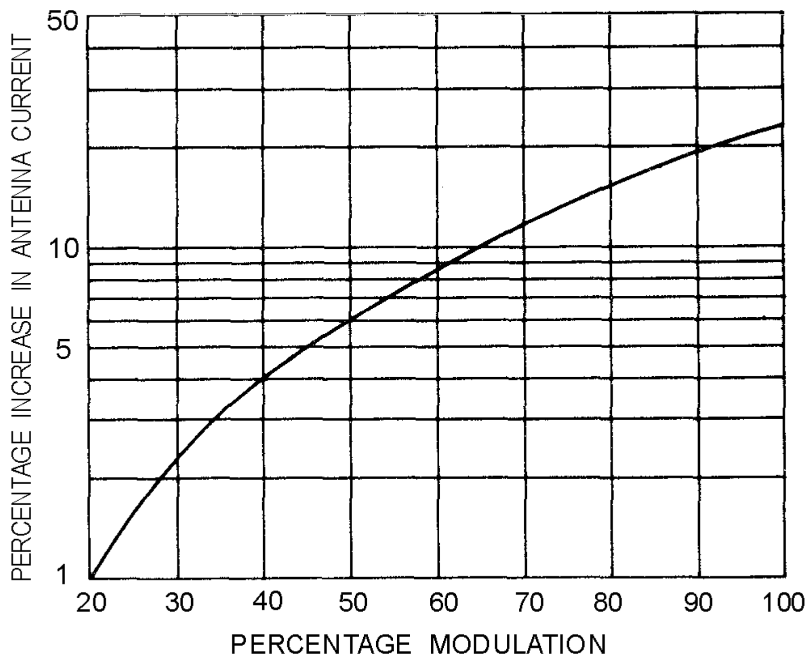

Figure 5-1.—Antenna current increase with amplitude modulation.

The use of this formula is based on the assumption that the modulating voltage is a pure sine wave. Normal broadcasting, however, is characterized by complex envelope patterns, as illustrated in figure 5-2. In this light, the previous formula is not so clear. Consequently, the preceding formula should be viewed more correctly as the PERCENTAGE OF POSITIVE PEAK MODULATION. When the minimum voltage (E_{min}) rather than the peak voltage (E_{max}) is used to compute percentage of modulation, the computed percentage (shown below) is the PERCENTAGE OF NEGATIVE PEAK MODULATION:

$$\text{negative peak percentage of modulation} = \frac{100(E_0 - E_{min})}{E_0}$$

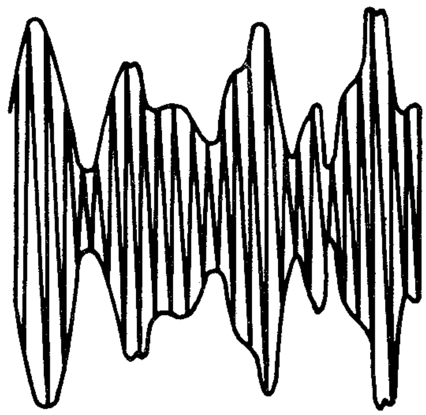

Figure 5-2.—Rf carrier amplitude-modulated by a complex wave envelope.

Since the preceding two modulation percentages often differ, you should define the AVERAGE PERCENTAGE OF MODULATION, as shown below (refer to fig. 5-3):

$$\text{average percentage of modulation} = \frac{100\ E_{max} - E_{min}}{2 \times E_o}$$

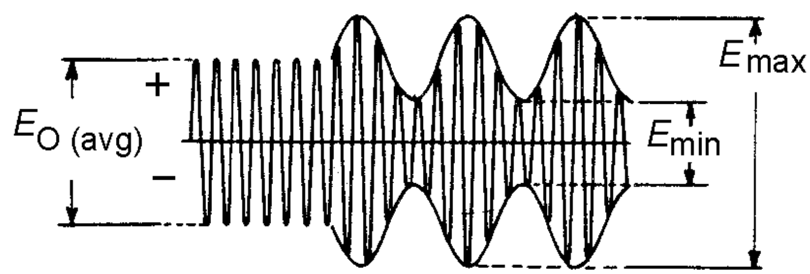

Figure 5-3.—Rf amplitude percentage modulation wave envelope.

From the preceding definitions of percentage of modulation, you should note that methods of *measuring* all three types of modulation percentages must be devised. When differing values are obtained, however, the cause may not necessarily be directly related to unequal positive and negative peaks of a complex modulation wave. Another possibility is distortion caused by carrier shift. Distortion may also be produced by effects other than the modulation process — for example, parasitic oscillation, nonlinear radio-frequency amplification of modulated signals, and distortion present in the audio amplifiers.

Unfortunately, continuous variations in the percentage of modulation create a number of additional problems. For example, damping is necessary so that a meter can provide an average reading despite fluctuations. An average reading, on the other hand, will not disclose the presence of transient overmodulation. This shortcoming is serious because of the large number of sideband frequencies produced in addition to the normal ones whenever overmodulation occurs. Not only do these extra frequencies interfere drastically with other transmissions, but they also may significantly distort the modulation signal. These considerations account for the importance of using a meter that responds to modulation peak; specifically, both positive-peak and negative-peak overmodulation must be indicated. Positive-peak overmodulation occurs when the *positive* modulation exceeds 100%; negative-peak overmodulation occurs when the *negative* modulation exceeds 100%.

Oscilloscope Measurement Methods

The oscilloscope is widely used as an amplitude-modulation monitor and measuring instrument. Since it is capable of presenting visual indications of the modulated output of AM transmitters, the oscilloscope is reliable for detecting overmodulation and determining the percentage of modulation. For example, the relative error of most measurements taken with a 5-inch crt is about 10%. Although such accuracy is adequate for many maintenance checks, the oscilloscope is usually considered more valuable as a monitor of general modulation conditions. It is also used to monitor the amplitude-modulated output of a radio transmitter when photographic records are desired.

Types of Modulation Display

Two types of modulation patterns are provided by the oscilloscope, depending upon the hookup used. These patterns are the WAVE-ENVELOPE PATTERNS, as shown in figures 5-2 and 5-3, and the TRAPEZOIDAL PATTERN, as shown in figure 5-4.

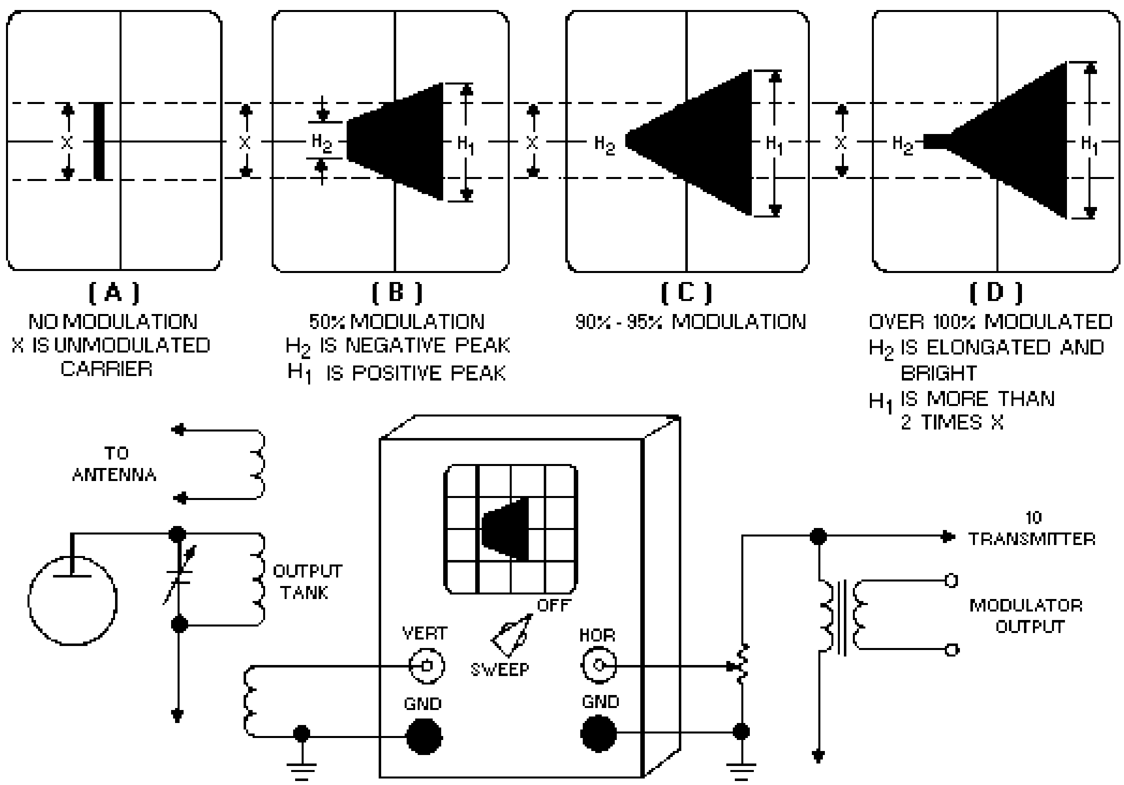

Figure 5-4.—Trapezoidal modulation patterns.

Figure 5-2 shows an oscilloscope presentation of an rf carrier that is amplitude-modulated by a complex wave, such as that of speech. Figures 5-4 and 5-5 show the effects of over 100% modulation on the carrier wave. The carrier wave envelope pattern (as shown in fig. 5-3) is obtained by applying the rf-modulated wave to the vertical input of the oscilloscope. The trapezoidal pattern is obtained in a similar manner except that the modulation signal from the transmitter is used to horizontally sweep the oscilloscope (instead of having the sweep signal generated internally by the oscilloscope). Both methods are limited by the frequency response of the oscilloscope; therefore, these methods find greater applicability in the lf to hf ranges.

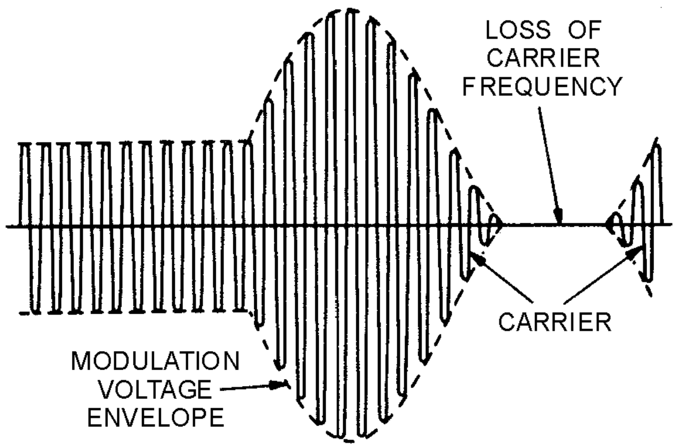

Figure 5-5.—Overmodulated rf carrier.

VHF AND UHF MEASUREMENTS

In the vhf and uhf ranges, modulation is normally measured by applying a specific-level, 1-kilohertz tone to the input of the modulator. This, in turn, produces a significant drop in the plate voltage of the final output stage of the modulator. The correct setting of output plate voltage ensures that overmodulation will not occur.

SINGLE-SIDEBAND MEASUREMENTS

Single-sideband modulation is a form of amplitude modulation in which only one sideband is transmitted with a suppressed carrier. Since balanced modulators are used to provide carrier cancellation, the exact balancing of the carriers to provide cancellation requires a null adjustment. The null can be observed and adjusted by using either a detector and an indicator, such as a voltmeter, or an oscilloscope for observation of the output while tuning the transmitter.

Measurements peculiar to sideband technology also include special modulation-amplitude and modulation-distortion checks. If the sideband modulator is overdriven or mistuned or the associated linear amplifiers are improperly loaded or overdriven, spurious output frequencies are produced. These are harmonically related to the driving signals and can cause splatter over a large range of frequencies, thus causing interference to other transmitting stations.

To determine the proper amplitude so that the modulation will not cause distortion or splatter, you use the audio two-tone modulation test. The resulting signals are shown in views A, B, and C of figure 5-6. The two-tone test is used for initial adjustment and for precise checking because it will indicate distortion. The two-tone test corresponds to the wave envelope method of AM modulation checking. Two signals of equal amplitude but of slightly different frequencies beating together are applied to the sideband modulator input to produce a single tone of approximately 1,000 hertz. On an oscilloscope, the output appears as a series of fully modulated sine waves and is similar to a 100-percent-amplitude-modulated waveform, as shown in view A. A spectrum analyzer presentation is shown in view B.

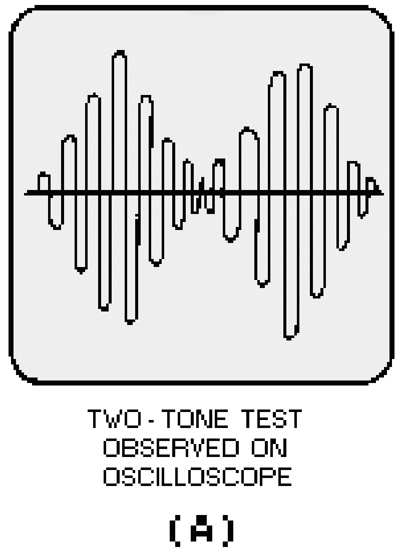

Figure 5-6A.—Examples of ideal two-tone test waveforms.

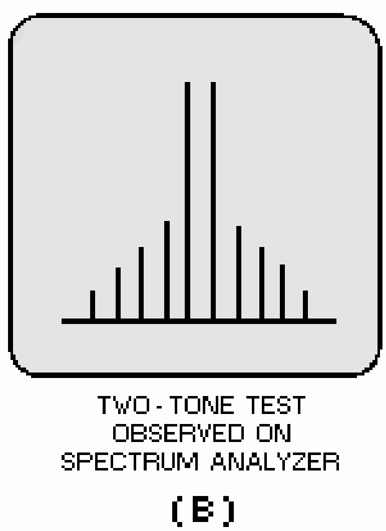

Figure 5-6B.—Examples of ideal two-tone test waveforms.

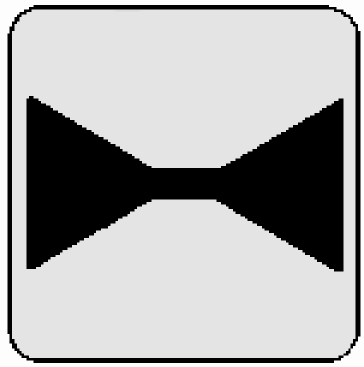

Figure 5-6C.—Examples of ideal two-tone test waveforms.

When the trapezoidal method is used, two opposed triangles appear on the oscilloscope, as shown in figure 5-6, view C. When equally balanced modulators are used, the triangles are mirror images. Elliptical or straight-line patterns appear when the phase-distortion check is used.

It is also possible to make a rough operating adjustment by varying the audio drive from the microphone so that on peak swings a definite value of final plate current is not exceeded. This check depends upon the initial accuracy of calibration and response characteristics of the ammeter in the final stage, as well as other factors.

FREQUENCY MODULATION

In frequency modulation, the carrier amplitude remains constant, and the output frequency of the transmitter is varied about the carrier (or mean) frequency at a rate corresponding to the audio frequencies. The extent to which the frequency changes in one direction from the unmodulated (carrier) frequency is called the FREQUENCY DEVIATION.

Deviation in frequency is usually expressed in kilohertz. It is equal to the difference between the carrier frequency and either the highest or lowest frequency reached by the carrier in its excursions with modulation. There is no modulation percentage in the usual sense. With suitable circuit design, the frequency deviation may be made as large as desired without encountering any adverse effects that are equivalent to the overmodulation in amplitude-modulation transmissions. However, the maximum permissible frequency deviation is determined by the width of the band assigned for station operation.

In frequency modulation, the equivalent of 100% modulation occurs when the frequency deviation is equal to a predetermined maximum value. There are several methods of measuring the modulation in frequency-modulated transmissions.

The frequency-deviation measurement of a frequency-modulated signal is normally performed with either a spectrum analyzer or with a modulation analyzer. The modulation analyzer method is more commonly used because of its accuracy. Typical accuracies for a modulation analyzer are within ±1%. Figure 5-7 shows a typical modulation analyzer.

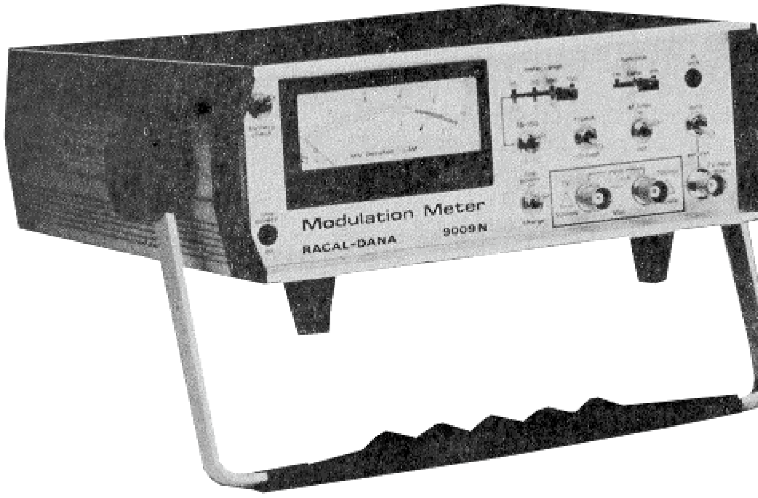

Figure 5-7.—Typical modulation analyzer.

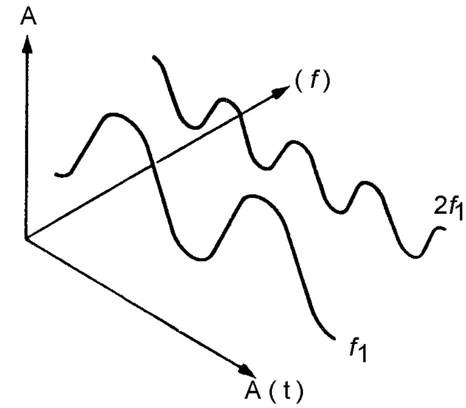
Q-3. What is meant by frequency deviation?

SPECTRUM WAVEFORM ANALYSIS AND MEASUREMENTS

An analysis of a complex waveform, prepared in terms of a graphic plot of the amplitude versus frequency, is known as SPECTRUM ANALYSIS. Spectrum analysis recognizes the fact that waveforms are composed of the summation of a group of sinusoidal waves, each of an exact frequency and all existing together simultaneously.

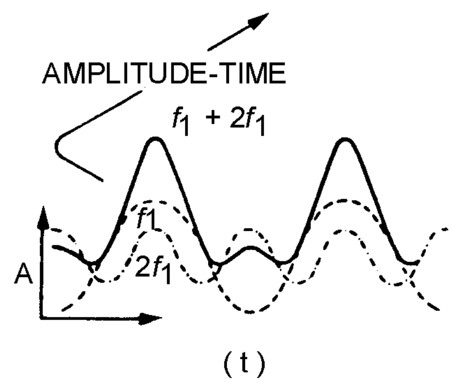
Three axes of degree (amplitude, time, and frequency) are important when considering varying frequency. The time-domain (amplitude versus time) plot is used to consider phase relationships and basic timing of the signal and is normally observed with an oscilloscope. The frequency-domain (amplitude versus frequency) plot is used to observe frequency response - the spectrum analyzer is used for this purpose. Figure 5-8 illustrates the differences between frequency- and time-domain plots. View A illustrates a three-dimensional coordinate of a fundamental frequency (f_1) and its second harmonic ($2f_1$) with respect to time, frequency, and amplitude. View B shows the time-domain display as it would be seen on an oscilloscope. The solid line, $f_1 + 2f_1$ is the actual display. The dashed lines, f and $2f_1$ are drawn to illustrate the fundamental and second harmonic frequency relationship used to formulate the composite signal $f_1 + 2f_1$. View C is the frequency-domain display as it would be seen on a spectrum analyzer. Note in view C that the components of the composite signal are clearly seen.

Q-4. A spectrum analyzer is designed to display what signal characteristic?



(A)

Figure 5-8A.—Time versus frequencies.



(B)

Figure 5-8B.—Time versus frequencies.

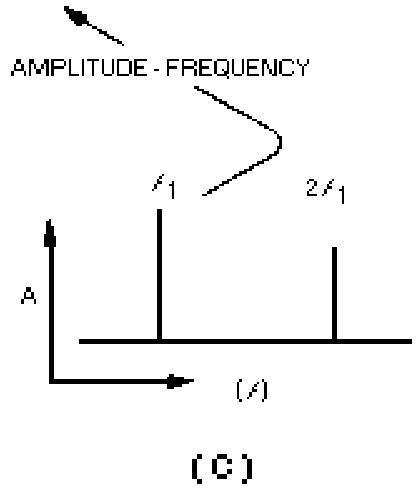


Figure 5-8C.—Time versus frequencies.

FREQUENCY-DOMAIN DISPLAY CAPABILITIES

The frequency domain contains information not found in the time domain. The spectrum analyzer can display signals composed of more than one frequency (complex signals). It can also discriminate between the components of the signal and measure the power level at each one. It is more sensitive to low-level distortion than an oscilloscope. Its sensitivity and wide, dynamic range are also useful for measuring low-level modulation, as illustrated in views A and B of figure 5-9. The spectrum analyzer is useful in the measurement of long- and short-term stability such as noise sidebands of an oscillator, residual fm of a signal generator, or frequency drift of a device during warm-up, as shown in views A, B, and C of figure 5-10.

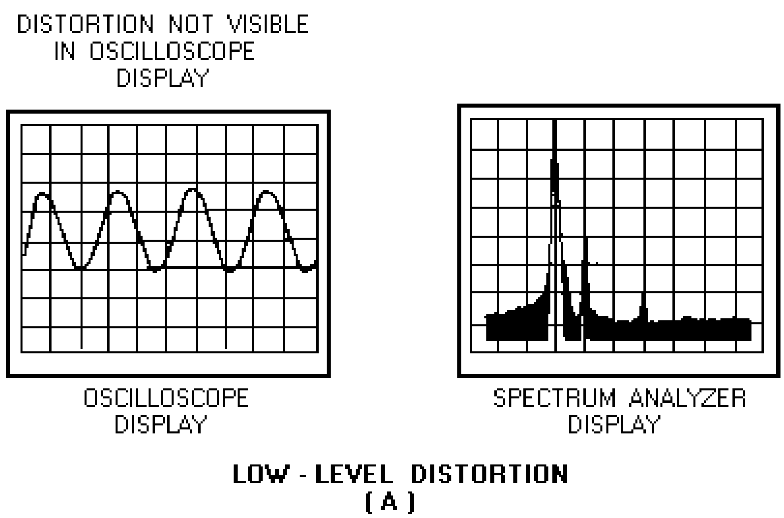

Figure 5-9A.—Examples of time-domain (left) and frequency-domain (right) low-level signals.

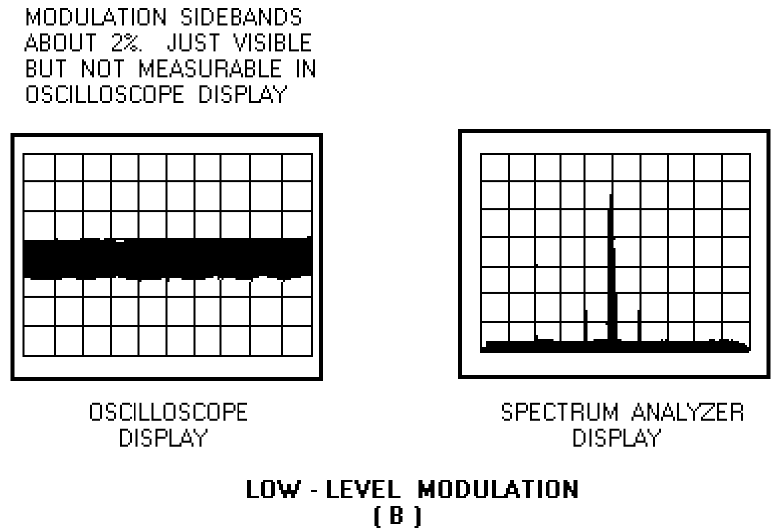

Figure 5-9B.—Examples of time-domain (left) and frequency-domain (right) low-level signals.

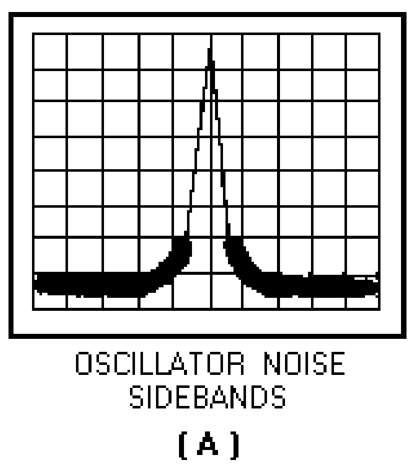

Figure 5-10A.—Spectrum analyzer stability measurements.

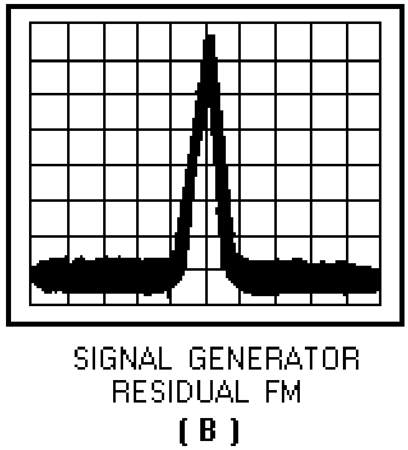

Figure 5-10B.—Spectrum analyzer stability measurements.

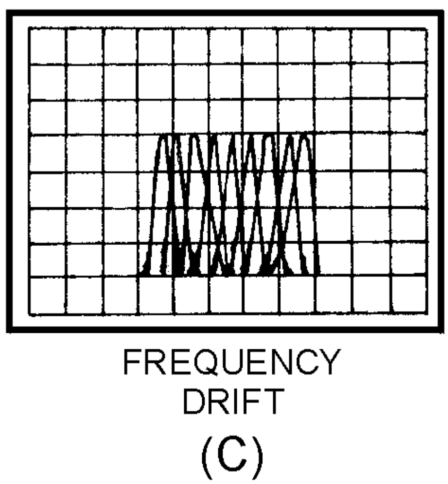

Figure 5-10C.—Spectrum analyzer stability measurements.

The swept-frequency response of a filter or amplifier and the swept-distortion measurement of a tuned oscillator are also measurable with the aid of a spectrum analyzer. However, in the course of these measurements, a variable persistence display or an X-Y recorder should be used to simplify readability. Examples of tuned-oscillator harmonics and filter response are illustrated in figure 5-11. Frequency-conversion devices such as mixers and harmonic generators are easily characterized by such parameters as conversion loss, isolation, and distortion. These parameters can be displayed, as shown in figure 5-12, with the aid of a spectrum analyzer.

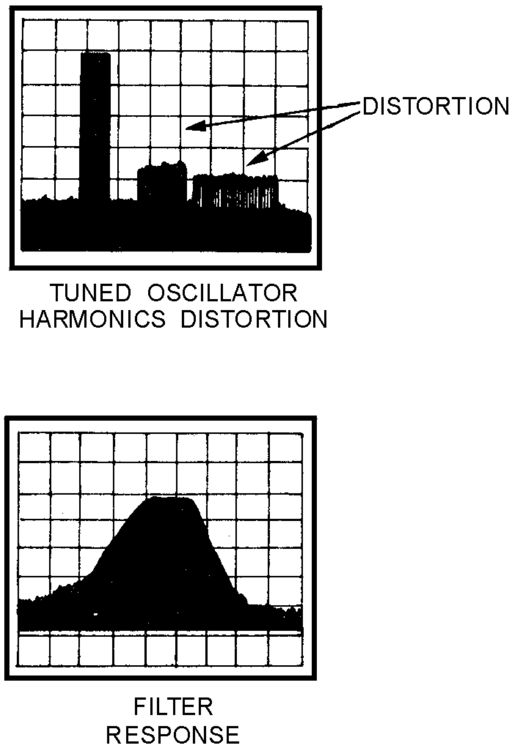

Figure 5-11.—Swept-distortion and response characteristics.

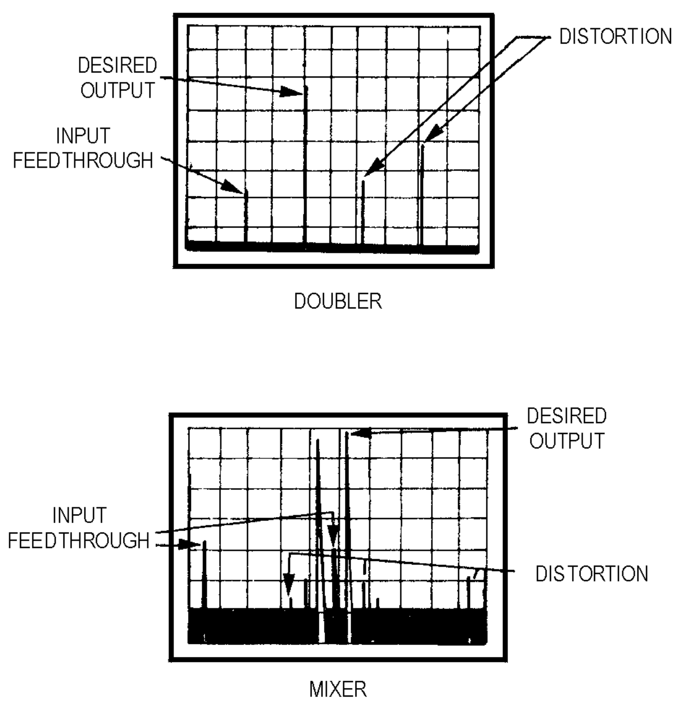

Figure 5-12.—Frequency-conversion characteristics.

Present-day spectrum analyzers can measure segments of the frequency spectra from 0 hertz to as high as 300 gigahertz when used with waveguide mixers.

SPECTRUM ANALYZER APPLICATIONS

Figure 5-13 shows a typical spectrum analyzer. The previously mentioned measurement capabilities can be seen with a spectrum analyzer. However, you will find that the spectrum analyzer generally is used to measure spectral purity of multiplex signals, percentage of modulation of AM signals, and modulation characteristics of fm and pulse-modulated signals. The spectrum analyzer is also used to interpret the displayed spectra of pulsed rf emitted from a radar transmitter.

33NP0180

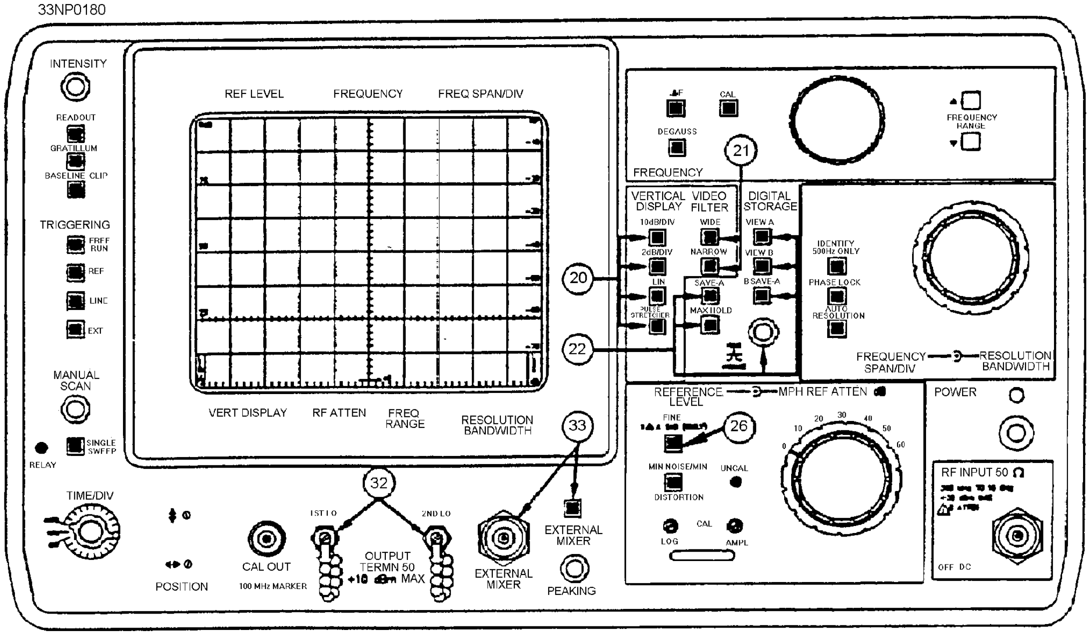

Figure 5-13.—Typical spectrum analyzer.

COMPLEX WAVEFORMS

Complex waveforms are divided into two groups, PERIODIC WAVES and NONPERIODIC WAVES. Periodic waves contain the fundamental frequency and its related harmonics. Nonperiodic waves contain a continuous band of frequencies resulting from the repetition period of the fundamental frequency approaching infinity and thereby creating a continuous frequency spectrum.

MODULATION MEASUREMENTS

In all types of modulation, the carrier is varied in proportion to the instantaneous variations of the modulating waveform. The two basic properties of the carrier available for modulation are the AMPLITUDE CHARACTERISTIC and ANGULAR (frequency or phase) CHARACTERISTIC.

Amplitude Modulation

The modulation energy in an amplitude-modulated wave is contained entirely within the sidebands. Amplitude modulation of a sinusoidal carrier by another sine wave would be displayed as shown in figure 5-14. For 100% modulation, the total sideband power would be one-half of the carrier power; therefore, each sideband would be 6 dB less than the carrier, or one-fourth of the power of the carrier. Since the carrier component is not changed with AM transmission, the total power in the 100-percent-modulated wave is 50% higher than in the unmodulated carrier. The primary advantage of the log display that is provided by the spectrum analyzer over the linear display provided by the oscilloscopes for percentage of modulation measurements is that the high dynamic range of the spectrum analyzer (up to 70 dB) allows accurate measurements of values as low as 0.06%. It also allows the measurements of low-level distortion of AM signals. Both capabilities are illustrated in figure 5-15, view A, view B, and view C. The chart in figure 5-16 provides an easy conversion of dB down from carrier into percentage of modulation.

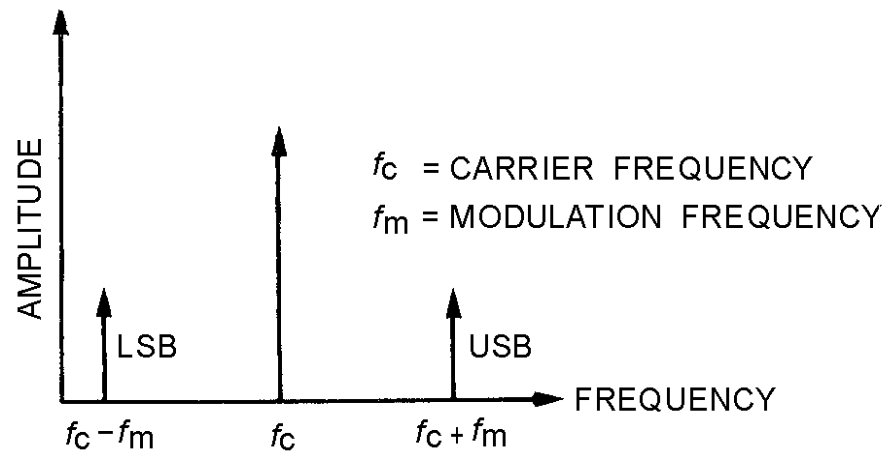

Figure 5-14.—Spectrum analyzer display of an AM signal.

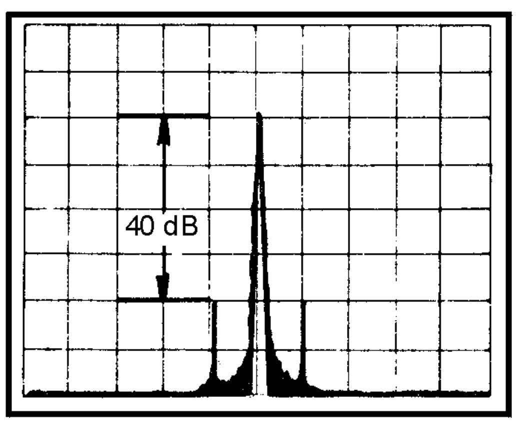

2% MODULATION
SIDEBANDS 40 dB DOWN

(A)

Figure 5-15A.—Spectrum analyzer displays of AM signals.

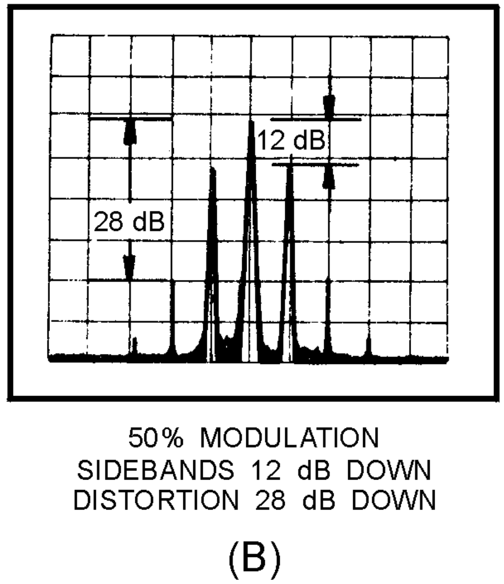

Figure 5-15B.—Spectrum analyzer displays of AM signals.

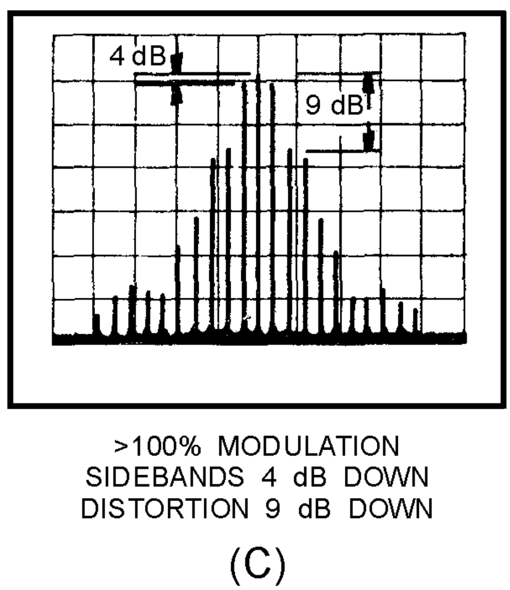

Figure 5-15C.—Spectrum analyzer displays of AM signals.

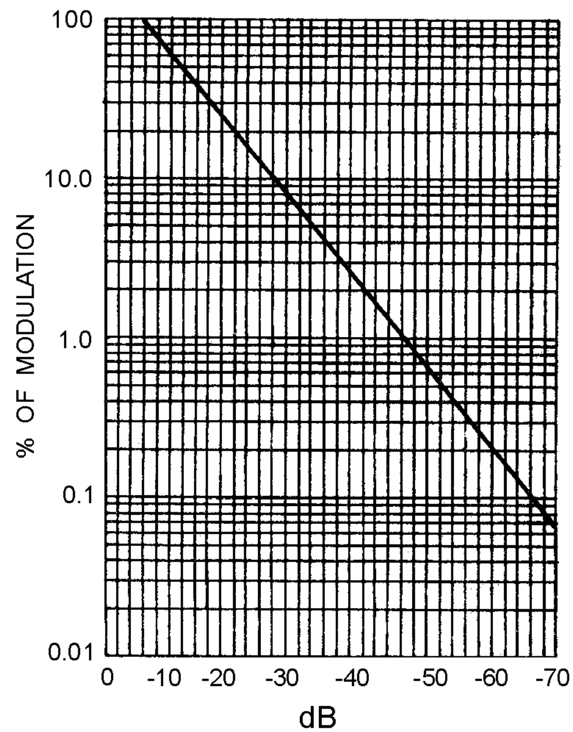

Figure 5-16.—Modulation percentage versus sideband levels.

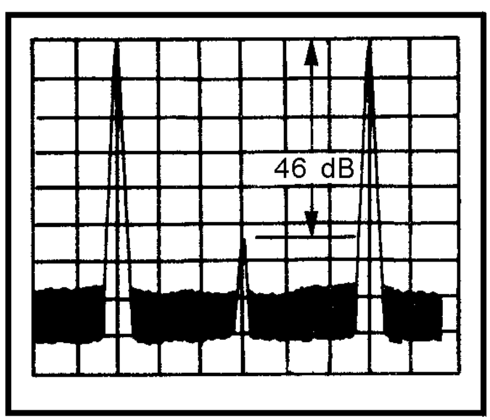
NOTE: Anything greater than -6 dB exceeds 100% modulation and produces distortion, as shown in figure 5-16.

In modern, long-range hf communications, the most important form of amplitude modulation is ssb (single-sideband). In ssb either the upper or lower sideband is transmitted, and the carrier is suppressed. Ssb requires only one-sixth of the output power required by AM to transmit an equal amount of intelligence power and less than half the bandwidth. Figure 5-17 shows the effects of balancing the carrier of an AM signal. The most common distortion experienced in ssb is intermodulation distortion, which is caused by nonlinear mixing of intelligence signals. The two-tone test is used to determine if any intermodulation distortion exists. Figure 5-18 illustrates the spectrum analyzer display of the two-tone test with the modulation applied to the upper sideband input.



CARRIER BALANCE 46 dB

Figure 5-17.—Double sideband carrier suppressed.

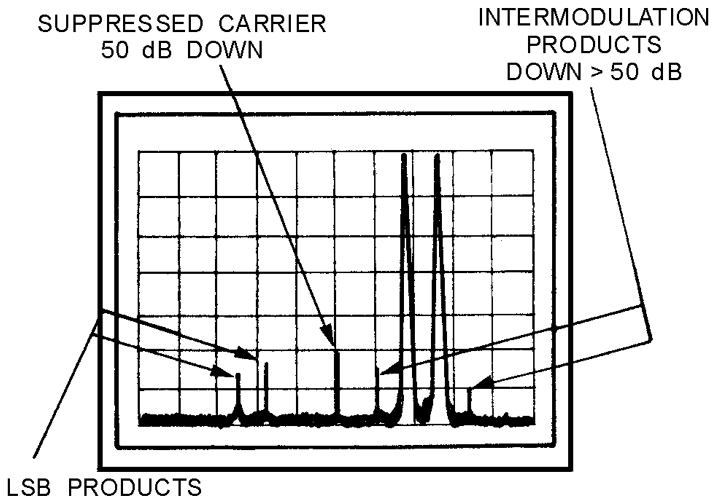


Figure 5-18.—Two-tone test.

Q-5. What is the advantage of single-sideband (ssb) transmission over AM transmission?

Frequency Modulation

In frequency modulation, the instantaneous frequency of the radio-frequency wave varies with the modulation signal. As mentioned in NEETS, module 12, the amplitude is kept constant. The number of times per second that the instantaneous frequency varies from the average (carrier frequency) is controlled by the frequency of the modulating signal. The amount by which the frequency departs from the average is controlled by the amplitude of the modulating signal. This variation is referred to as the FREQUENCY DEVIATION of the frequency-modulated wave. We can now establish two clear-cut rules for frequency deviation rate and amplitude in frequency modulation:

- Amount of frequency shift is proportional to the amplitude of the modulating signal.

(This rule simply means that if a 10-volt signal causes a frequency shift of 20 kilohertz, then a 20-volt signal will cause a frequency shift of 40 kilohertz.)

- Rate of frequency shift is proportional to the frequency of the modulating signal.

(This second rule means that if the carrier is modulated with a 1-kilohertz tone, then the carrier is changing frequency 1,000 times each second.)

The amplitude and frequency of the signal used to modulate the carrier will determine both the number of significant sidebands (shown in fig. 5-19) and the amplitude of the sidebands (shown in fig. 5-20). Both the number of significant sidebands and the bandwidth increase as the frequency of the modulating signal increases.

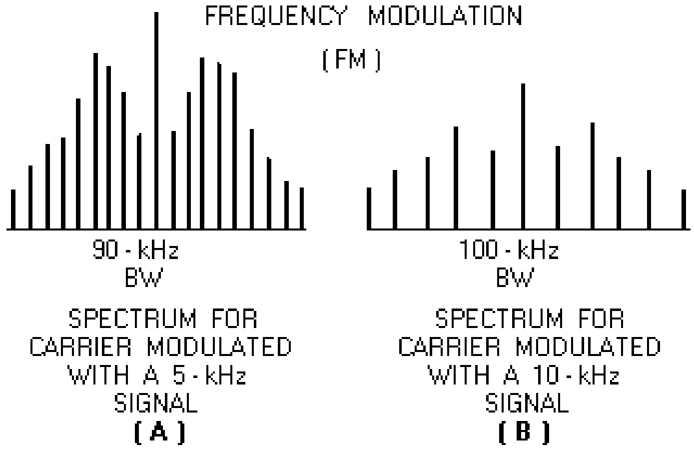

Figure 5-19.—Distribution of sidebands.

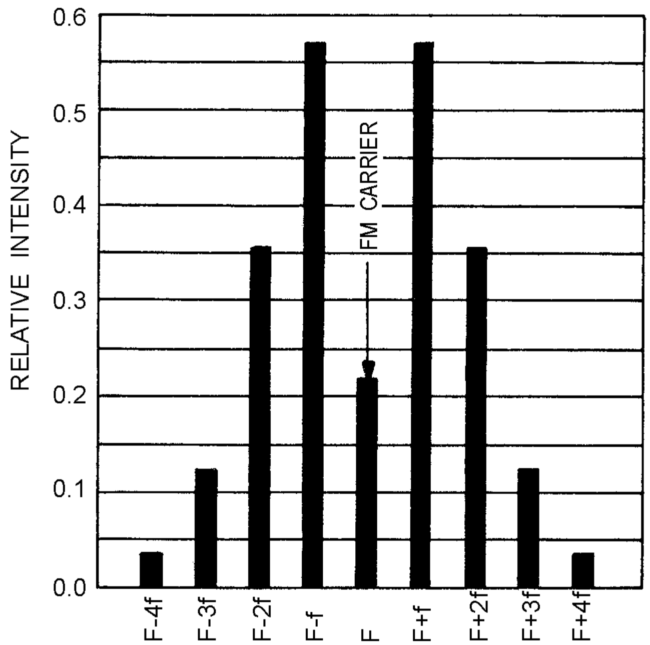

Figure 5-20.—Spectrum distribution for a modulation index of 2.

NEETS, module 12, should be consulted for an in-depth discussion of frequency-modulation principles.

Q-6. What happens to an fm signal as you increase the frequency of the modulating signal?

PULSED WAVES

An ideal pulsed radar signal is made up of a train of rf pulses with a constant repetition rate, constant pulse width and shape, and constant amplitude. To receive the energy reflected from a target, the radar receiver requires almost ideal pulse radar emission characteristics. By observing the spectra of a pulsed radar signal, you can easily and accurately measure such characteristics as pulse width, duty cycle, and peak and average power. The principles of radar are covered in NEETS, Module 18, *Radar Principles*, which can be consulted for an explanation of pulsed waves.

Rectangular Pulse

A rectangular wave is used to pulse-modulate the constant frequency rf carrier to produce the pulse radar output. The rectangular wave is made up of a fundamental frequency and its combined odd and even harmonics. Figure 5-21 shows the development of a rectangular wave.

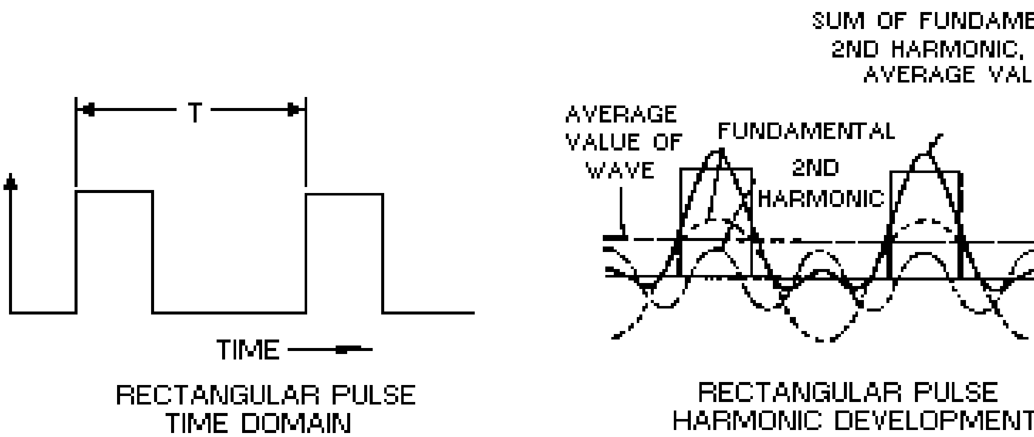

Figure 5-21.—Rectangular pulse.

Pulsed Wave Analysis

In amplitude modulation, sidebands are produced above and below the carrier frequency. A pulse is also produced above and below the carrier frequency, but the pulse is made up of many tones. These tones produce multiple sidebands that are commonly referred to as SPECTRAL LINES, or RAILS, on the spectrum analyzer display. Twice as many rails will be in the pulse-modulated output of the radar as there are harmonics contained in the modulating pulse (upper and lower sidebands), as shown in figure 5-22. In the figure, the pulse repetition frequency (prf) is equal to the pulse interval of 1/T. The actual spectrum analyzer display would show the lower lobes (shown below the reference line in the figure) on top because the spectrum analyzer does not retain any polarity information. Changing the pulse interval, or pulse width, of the modulation signal will change the amount of rails (prf), or number of lobe minima, as illustrated in figure 5-23.

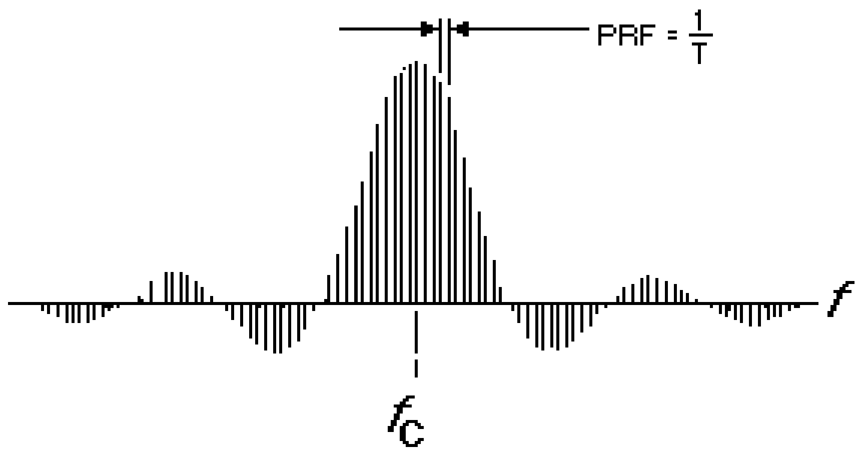

Figure 5-22.—Pulsed radar output.

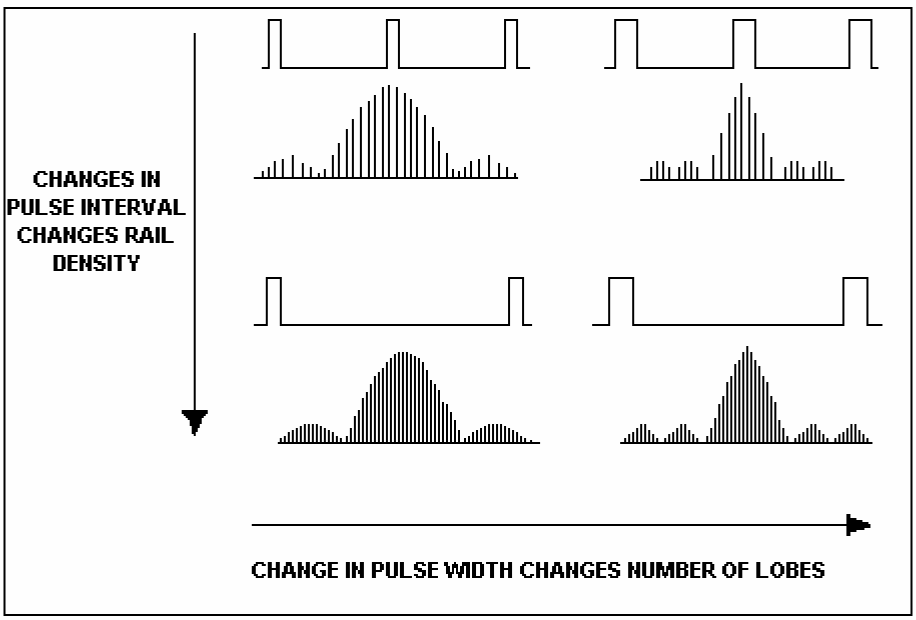

Figure 5-23.—Pulsed radar changes caused by modulating signal changes.

ANALYZING THE SPECTRUM PATTERN

The leading and trailing edges of the radiated pulse-modulated signal must have a sharp rise time and decay time and a constant amplitude between them. Incorrect pulse shape will cause frequency spread and pulling, which results in less available energy at the frequency to which the receiver is tuned. The primary reason for analyzing the spectrum is to determine the exact amount of amplitude and frequency modulation present. The amount of amplitude modulation determines the increase in the number of sidebands within the applied pulse spectrum; an increase in frequency modulation increases the amplitude of the side-lobe frequencies. In either case, the energy available to the main spectrum lobe is decreased.

SPECTRUM ANALYZER OPERATION

The information desired from the spectra to be analyzed determines the SPECTRUM ANALYZER requirements. Real-time analysis is used if a particular point in the frequency spectrum is to be analyzed, such as a line spectra display. Continuous- or swept-frequency analysis, which is the most common mode of observation, is used to display a wider portion of the frequency spectrum or (in some cases) the entire range of the spectrum analyzer in use. Changing the spectrum analyzer setting from one mode to another is accomplished by varying the scan time and the bandwidth of the spectrum analyzer or a combination of the two. Most real-time spectrum analyzers, however, are preceded by mechanical filters, which limit the input bandwidth of the spectrum analyzer to the desired spectra to be analyzed. Tunable- or swept-spectrum analyzers function basically the same as heterodyne receivers, the difference being that the local oscillator is not used but is replaced by a voltage-controlled oscillator (vco). The vco is swept electronically by a ramp input from a sawtooth generator. The output of the receiver is applied to a crt, which has its horizontal sweep in synchronization with the vco. The lower frequency appears at the left of the crt display. As the trace sweeps to the right, the oscillator increases in frequency. Figure 5-24 is a block diagram of a heterodyne spectrum analyzer.

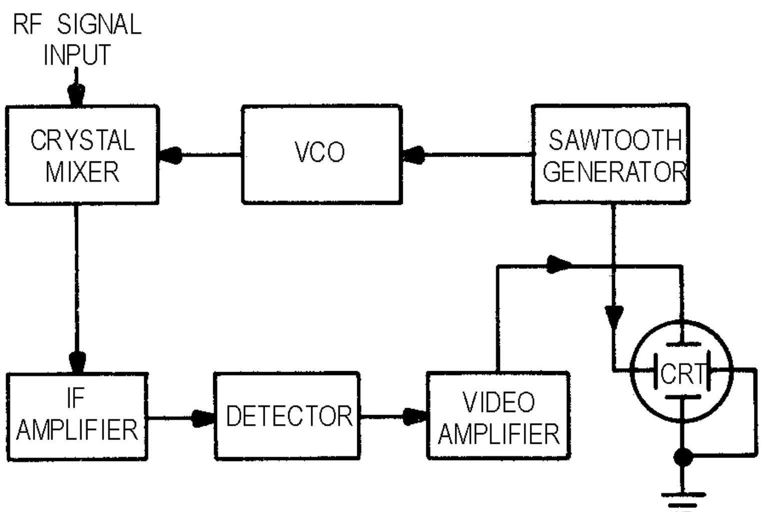

Figure 5-24.—Block diagram of a heterodyne spectrum analyzer.

Before the frequency of a signal can be measured on a spectrum analyzer, it must be RESOLVED. Resolving a signal means distinguishing it from other signals near it. Resolution is limited by the narrowest bandwidth of the spectrum analyzer because the analyzer traces out its own IF bandwidth shape as it sweeps through a signal. If the narrowest bandwidth is 1 kilohertz, the nearest any two signals can be, and still be resolved, is 1 kilohertz. Reducing the IF bandwidth indefinitely would obtain infinite resolution except that the usable IF bandwidth is limited by the stability of the spectrum analyzer. The smaller the IF bandwidth, the greater the capability of the analyzer to resolve closely spaced signals of unequal amplitudes. Modern spectrum analyzers have been refined to the degree that IF bandwidths are less than 1 hertz.

It is important that the spectrum analyzer be more stable in frequency than the signals being measured. The stability of the analyzer depends on the frequency stability of its vco. Scan time of the spectrum analyzer must be long enough, with respect to the amplitude of the signal to be measured, to allow the IF circuitry of the spectrum analyzer to charge and recover. This will prevent amplitude and frequency distortion.

Q-7. When referring to spectrum analyzers, what is meant by the term resolving signals?

TIME-DOMAIN REFLECTOMETRY

TIME-DOMAIN REFLECTOMETRY is a testing and measurement technique that has found increasing usefulness in testing transmission lines (both metallic and fiber-optic), cables, strip lines, connectors, and other wideband systems or components. Basically, time-domain reflectometry is an extension of an earlier technique in which reflections from an electrical pulse were monitored to locate faults and to determine the characteristics of power transmission lines. You can compare time-domain reflectometry to a closed-loop radar system in which the transmitted signal, a very fast step pulse, is fed into the system and the reflections resulting from discontinuities or impedance deviations in the system are monitored on a crt.

The technique used in time-domain reflectometry consists of feeding an impulse of energy into the system and then observing that energy as it is reflected by the system at the point of insertion. When the fast-rise input pulse meets with a discontinuity or impedance mismatch, the resultant reflections appearing at the feed point are compared in phase, time, and amplitude with the original pulse. By analyzing the magnitude, deviation, and shape of the reflected waveform, you can determine the nature of the impedance variation in the transmission system. Also, since distance is related to time and the amplitude of the reflected step is directly related to impedance, the comparison indicates the distance to the fault as well as the nature of the fault. Figure 5-25, view A, view B, view C, and view D, illustrates typical transmission line problems that can easily be identified by using a time-domain reflectometer (tdr). In addition to showing both the distance to and the nature (resistive, inductive, or capacitive) of each line discontinuity, time-domain reflectometry also reveals the characteristic impedance of the line and indicates whether losses are shunt or series. They are also used to locate and analyze connectors and splices.

Figure 5-25D.—Time-domain reflectometer display of transmission line problems.

A conventional method of evaluating high-frequency transmission systems and components has been through the use of standing wave ratio (swr) measurements to obtain an overall indication of transmission line performance. This method involves feeding a sine-wave signal into the system and measuring the maximum and minimum amplitudes of the standing waves that result from system discontinuities or load mismatches. The ratio between the minimum and maximum swr values is then taken as the system FIGURE OF MERIT. The swr measurement, however, does not isolate individual discontinuities or mismatches when multiple reflections are present; it only indicates their total effect. Time-domain reflectometry measurements, on the other hand, isolate the line characteristics in time (location). As a result, multiple reflections resulting from more than one discontinuity or impedance variation that are separated in distance on the line are also separated in time at the monitoring point and can be individually analyzed.

Prior to the advent of time-domain reflectometers, time-domain reflectometry was performed with the aid of sampling oscilloscopes and pulse generators with very fast rise times.

Figure 5-26 shows the earlier type of test setup, which is still an option. However, today's time-domain reflectometers have several advantages over the old pulse-generator and oscilloscope methods. Modern time-domain reflectometers are compact, lightweight, are often supplied with battery pack options for field use, and provide a direct readout of distances instead of time. Some equipments provide a paper-tape recording for a permanent record. Figure 5-27 shows a typical time-domain reflectometer.

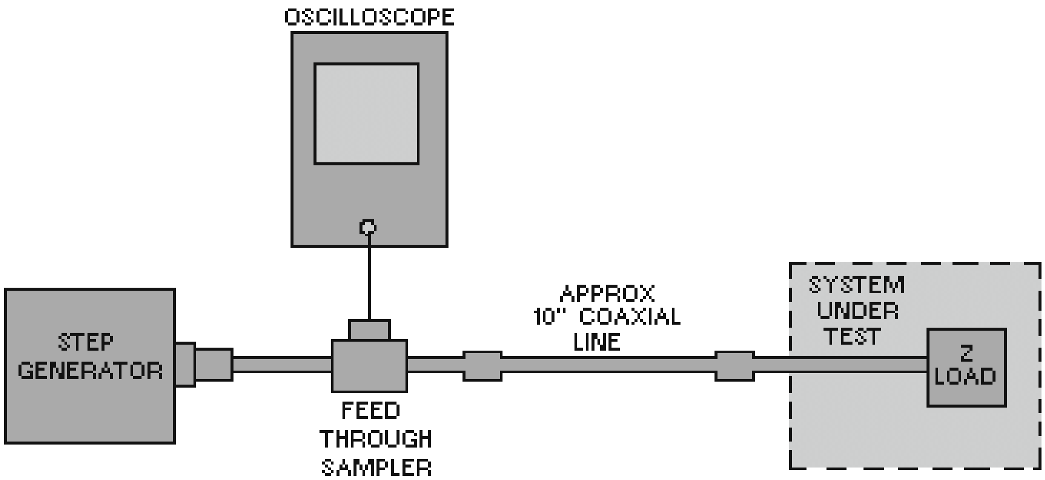

Figure 5-26.—Time-domain reflectometry, basic equipment setup.

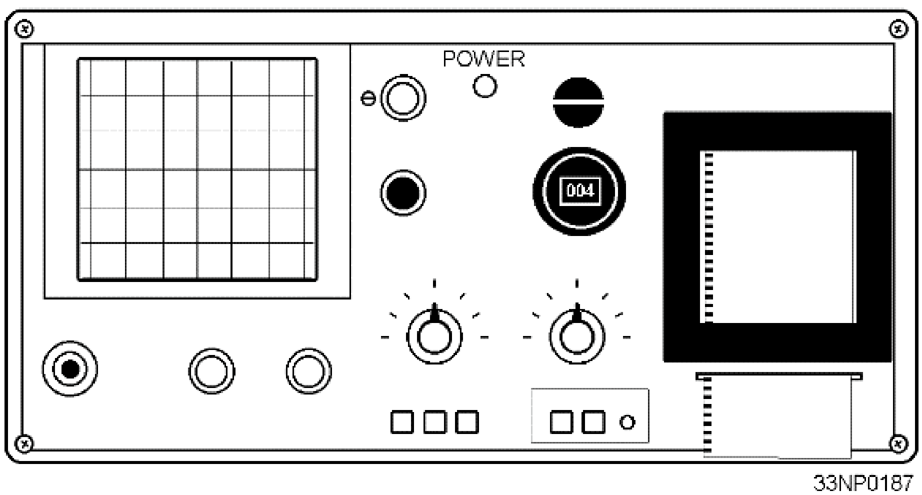

Figure 5-27.—Typical time-domain reflectometer.

Q-8. Why are time-domain reflectometers often compared to a radar system?

Q-9. What is the main advantage of using a time-domain reflectometer (tdr) to test a transmission line?

SWEPT-FREQUENCY TESTING EQUIPMENT

SWEPT-FREQUENCY testing is used to determine the bandwidth, alignment, frequency response, impedance matching, and attenuation in various circuits, systems, and components. Swept-frequency testing can be used to quickly determine the broadband response of a device that otherwise would require a number of separate measurements and manual plotting of the response curve. Swept-frequency techniques are applicable over the entire electronic spectrum from vlf to ehf and are generally limited only by your resourcefulness and the basic limitation of the equipment employed. The basic swept-frequency arrangement is shown in figure 5-28.

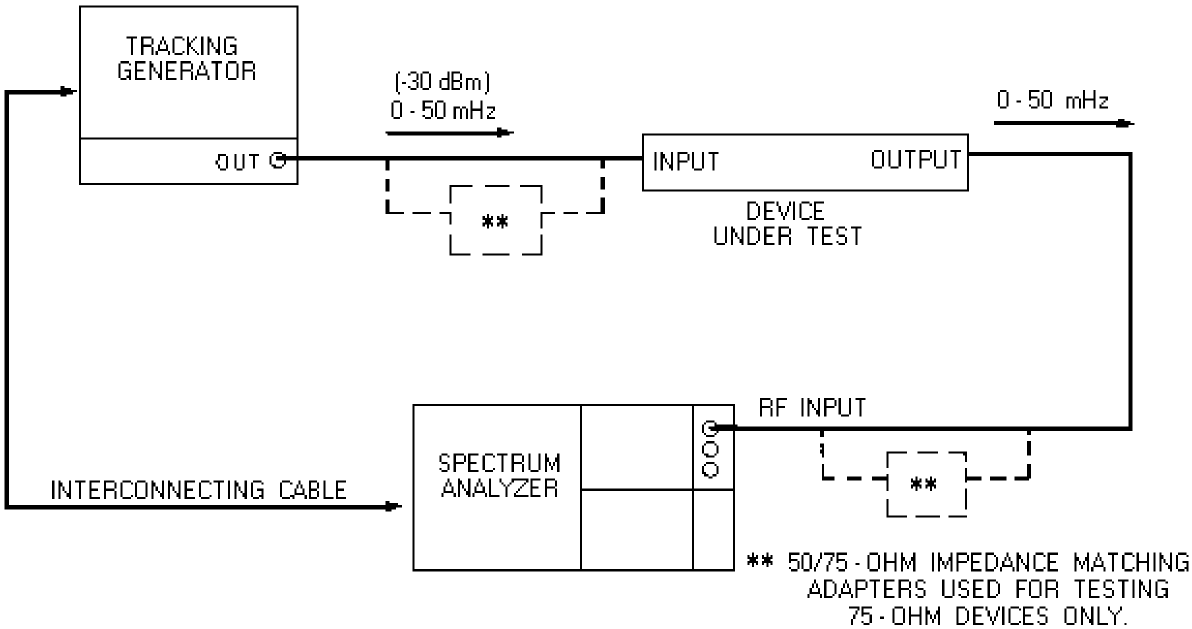

Figure 5-28.—Frequency-response test.

The swept-frequency technique can effectively determine the frequency response of an amplifier or filter and is useful in the alignment or bandwidth determination of an IF or rf stage. The test equipment permits direct visual readout on the crt of the spectrum analyzer. The spectrum analyzer can also be connected to an X-Y chart recorder if a permanent record or print is desired. Figure 5-29 shows a spectrum analyzer crt display of the frequency response of a multicoupler. The tracking generator used must be capable of sweeping the desired frequency range of the device under test.

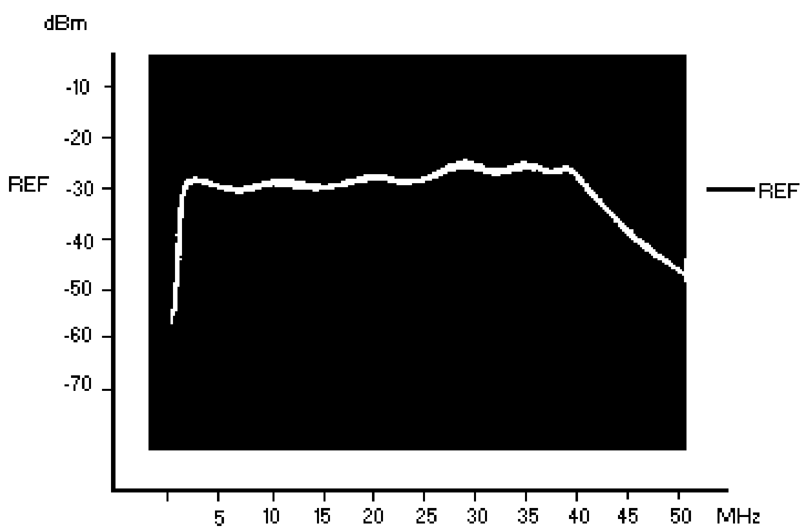

Figure 5-29.—Typical spectrum analyzer frequency-response display.

Q-10. What is the purpose of swept-frequency testing?

TRACKING GENERATOR

Figure 5-30 shows a typical tracking generator used with the Hewlett-Packard 141 T spectrum analyzer. A TRACKING GENERATOR is basically a sweep generator in which the sweep rate is matched to that of the spectrum analyzer. The output circuitry of the tracking generator contains a network that ensures a constant output amplitude over the entire range being swept. When the fm signal produced by the tracking generator is applied to a device or circuit under test, the instantaneous output amplitude is always proportional to the response of the circuit to the frequency at that instant. Thus, the original fm input signal is changed in passing through the circuit under test. The output signal, therefore, would consist of an fm signal that is also amplitude-modulated. For equal deviations, the positive and negative portions of this envelope are symmetrical, making it necessary to observe only one side of the envelope. After the detection stage in the spectrum analyzer, only the modulation remains to appear on the face of the crt. This presentation will appear as a continuous curve because of the persistence of vision and the phosphor characteristic of the crt. The polarity of the detector determines whether a positive or a negative output is displayed. The frequency at any point on the crt display can be analyzed by arresting the scan of the spectrum analyzer either electronically or manually at the point of interest. For greater accuracy in frequency determination, a frequency counter may be attached to the output of the tracking generator at the point of the arrested scan.

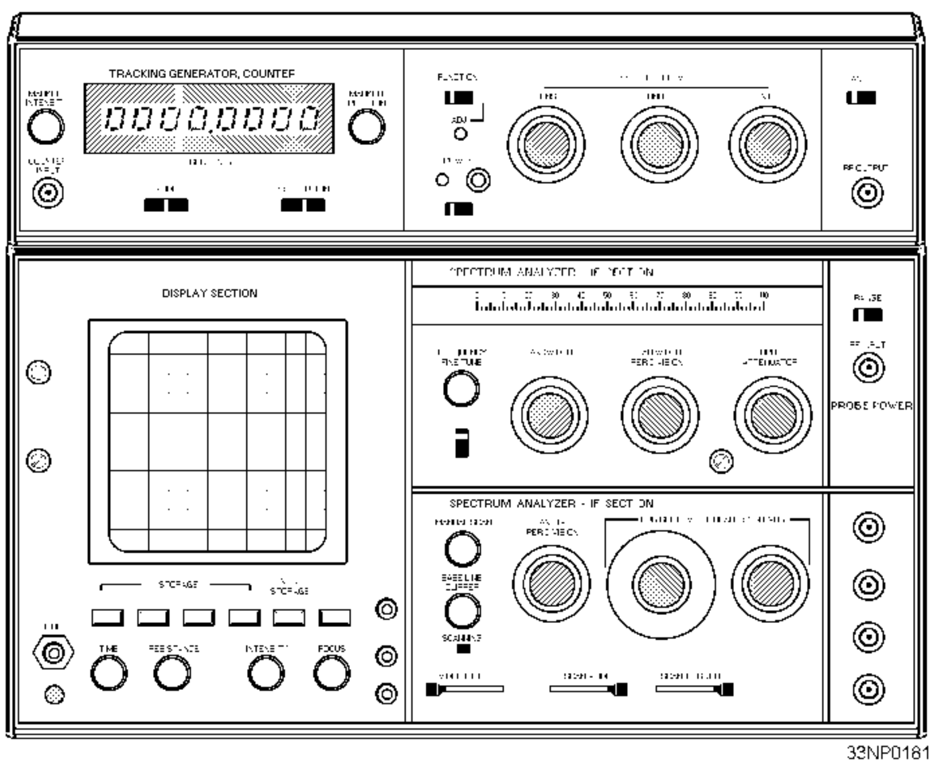

Figure 5-30.—Tracking generator used with a spectrum analyzer.

IMPEDANCE MATCHING

Conventional tuners cannot be used successfully to cancel source or load reflections in swept-frequency measurements. This is because the tuning is effective only at single frequencies; therefore, pads or isolators are required. However, by the use of automatic-level control, the power output of the sweep generator can be maintained relatively constant at the point of measurement. The source impedance may thus be maintained very close to the nominal value. With this arrangement, any impedance variation in the connecting cables, connectors, and adapters is effectively cancelled since these components are within the leveling loop. The attenuation of a device under test will be displayed on the associated crt as a continuous response curve as it is scanned. This will result in an attenuation versus frequency plot of the device under test only.

IMPEDANCE

Circuit impedance is measured conveniently by using the reflectometer principle. The individual values of the incident and reflected signals (swr) in a transmission line feeding an unknown impedance are measured. The ratio between these signals indicates how closely the load impedance matches that of the transmission line.

Another method is the use of an auto-mechanical load control to hold the forward power at a constant level while the return load of a specific load is measured. A short is then placed in the circuit, and 100% reflected power is measured. The loss detected is then calculated to obtain swr figures.

NOISE FIGURE

By using a frequency-sweeping receiver and an automatic noise-figure meter, you can make noise-figure measurements on broadband microwave devices, such as a traveling-wave-tube amplifier. To conduct such a test properly, you must first check the receiver noise figure.

Q-11. In swept-frequency testing the impedance of a transmission line, what electrical characteristic is actually being measured?

SWEEPING ANTENNAS

Antenna system testing is one of the more common and useful applications for using the swept-frequency technique. The main parameters that an antenna system is tested for are vswr, frequency response, and impedance. Figure 5-31 shows a typical test setup for testing a transmitting antenna for vswr. Remember that any transmitting antenna can also act as a receiving antenna and send induced power from adjacent antennas back to the test equipment. You should make an initial power check on the antenna to prevent damage to your test equipment. Figure 5-32 shows a typical hf transmitting antenna vswr display as measured using the swept-frequency technique. The setup for testing a receiving antenna vswr, shown in figure 5-33, is similar, with the exception of the attenuators. The measured vswr (within the operating frequency range) of any broadband antenna should not exceed a vswr of 2.5 to 1. The vswr for any single-tuned antenna should not exceed 1.5 to 1 at the tuned frequency.

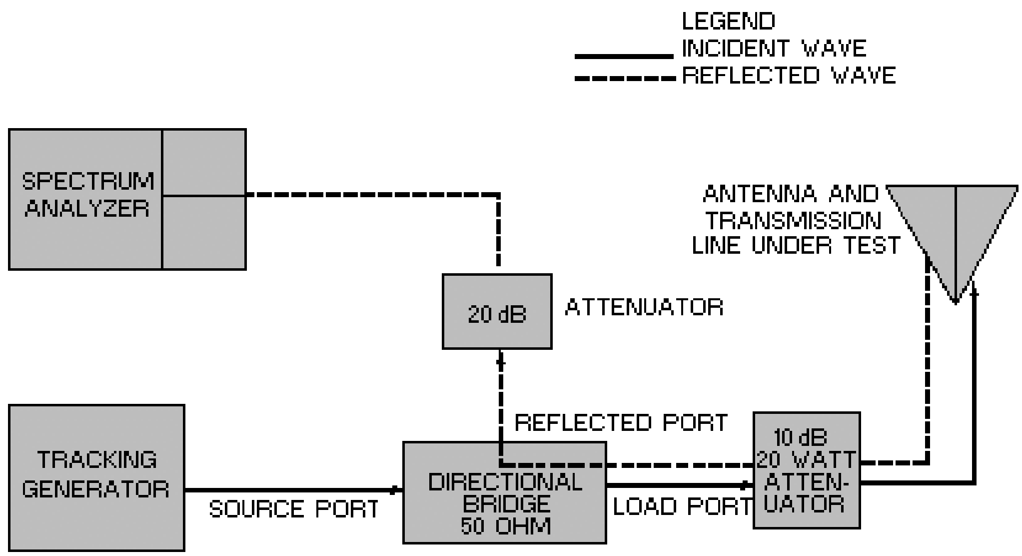

Figure 5-31.—Vswr test for transmitting antennas.

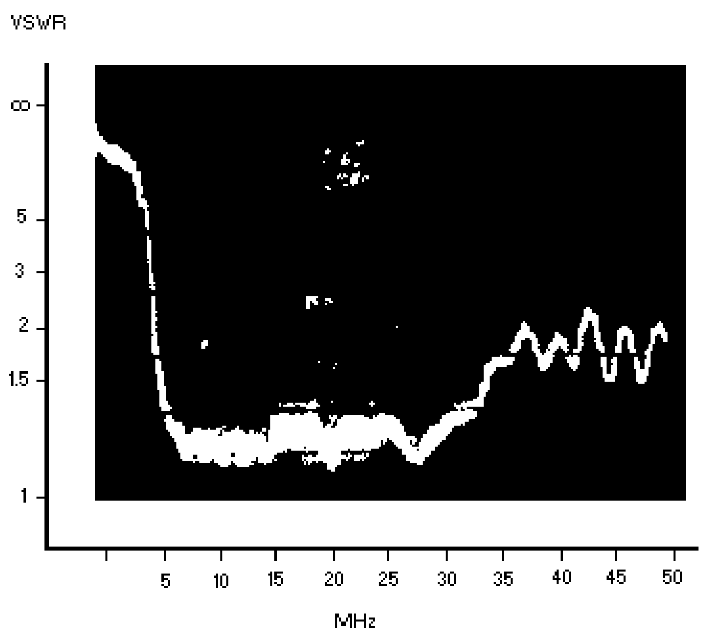

Figure 5-32.—Typical spectrum analyzer vswr display.

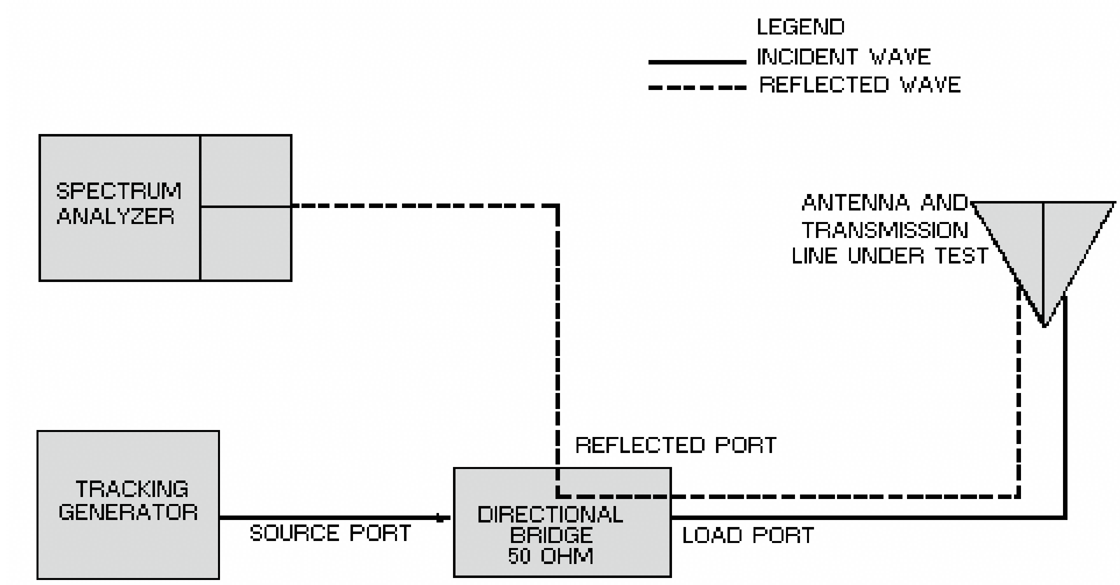

Figure 5-33.—Vswr test for receiving antennas.

Q-12. What precautions must be taken when sweeping a transmitting antenna?

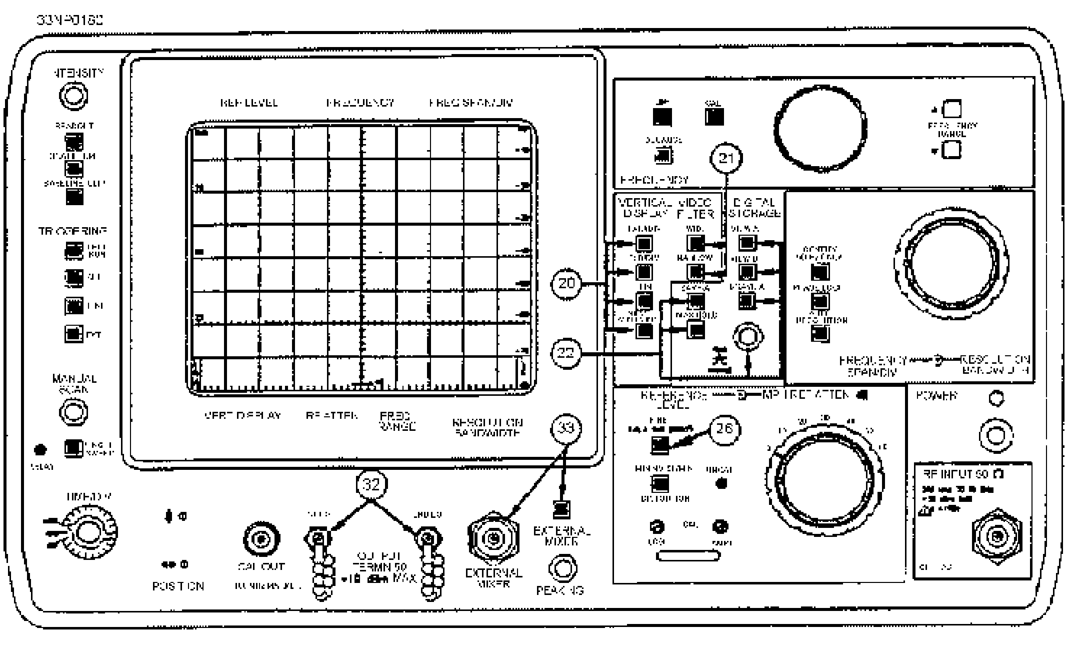
SUMMARY

This chapter has presented information on waveform interpretation. The information that follows summarizes the important points of this chapter.

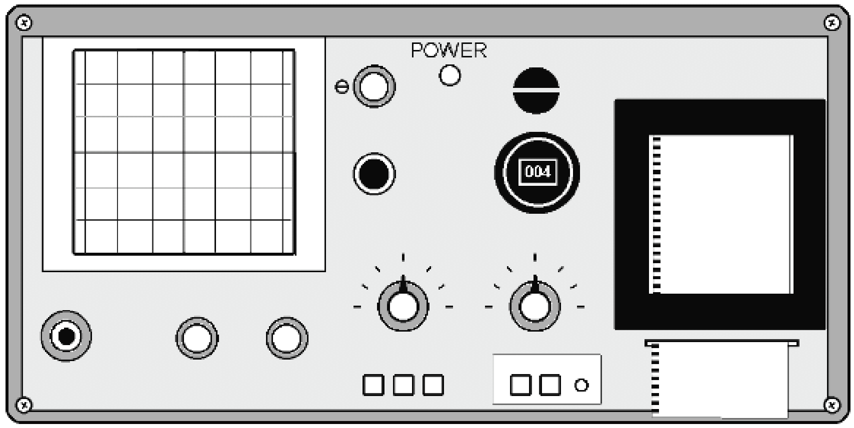
Interpretation of a waveform is best accomplished with test equipment that gives you a visual indication of the waveform. The most common devices used in systems applications are **OSCILLOSCOPES** and **SPECTRUM ANALYZERS**.

An amplitude-modulated signal can be tested with either an oscilloscope or a spectrum analyzer to determine its percentage of modulation, sideband characteristics, and carrier frequency. Frequency-modulated signals are normally tested with a spectrum analyzer or a modulation analyzer.

Oscilloscopes are designed to view a time-domain waveform (amplitude versus time). Spectrum analyzers are designed to view a frequency-domain waveform (amplitude versus frequency). One advantage of using a spectrum analyzer is its ability to graphically display the composition of **COMPLEX WAVEFORMS**.



TIME-DOMAIN REFLECTOMETERS work on a principle similar to that used in radar. A precise signal is produced by the time-domain reflectometer and injected into the device under test (usually a transmission line); and the resulting reflections are displayed to discover such things as impedance mismatches, opens, and shorts. The display sections of time-domain reflectometers are calibrated to give you a graphical display of amplitude versus distance.



33NP0187

SWEPT-FREQUENCY TESTING is performed by using a **TRACKING GENERATOR** to inject a signal into a device and then monitoring the output of the device with a spectrum analyzer. The tracking generator is designed to sweep or scan through the entire frequency range of the device being tested. Its sweep rate must be matched with the sweep rate of the spectrum analyzer.

ANSWERS TO QUESTIONS Q1. THROUGH Q12.

A-1. Distortion.

A-2. 60% to 95%.

A-3. The difference between the carrier frequency of an fm signal and its maximum frequency excursion when modulated.

A-4. Amplitude versus frequency (the frequency domain of the signals).

A-5. The same amount of intelligence can be transmitted with one-sixth of the output power with less than one-half the bandwidth.

A-6. Both the bandwidth and the number of significant sidebands increase.

A-7. The ability of the analyzer to discriminate between display signals of slightly different frequencies.

A-8. Both transmit a pulse and analyze the signal reflection.

A-9. A Tdr will indicate the nature of and the distance to or location of any faults.

A-10. To determine various characteristics of a component, piece of equipment, or system over its operational frequency range.

A-11. Swr on the transmission line.

A-12. You must ensure that power induced from any adjacent transmitting antennas does not damage your test equipment.

APPENDIX I

GLOSSARY

ABSORPTION WAVEMETER—A device used for measuring frequency, consisting of a tuned circuit or cavity that is loosely coupled to the frequency being measured. Maximum energy is absorbed at the resonant frequency.

BOLOMETER—An rf detector that converts rf power to heat, which causes a change in the resistance of the material used in the detector. This change in resistance varies in proportion with the amount of applied power and is used to measure the amount of applied power.

CALORIMETER—A device that measures rf power by measuring the heat the rf power generates.

CAVITY WAVEMETER—An instrument used to measure microwave frequencies. The resonant frequency of the cavity is determined by its inside dimensions.

COAXIAL-LINE WAVEMETERS—A shorted section of a coaxial line used to measure rf frequencies. It is calibrated in either wavelength or frequency.

CROSS MODULATION—An intermodulation condition that occurs when a carrier is modulated by an undesired signal.

CURRENT PROBE—An inductive device used for measuring the current in a conductor. Probes are designed to be clamped around the insulated conductor.

CURRENT TRACER—An inductively coupled device used for tracing current paths to determine the cause of low-impedance faults on a printed-circuit board.

DECADE RESISTOR (DECADE RESISTANCE BOX)—It typically has two or more sections, each containing 10 precision resistors wired to selector switches. A piece of test equipment that provides a ready source of various resistances for engineering and measurement applications.

DECIBEL (dB)—A standard unit for expressing *relative* power levels as the ratio of power out to power in.

dBm—A unit used to express power levels above or below a l-milliwatt reference level at a designated load impedance (usually 600 ohms).

DIFFERENTIAL VOLTMETER—A precision voltmeter that measures an unknown voltage by comparing it to a precision internal-reference voltage supply.

ELECTROSTATIC-DISCHARGE SENSITIVE (ESDS) DEVICE—Electronic components that are susceptible to damage from static charges.

FIBER OPTICS—Conductors that are usually constructed of plastic or glass fibers that readily pass light. Used primarily for transmission of high-speed data over relatively short distances.

FREQUENCY DEVIATION—Refers to the difference between the carrier frequency of an fm signal and the instantaneous frequency of its modulated wave.

FREQUENCY DOMAIN—A plot of frequency versus amplitude as shown by a spectrum analyzer display.

FREQUENCY RESPONSE—(I) The ability of a component or device to operate over a portion of the frequency spectrum. (2) In reference to test equipment, that portion of the frequency spectrum that the test equipment is capable of sensing and measuring accurately.

GALVANOMETER—A meter used to measure small values of current by electromagnetic or electrodynamic means.

IMPEDANCE ANGLE METER—A device that measures circuit impedance by comparing the phase angle between voltage and current.

INSERTION LOSS—The difference between the amount of power applied to a load before and after the insertion of a device in the line.

INTEGRATED CIRCUIT (IC)—(1) A circuit in which many elements are fabricated and interconnected by a single process (into a single chip), as opposed to a nonintegrated circuit in which the transistors, diodes, resistors, and other components are fabricated separately and then assembled. (2) Elements inseparably associated and formed on or within a single substrate.

INTERMODULATION DISTORTION—Nonlinear distortion characterized by the appearance (at the system output) of frequencies equal to the sums and differences of two or more frequencies present at the input.

LOAD—(I) A device through which an electric current flows that changes electrical energy into another form. (2) Power consumed by a device or circuit in performing its function.

LOGIC CLIPS—A device that can be clipped onto an in-circuit, dual-in-line package (DIP) logic IC to determine the logic state of each pin of the IC.

LOGIC PROBE—A hand-held probe used to determine the logic state (high or low) of test points in a logic circuit. A logic high is represented by a lit indicator light on the probe.

LOGIC PULSER—A hand-held probe used to pulse, or change the logic state, of in-circuit logic ICs.

METROLOGY CALIBRATION (METCAL) PROGRAM—A Navy calibration program designed to ensure the accuracy of test equipment through comparisons with calibration laboratory standards of known accuracy.

MICROPHONICS—Electrical noise caused by the mechanical motion of the internal parts of a device. The term is usually associated with vacuum tubes.

MODULATION INDEX—When a sine wave is used to modulate an fm signal, the ratio of the frequency deviation to the frequency of the modulating wave.

NATIONAL BUREAU OF STANDARDS (NBS)—A bureau of the United States government that is responsible for maintaining the nation's electrical and physical standards. The accuracy of all *calibrated* test equipment is traceable to NBS through the Navy's METCAL program.

OPTICAL TIME-DOMAIN REFLECTOMETER (OTDR)—A piece of test equipment used to test a fiber-optic cable for such things as attenuation, localized losses, and defects. It transmits an optical pulse (usually a laser) into the fiber-optic cable and analyzes the resulting reflections in terms of amplitude versus distance.

PARALLAX ERROR—The error in meter readings that results when you look at a meter from some position other than directly in line with the pointer and meter face. A mirror mounted on the meter face aids in eliminating parallax error.

PARASITIC—In electronics, an undesirable frequency in an electronic circuit. Usually associated with vacuum-tube amplifiers and oscillators.

PERCENT OF MODULATION—In AM signals, the ratio of half the difference between the maximum and minimum amplitudes of a modulated wave to its average amplitude.

RF IMPEDANCE BRIDGE—A piece of test equipment used for measuring the combined resistance and reactance of a component, piece of equipment, or system at rf frequencies.

SENSITIVITY—In reference to test equipment, the ratio of the response of the test equipment to the magnitude of the measured quantity. Sometimes expressed indirectly by stating the property by which sensitivity is computed (e.g., ohms per volt).

STANDARD—An exact value of an electrical quantity (established by international agreement), which serves as a model for measurement of that quantity.

STANDING WAVE—The distribution of voltage and current along a transmission line formed by the incident and reflected waves, which has minimum and maximum points on a resultant wave that appears to stand still.

STROBOSCOPE—An instrument that allows viewing of rotating or reciprocating objects by producing the optical effect of a slowing or stopping motion.

SWEPT-FREQUENCY TESTING—Testing the frequency response of a component or system by applying an rf signal, in which the frequency is varied back and forth through a set frequency range at a steady rate, to the input of a device. The output is then monitored to determine the amplitude of the output with respect to frequency.

THERMISTOR—(1) A semiconductor device in which the resistance varies with temperature. (2) A type of bolometer characterized by a decrease in resistance as the dissipated power increases.

TIME-DOMAIN REFLECTOMETER—A piece of test equipment used to test a transmission line for defects, such as shorts and opens. It transmits an electrical pulse into the transmission line and analyzes the resulting reflections in terms of emplidute versus distance.

TRAIC—A three-terminal device that is similar to two SCRs back-to-back with a common gate and common terminals. Although similar in construction and operation to the SCR, the Triac controls and conducts current flow during both alternations of an ac cycle.

TUNING FORK—A two-pronged mechanical device that is designed to vibrate only at its natural frequency. In electronics, it is used primarily to determine the correct speed of a motor.

UNIJUNCTION TRANSISTOR (UJT)—A three-terminal, semiconductor device with a negative-resistance characteristic that is used in switching circuits, oscillators, and wave-shaping circuits.

VOLUME UNIT (VU)—Unit of measurement of a complex audio signal such as voice or music. A 0 level is referenced to 1 milliwatt of power into a 600-ohm load.

WAVEMETERS—(1) Calibrated resonant circuits that are used to measure frequency. (2) An instrument for measuring the wavelength of an rf wave.

ZENER DIODE—A pn-junction diode designed to operate in the reverse-bias breakdown region.

Assignment Questions

<u>Information</u>: The text pages that you are to study are provided at the beginning of the assignment questions.

ASSIGNMENT 1

Textbook assignment: Chapter 1, "Basic Measurements," pages 1-1 through 1-26. Chapter 2, "Component Testing," pages 2-1 through 2-8.

1-1. What is the purpose of the Navy's Metrology Calibration Program?

1. To provide the fleet with new types of test equipment
2. To provide quality control for your test equipment
3. To improve the efficiency of sophisticated electronic systems
4. To establish test equipment pools from which technicians can borrow

1-2. At each higher echelon METCAL calibration laboratory, the accuracy of the test equipment increases by a factor of

1. 10
2. 2
3. 100
4. 4

1-3. Most equipment technical manuals contain voltage charts. For which of the following purposes are they used?

1. To list the equipment's power supplies
2. To list the input power requirements of the equipment
3. To provide handy reference guides for calculating voltage drops across fixed impedances
4. To list correct voltages at major test points

THIS SPACE LEFT BLANK INTENTIONALLY.

1-4. Which, if any, of the following statements correctly describes the effect input impedance of test equipment can have on readings taken?

1. The greater the input impedance of your test equipment, the less accurate the readings
2. The lower the input impedance of your test equipment, the more accurate the readings
3. A piece of test equipment with an infinite input impedance will absorb no energy and readings will be more accurate
4. None of the above

1-5. A piece of test equipment with a low input impedance can cause readings taken to be inaccurate. To eliminate this problem, the input impedance of your test equipment should exceed the impedance of the circuit under test by what minimum ratio?

1. 1 to 1
2. 2 to 1
3. 10 to 1
4. 100 to 1

THIS SPACE LEFT BLANK INTENTIONALLY.

USE THE FOLLOWING INFORMATION TO ANSWER QUESTION 1-6: YOU NEED TO TAKE A CRITICAL VOLTAGE READING, BUT YOU DO NOT HAVE A HIGH IMPEDANCE METER AVAILABLE. INSTEAD, YOU CONNECT TWO LOWER IMPEDANCE METERS IN SERIES AND PLACE THEM ACROSS THE COMPONENT IN QUESTION. YOU ADD THE READINGS SHOWN ON THE TWO METERS TO GET YOUR MEASUREMENT.

1-6. Compared to using just one of the lower impedance meters, what is the advantage of using two meters connected in series?

1. Input impedance increases and voltage-measuring accuracy increases
2. Frequency response of the test setup doubles
3. Accuracy of current measurements decreases
4. Input impedance decreases and voltage-measuring accuracy increases

1-7. On an analog multimeter, where on the scale are the most accurate readings taken?

1. At the highest end of the scale
2. At the lowest end of the scale
3. Midscale
4. It makes no difference if the meter is properly calibrated

1-8. What can you do to reduce the problem of meter-reading errors caused by parallax?

1. Close one eye when reading the meter
2. Use short meter leads
3. Use a meter that has a mirror built into the scale
4. View the meter face from either the left or right side, but not directly in front

1-9. For what primary reason are oscilloscopes used in circuit testing?

1. They provide a visual presentation of the signal under test
2. They present a low input impedance to the circuit under test
3. They provide numerical readouts of signals under test
4. They measure voltages more accurately than other pieces of test equipment

1-10. THIS QUESTION HAS BEEN DELETED.

1-11. Digital multimeters effectively eliminate which of the following disadvantages of analog meters?

1. Parallax
2. Low impedance
3. Poor accuracy
4. All of the above

1-12. Which of the following pieces of test equipment is most accurate for measuring dc voltages?

1. Vtvm
2. Oscilloscope
3. Digital voltmeter
4. Differential voltmeter

1-13. If you exceed the frequency limitations of your voltmeter, which of the following results is likely?

1. The meter will be destroyed
2. The circuit under test will be damaged
3. The measurement will be inaccurate
4. The meter will indicate average voltage

1-14. When performing measurements with an oscilloscope, you should ensure that the trace extends across what minimum portion of the vertical viewing area?

1. 15%
2. 25%
3. 45%
4. 60%

1-15. When using an oscilloscope to measure a high voltage, you should use which of the following procedures?

1. Use the logic probe instead of the normal probe
2. Use the high voltage probe instead of the normal probe
3. Use two oscilloscopes connected in series
4. Place a 10-ohm shunt across the vertical input of the oscilloscope

1-16. Oscilloscopes are normally calibrated to display which of the following types of voltages?

1. Peak
2. Average
3. Peak-to-peak
4. Both 2 and 3 above

1-17. When using an oscilloscope to observe a sine wave, what, if anything, must you do to determine the rms voltage?

1. Divide the observed peak-to-peak voltage by 3.65
2. Multiply the observed peak-to-peak voltage by 2; then divide by 1.414
3. Divide the observed peak-to-peak voltage by 2; then multiply by 0.707
4. Nothing

1-18. The frequency-measuring capabilities of a digital multimeter can be extended by using which of the following devices?

1. An rf probe
2. A frequency doubler
3. A high-voltage probe
4. A frequency divider network

1-19. When performing ac voltage measurements, you should use which of the following pieces of equipment to obtain the most accurate reading?

1. A differential voltmeter
2. An oscilloscope
3. A Simpson 260
4. A wattmeter

1-20. For which of the following purposes would you connect two ammeters in parallel?

1. To perform voltage measurements
2. To increase frequency-measuring capabilities
3. To decrease input impedance
4. To increase input impedance

1-21. When taking measurements with two ammeters connected in parallel, how do you determine the resulting readings?

1. The current equals the sum of both meter readings
2. The current equals the difference of the two meter readings
3. The current equals the product of the two readings divided by their sum
4. Read either meter directly; the same current flows through both meters

1-22. Current tracers indicate the presence of a current in which of the following ways?

1. By the lighting of an indicator lamp
2. By a clicking noise
3. Both 1 and 2 above
4. By the movement of a meter

1-23. Which of the following is an advantage of using a current probe?

1. It is the most accurate method of measuring current
2. It senses current by induction without being connected directly into the circuit
3. It is battery operated
4. It is capable of measuring current at frequencies above 40 GHz

1-24. When troubleshooting a specific piece of equipment, you can find an accurate listing of resistance readings for specific test points in which of the following documents?

1. In equipment PMS cards
2. In test equipment manuals
3. In equipment technical manuals
4. In Naval Ships Technical Manuals

1-25. An ohmmeter that is used for field work should meet which of the following criteria?

1. It should be extremely accurate
2. It should be portable
3. It should be simple to operate
4. Both 2 and 3 above

1-26. When you use an analog multimeter to measure resistance, which of the following actions should you take first?

1. Make sure the meter is zeroed
2. Set the meter for dc voltage
3. Set the meter for ac voltage
4. Make sure the meter leads do not exceed 36 inches

1-27. Digital multimeters are used to test semiconductors for which of the following reasons?

1. They produce voltage sufficient to gate all Zener diodes
2. Their LED displays are easier to read than analog displays
3. They typically limit the current flow through the semiconductor to less than 1 milliamp
4. They produce in excess of the 500 milliamps normally required to gate a PN junction

1-28. Compensation for the resistance in test leads of digital multimeters used to perform resistance measurements is accomplished by which, if any, of the following methods?

1. Short the leads, note the lead resistance displayed, and add this value to subsequent resistance measurements
2. Short the leads, note the lead resistance displayed, and subtract the value from subsequent resistance measurements
3. Add 10% to the reading
4. None of the above

1-29. Which of the following is a typical use for a megger?

1. Testing MOSFETs
2. Testing filter capacitors
3. Testing thermistor mounts
4. Testing an ac power cord for insulation breakdown

1-30. When large capacitors are stored as spare parts, why should their terminals be shorted with a piece of wire?

1. It prevents dielectric leakage
2. It prevents deterioration of the plates
3. It prevents the capacitors from becoming charged when in close proximity to an rf field
4. It prevents electrolytic capacitors from changing value during periods of storage

1-31. Capacitance meters can be grouped into which of the following basic categories?

1. Wheatstone type and Kelvin Varley type
2. Bridge-type and reactance-type
3. Depletion-type and enhancement-type
4. Resistive-type and reactive-type

1-32. Which of the following statements correctly describes the accuracy and use of a reactance-type capacitance meter?

1. It gives approximate values and is usually portable
2. It gives approximate values and is used in calibration laboratories only
3. It is very accurate and is usually portable
4. It is very accurate and is used to measure capacitors that have a high power factor

1-33. Which of the following types of inductor core materials produces the greatest inductance?

1. Mica
2. Magnetic metal
3. Polyparoloxylene
4. Nonmagnetic metal

1-34. As frequency increases, the inherent resistance of the inductor causes which of the following types of losses to become more critical?

1. Hysteresis
2. Skin effect
3. Eddy currents
4. Standing waves

1-35. Most capacitance test sets are capable of testing capacitors and what other type of component?

1. TRIACS
2. Inductors
3. Resistors
4. Barretters

1-36. When using reactance-type test equipment to measure inductance, what relationship exists between the inductor and the voltage drop across the reactance of the inductor?

1. The voltage drop is directly proportional to the value of inductance
2. The voltage drop is inversely proportional to the value of inductance
3. The voltage drop is proportional to the dielectric constant (K) of the inductor
4. The voltage drop is inversely proportional to the frequency of the applied voltage

.

1-37. Aboard ship you should be able to troubleshoot equipment failures to the component level for which of the following reasons?

1. Ships must be self-sustaining units when deployed
2. Storage space on board ships limits the number of bulky items or electronic modules that can be stored
3. Individual components may be easier to obtain than modules or larger equipment pieces
4. All of the above

1-38. What is the most common cause of electron tube failures?

1. Vibration damage
2. Open filaments
3. Shorted elements
4. Power supply voltage surges

1-39. The simplest way to test a tube is by which of the following methods?

1. Using a tube tester
2. Measuring tube element voltages
3. Feeling for signs of overheating
4. Substituting tubes

1-40. Test conditions for the electron tube tester described in the text are set by which of the following methods?

1. By a technician setting switches
2. By using a magnetic tape program
3. By using a prepunched card program
4. By inserting the tube into the appropriate socket

1-41. The electron tube tester can be used to test common low-power tubes for which of the following conditions?

1. Gas
2. Quality
3. Leakage
4. Each of the above

1-42. Pushbuttons on the electron tube tester are used to test for which of the following conditions?

1. Emission
2. Transconductance
3. Other quality tests
4. Each of the above

1-43. Which of the following tests is automatically performed when the electron tube tester card switch is first actuated?

1. Gas
2. Shorts
3. Opens
4. Quality

1-44. Which of the following methods is normally used to test high-power amplifier tubes?

1. Using tube testers
2. Performing interelectrode resistance checks
3. Making gain measurements with an oscilloscope
4. Observing built-in meters that measure grid and plate current and power output

1-45. Which, if any, of the following problems occur when klystrons are left in storage or not used for more than 6 months?

1. They become gassy
2. The elements become tarnished and ruin the tube
3. All external metallic parts become tarnished and must be cleaned prior to use
4. None

1-46. Which of the following actions should you take to restore operation if the klystron is gassy?

1. Replace the klystron with a new one
2. Return it to the nearest depot for intermediate maintenance
3. Evacuate the gas by igniting the tube's getter
4. Operate it at reduced beam voltage for approximately 8 hours

1-47. Traveling-wave tubes (twt) should be replaced if they deviate from design specifications by what minimum percentage?

1. 1%
2. 10%
3. 25%
4. 33%

1-48. If a twt used as an oscillator fails, which of the following indications should you observe?

1. The twt will become noisy
2. Equipment line fuses will blow
3. The twt will have reduced output power
4. The twt will fail to break into oscillation when all other conditions are normal

1-49. Which of the following is an appropriate reason to use transistors instead of electron tubes?

1. Transistors are more rugged than electron tubes
2. Transistors are not as heat sensitive as electron tubes
3. Transistors are not as sensitive as electron tubes to voltage overloads
4. Transistors are capable of handling greater amounts of power than electron tubes

1-50. When using an ohmmeter to test a transistor's base-to-emitter or base-to-collector junction, what minimum back-to-forward resistance ratio should you expect to read?

1. 5 to 1
2. 10 to 1
3. 50 to 1
4. 100 to 1

1-51. When taking forward and reverse resistance readings between a transistor's emitter and collector, what type of reading should you get?

1. Both the forward and reverse readings should be nearly the same
2. A short in both the forward and reverse directions
3. Less than 15 ohms when measuring in the forward direction and infinite in the reverse direction
4. Less than 15 ohms in the reverse direction and infinite in the forward direction

1-52. When using an ohmmeter to test transistors, you should avoid using R×1 range for which of the following reasons?

1. The R×1 range is not as accurate as the other ranges
2. Most ohmmeters do not produce sufficient voltage on the R×1 range to properly bias a transistor junction
3. Some ohmmeters produce in excess of 100 milliamps of current on the R×1 range and could possibly damage the transistor
4. The R×1 scale is not capable of measuring the high resistances that are typical of a PN junction when forward biased

1-53. When using a soldering iron to replace transistors, you must be sure there is no current leakage between the power source and the tip of the iron. Which of the following actions should you take if current leakage is detected?

1. Reduce the wattage of the heating element
2. Use an isolation transformer to power the soldering iron
3. Use a soldering gun instead of a soldering iron
4. Isolate the soldering iron from ground by disconnecting the soldering iron safety ground wire

1-54. Which of the following is a description of ESDS devices?

1. Components that are sensitive to electrostatic discharge
2. Components that are sensitive to the electromagnetic pulse produced by a nuclear detonation
3. State-of-the-art devices used to detect electronic emissions
4. Devices designed to withstand any type of electromagnetic or electrostatic interference

1-55. MOS and CMOS devices without input diode protection circuitry belong in which, if any, of the following ESDS device categories?

1. Sensitive devices
2. Very sensitive devices
3. Moderately sensitive devices
4. None of the above

1-56. Wearing a grounded wrist strap when repairing electronic circuit boards serves which of the following purposes?

1. It identifies you as being 2M qualified
2. It protects ESDS devices from damage
3. It protects the technician from electrical shock
4. It protects you from rf burns when working near radar antennas

1-57. What, if any, precaution should you take before you open a package that contains an ESDS device?

1. Rub the package against a dissimilar material
2. Discharge any static electricity by connecting a grounded lead to the package
3. Measure the static charge on the package with an oscilloscope to ensure that it is within tolerance
4. None

ASSIGNMENT 2

Textbook assignment: Chapter 2, "Component Testing," pages 2-8 through 2-48. Chapter 3, "Quantitative Measurements," pages 3-1 through 3-15.

2-1. Which of the following servicing techniques applies to semiconductors?

1. Substituting a semiconductor with a known good semiconductor is a simple way to test them
2. Voltage and resistance measurements are taken prior to substituting semiconductors
3. Substituting semiconductors is cumbersome if more than one is bad or if they are soldered into the circuit
4. All of the above

2-2. What minimum ratio of back-to-forward resistance should you expect when testing a diode?

1. 1 to 1
2. 10 to 1
3. 50 to 1
4. 100 to 1

2-3. Which of the following characteristics of a diode cannot be determined by using a multimeter?

1. How the diode reacts to various voltages
2. How the diode reacts to various frequencies
3. Both 1 and 2 above
4. How the diode reacts to forward and reverse dc biasing

2-4. How are SCRs normally used in the Navy?

1. As rectifiers
2. As power control devices
3. As voltage regulators
4. As switching diodes in digital applications

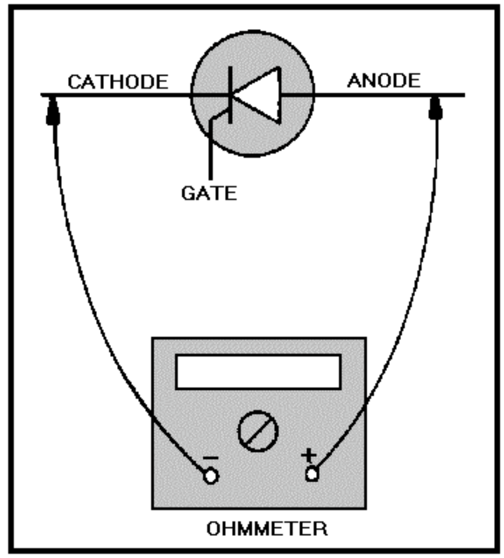

Figure 2A. —Testing an SCR with an ohmmeter.

IN ANSWERING QUESTIONS 2-5 AND 2-6, REFER TO FIGURE 2A. NOTE THAT THE CONNECTIONS OF THE OHMMETER ARE ALREADY MADE.

2-5. To forward bias an SCR, which elements should you short together?

1. The gate and anode
2. The cathode and anode
3. The cathode and gate
4. All three elements

2-6. What, if anything, will be the result of removing the short after it has been made?

1. Current flow from the cathode to the anode will stop
2. Current flow from the anode to the cathode will stop
3. Current can flow in either direction between the anode and cathode
4. Nothing

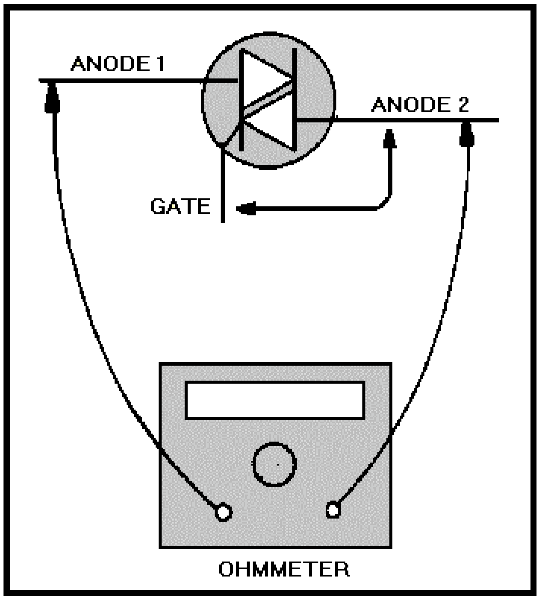

Figure 2B. —Testing a TRIAC with an ohmmeter.

IN ANSWERING QUESTION 2-7, REFER TO FIGURE 2B.

2-7. With a momentary short connected between the gate and anode 2, the TRIAC will be forward biased and allow current to flow between what elements?

1. From the gate to anode 1
2. From the gate to anode 2
3. From anode 1 to anode 2 only
4. In either direction between the two anodes

THIS SPACE LEFT BLANK INTENTIONALLY.

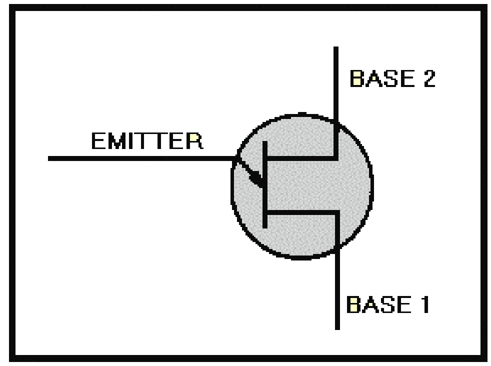

Figure 2C. —Unijunction transistor.

IN ANSWERING QUESTIONS 2-8 AND 2-9, REFER TO FIGURE 2C.

2-8. What readings should you expect to find when you measure the resistance between bases 1 and 2 of a UJT?

1. A short regardless of the polarity of the meter leads
2. A high resistance value regardless of the polarity of the meter leads
3. Approximately 15 ohms between base 1 and base 2 with the negative meter lead connected to base 1
4. Approximately 15 ohms between the two bases with the negative meter lead connected to base 2

2-9. For which, if any, of the following reasons do JFETs have circuit applications similar to those of vacuum tubes?

1. JFETs have a high input impedance and are voltage-responsive
2. JFETs have a low input impedance and a frequency response comparable to that of vacuum tubes
3. JFETs have a high input impedance and are current-responsive
4. None of the above

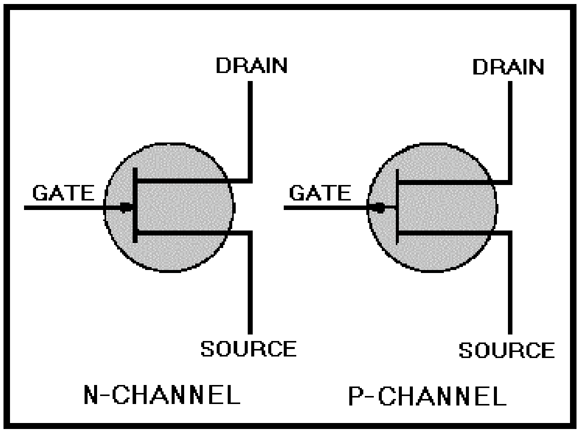

Figure 2D. —Junction FET.

IN ANSWERING QUESTION 2-10, REFER TO FIGURE 2E.

2-10. With the negative lead of an ohmmeter attached to the gate and the positive lead attached to the source, which of the JFETs in figure 2D would be good if the meter shows infinity?

1. P-channel
2. N-channel
3. Both 1 and 2 above
4. Neither 1 or 2

THIS SPACE LEFT BLANK INTENTIONALLY.

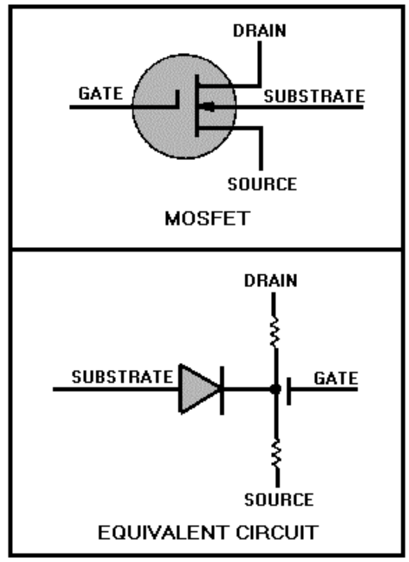

Figure 2E. —MOSFET (depletion/enhancement type) and equivalent circuit.

IN ANSWERING QUESTIONS 2-11 AND 2-12, REFER TO FIGURE 2E.

2-11. When measuring resistance between the drain and source of a depletion/enhancement type of MOSFET, what readings should you expect?

1. 15 ohms in one direction and infinity in the other direction
2. The same value of resistance in both directions
3. A short in one direction and infinity in the other
4. Infinite reading regardless of meter lead polarities

2-12. When measuring resistance between the gate, source, and drain of a depletion/enhancement type of MOSFET with the negative lead attached to the gate, what readings should you expect?

1. Both readings should be infinity
2. Both readings should be between 15 ohms and 100 ohms
3. Both readings should be approximately 1,000 ohms
4. Both readings should be less than 10 ohms

2-13. When unsoldering a MOSFET from a printed circuit board, you should avoid using a vacuum plunger solder sucker for which of the following reasons?

1. Solder suckers can generate high electrostatic charges that can damage MOSFETs
2. Solder suckers create a vacuum that can physically damage MOSFETs
3. Solder suckers are not authorized for any type of equipment repair
4. Solder suckers require the use of a high wattage soldering iron that may damage MOSFETs

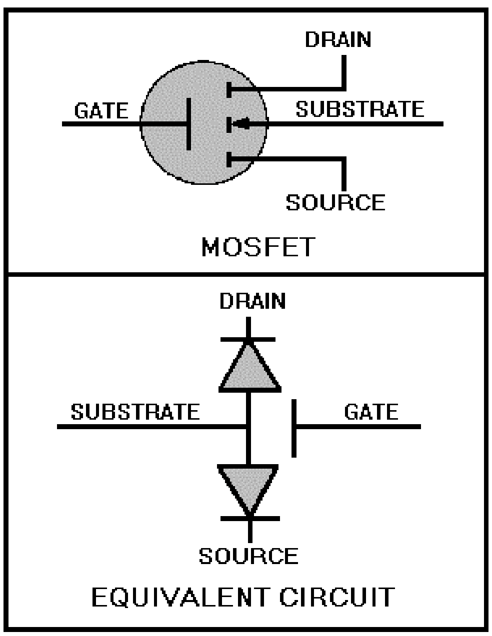

Figure 2F. —MOSFET (enhancement type) and equivalent circuit.

IN ANSWERING QUESTION 2-14, REFER TO FIGURE 2F.

2-14. When comparing resistance readings of an enhancement type of MOSFET to those of a depletion/enhancement type of MOSFET, which, if any, of the following differences should you notice?

1. The resistance between the substrate and the gate of the enhancement type should be less than 15 ohms
2. The measurement between the drain and source of the enhancement type should read infinite regardless of meter lead polarity
3. The resistances between the gate and the drain and between the gate and the source of the enhancement type should be noticeably higher
4. None of the above

2-15. Which of the following is/are (an) advantage(s) of integrated circuits when compared to circuits made up of separate components and interconnections?

1. Lower power consumption
2. Smaller size of the equipment
3. Lower equipment cost
4. All of the above

2-16. Which of the following is a characteristic of linear ICs?

1. They do not require regulated power supplies
2. They are typically sensitive to their supply voltages
3. They are never classed as electrostatic discharge sensitive devices
4. They are comparable in size to their equivalent transistor circuits

2-17. For which of the following reasons would you classify an IC as a "black box" device?

1. Because ICs are always black in color
2. Because all you can check are the inputs and outputs, not the internal operation of ICs
3. Because printed circuit boards that contain ICs cannot be repaired
4. Because ICs are designed to be repairable components

2-18. Test equipment used to detect the logic state of a digital IC should have which of the following characteristics?

1. A capability of measuring rms voltages
2. A frequency response in excess of 40 GHz
3. A high input impedance
4. A low input impedance

2-19. Which of the following statements describes) the use of logic clips?

1. Logic clips are designed to monitor the input and output of an IC simultaneously
2. Logic clips can only be used to test an IC that is out of the circuit
3. Logic clips can only be used with flat pack ICs
4. All of the above

2-20. For which of the following purposes are logic comparators used?

1. To test linear ICs
2. To compare different types of ICs
3. To inject pulse trains into digital ICs
4. For in-circuit testing of digital ICs by comparing them with reference ICs

2-21. Which of the following is an advantage of using a logic probe instead of an oscilloscope to test a digital IC?

1. Logic probes are usually larger than an oscilloscope but much lighter
2. Logic probes have a low input impedance
3. Logic probes are battery powered and do not react to line voltage variations
4. Logic probes are capable of detecting short-duration pulses that most oscilloscopes cannot display

2-22. For which of the following purposes are logic pulsers used?

1. To detect the logic state of digital ICs
2. To detect the logic state of linear ICs
3. To inject a pulse or pulse train into a logic circuit
4. To inject a 1-kHz sine wave into a circuit for signal tracing

2-23. Which of the following is a typical application for a logic analyzer?

1. To program EPROMs
2. To test individual logic ICs
3. To analyze the spectral purity at the output of a logic IC
4. To perform timing analysis by monitoring and comparing more than one timing signal simultaneously

2-24. Which of the following instruments is used to test the specific gravity of a lead-acid battery's electrolyte?

1. Hydrometer
2. Hygrometer
3. Electrometer
4. Gravitometer

2-25. Smoking is prohibited in the vicinity of lead-acid storage batteries for which of the following reasons?

1. Cigarette smoke neutralizes the electrolyte
2. Lead-acid batteries produce explosive hydrogen when they are being charged
3. Fumes produced by a lead-acid battery mixed with cigarette smoke produce a toxic by-product
4. All of the above

2-26. When testing dry cell batteries, which of the following procedures should you follow?

1. The battery should be tested under load conditions
2. The battery should not be tested under load conditions
3. The battery should be tested at various temperatures
4. Both 2 and 3 above

2-27. Which of the following dry cell batteries is rechargeable?

1. NICAD
2. Alkaline
3. Carbon-zinc
4. Mercury cells

2-28. Which of the following is the correct maximum charge rate for a NICAD battery rated at 300 milliampere hours?

1. 300 milliamperes for 15 hours
2. 60 milliamperes for 15 hours
3. 30 milliamperes for 15 hours
4. 600 milliamperes for 15 hours

2-29. Which of the following is a characteristic of fixed rf attenuators?

1. They are used to match impedances
2. They are designed to handle small amounts of rf power
3. They are usually built into the equipment in which they are used
4. They are capable of handling several kilowatts of power

2-30. Which of the following is an easy method of performing an operational test on a decade resistor?

1. Use an swr meter
2. Use the resistance substitution method
3. Read the resistance with an ohmmeter
4. Apply an rf voltage across the decade, measuring the voltage drop and computing the resistance

2-31. Which of the following is/are the disadvantages of glass-core, fiber-optic cables?

1. They are smaller in diameter than plastic-core fibers
2. They are extremely susceptible to mechanical damage
3. They exhibit signal losses as high as 25 dB/km
4. Both 2 and 3 above

2-32. Which of the following types of test equipment should you use to measure the losses in a fiber optic cable if only one end of the cable is accessible?

1. An optical ohmmeter
2. A Wheatstone bridge
3. An optical power meter
4. An optical time-domain reflectometer

2-33. When using the AN/USM-465 portable service processor, which of the following procedures is possible?

1. Identifying faulty components on digital printed circuit boards
2. Troubleshooting its own printed circuit boards
3. When using the guided probe, it will tell you if you have placed the probe on the wrong test point
4. All of the above

2-34. Which of the following measurements add resistance and inductive and capacitive reactance?

1. Q
2. Resonance
3. Impedance
4. Figure of merit

2-35. Bridge circuits are used in the measurement of impedance for which of the following reasons?

1. Bridges are one of the most accurate devices for measuring impedance
2. Bridges are only slightly less accurate than vtvm's when measuring impedance
3. Bridges are useful in measuring frequency
4. Both 2 and 3 above

2-36. Bridge circuits typically contain which of the following sections?

1. A measuring circuit and comparing circuit
2. A detector circuit
3. A power circuit
4. All of the above

2-37. When approximate values for resistance, capacitance, or inductance to be measured by a bridge are unknown, which, if any, of the following actions should you take?

1. Connect two bridges in parallel to make the measurement
2. Assign a temporary value to the component and set up the bridge accordingly
3. Place an adjustable shunt across the meter terminals
4. None of the above

2-38. The most serious errors affecting the accuracy of bridge measurements can be attributed to which of the following problems?

1. The capacitive and inductive characteristics of the connecting leads
2. The resistance of the test leads
3. D'Arsonval meter movements used as detectors
4. Improper selection of meter shunts

2-39. Which of the following considerations should be given when applying external excitation to a bridge circuit?

1. The voltage applied should equal the maximum voltage rating of the component under test
2. The higher the voltage, the more accurate the measurement
3. Apply only enough voltage to obtain a reliable indicator deflection
4. External excitation should be limited to 115 v 60 Hz

2-40. It is difficult to measure resistances less than 1 ohm with a bridge because of which of the following factors?

1. Contact resistance is present between the resistor being measured and the binding posts of the bridge
2. Excessive supply voltage is required to excite the galvanometer
3. The frequency of the excitation source creates excessive skin currents in the resistor under test
4. The excitation voltage causes low-value resistors to heat excessively

2-41. What type of bridge is recommended for measuring resistances less than 1 ohm?

1. Wheatstone bridge
2. Schering bridge
3. Maxwell bridge
4. Kelvin bridge

2-42. When using resistance-ratio bridges to measure capacitance, inductance, or resistance, you should compare the unknown component with which of the following components?

1. A capacitor
2. An inductor
3. A resistor
4. A similar standard

2-43. A Hay bridge measures unknown inductances by comparing them with which, if any, of the following components?

1. A standard inductor
2. A standard resistor
3. A standard capacitor
4. None of the above

2-44. What is the advantage of using a Maxwell bridge over a Hay bridge?

1. The Maxwell bridge can measure greater range of inductances
2. The Maxwell bridge can measure much smaller resistances
3. The Maxwell bridge can provide a greater accuracy over a smaller range
4. The Maxwell bridge can measure inductances having a high Q

2-45. Which of the following pieces of test equipment measure(s) the magnitude and phase angle of an unknown impedance?

1. The vector bridge
2. The impedance-angle meter
3. Both 1 and 2 above
4. The Hay bridge

2-46. Maximum transfer of rf energy between transmitter/receiver and antenna will occur under which of the following circumstances?

1. When the transmitter or receiver is properly matched to the antenna
2. When the receiver is tuned one sideband above the transmitter
3. When the transmitter is tuned one sideband above the receiver
4. Both 2 and 3 above

2-47. Rf impedance bridge measurements require the use of which of the following pieces of equipment?

1. An ac power source, a detector, and a Wheatstone bridge
2. An rf signal generator, an oscilloscope, and a power supply
3. An rf signal generator, an rf bridge, and a detector
4. A Schering bridge, a detector, and an rf power supply

2-48. What unit of measure is used to express the power level of a complex voice signal?

1. Vu
2. dB
3. dBm
4. Watt

2-49. The function of a dB meter is described in which of the following descriptions?

1. A current-measuring device
2. A user-calibrated constant current device
3. An electronic voltmeter calibrated in terms of dB
4. A frequency selective voltmeter calibrated in terms of true power

2-50. Electrodynamic wattmeters are used to measure which of the following types of power?

1. Ac power
2. Dc power
3. Both 1 and 2 above
4. Shf power in the 2-32 GHz frequency range

2-51. An electrodynamic wattmeter can be converted into an instrument for measuring reactive power by which of the following methods?

1. Installing a capacitor in series with the input
2. Shunting the meter movement with a 0. 1 ufd capacitor
3. Replacing the resistor which is normally in series with the voltage coil with a large inductance
4. Shunting the input terminals with an LC network adjusted to the resonant frequency of the signal being measured

2-52. What precaution(s), if any, must be taken when checking components with the Huntron Tracker 2000?

1. Voltages must not exceed 5 V dc
2. Voltages must not exceed 5 V ac
3. Device to be tested must have all power turned off and capacitors discharged
4. None of the above

2-53. When you are testing components by comparison, what is the most common mode used on the Huntron Tracker?

1. Automatic
2. Pulse generator
3. Single sweep
4. Alternate

2-54. Why is it necessary to electrically isolate a component while testing individual components with the Huntron Tracker 2000?

1. A resistor in series may give you an inaccurate signature
2. A diode in series may give you an inaccurate signature
3. A resistor in parallel may give you an inaccurate signature
4. All of the above

ASSIGNMENT 3

Textbook assignment: Chapter 3, “Quantitative Measurement,” pages 3-26 through 3-39. Chapter 4, “Qualitative Measurements,” pages 4-1 through 4-14. Chapter 5, “Introduction to Waveform Interpretation,” pages 5-1 through 5-35.

3-1. The AN/URM-120 in-line wattmeter is capable of measuring which of the following values?

1. Rf levels up to 500 watts between 30 MHz and 1,000 MHz
2. Rf levels up to 1 kW between 2 MHz and 30 MHz
3. Both 1 and 2 above
4. Af levels up to 500 watts between 1 kHz and 15 kHz

3-2. When rf power is applied to a bolometer, the heat generated by the semiconductor bead results in which of the following characteristic changes?

1. A capacitive change
2. An inductive change
3. A resistive change
4. A frequency change

3-3. The Hewlett-Packard 431 C power meter is capable of measuring power within which of the following frequency ranges in a coaxial system?

1. 1 MHz to 9 MHz
2. 10 MHz to 18 GHz
3. 41 GHz to 100 GHz
4. 101 GHz to 1,000 GHz

3-4. Calorimeters measure power by converting the input electromagnetic energy into which of the following forms?

1. Heat
2. Dc power
3. Pulsed rf energy
4. Electrodynamic energy

3-5. Which of the following relationships exist(s) between the temperature increase of the calorimetric body of a static calorimeter and the applied power?

1. The temperature increase is proportional to the frequency of the applied power
2. The temperature increase is inversely proportional to the amount of applied power
3. The temperature increase is directly proportional to the time of the applied power
4. Both 2 and 3 above

3-6. Which of the following statements describe(s) the method of using a twin calorimeter?

1. Rf power is applied to one calorimetric body and the other body acts as a temperature reference
2. The steady-state temperature difference between the two calorimetric bodies is used as a measure of rf power
3. Both 1 and 2 above
4. Power is applied to both calorimetric bodies through a directional coupler

3-7. Flow calorimeters are classified by the type of measurement performed, the type of heating used, and what other characteristic?

1. Number of calorimetric bodies
2. Type of circulation method used
3. Type of rf loads that they employ
4. Number of calorimetric fluids used

3-8. When performing measurements above 1 GHz in a flow calorimeter, which of the following dielectrics do you normally use?

1. Water
2. Oil
3. MEK
4. H_2SO_4

3-9. Which of the following government agencies is/are responsible for maintaining our primary?

1. U. S. National Bureau of Standards
2. U. S. Naval Observatory
3. Department of Weights and Measures
4. All of the above

3-10. When using a stroboscope to measure an unknown frequency, which, if any, of the following steps should you take?

1. Start the measurement at the lowest frequency that the stroboscope can deliver and increase the flashing rate until a single image is obtained
2. Start the measurement at the highest frequency that the stroboscope can deliver and reduce the flashing rate until a single stationary image is obtained
3. Start the measurement at the midscale range of the stroboscope and adjust the flashing rate, in either direction, until a harmonic of the primary frequency is obtained
4. None of the above

THIS SPACE LEFT BLANK INTENTIONALLY.

3-11. If you anticipate using a stroboscope over an extended period of time, which of the following actions can you take to extend flasher-tube life?

1. Operate the stroboscope at a submultiple of the fundamental synchronous speed
2. Lower the plate voltage of the flasher tube
3. Lower the filament voltage of the flasher tube
4. Operate the stroboscope at a multiple of the fundamental synchronous speed

3-12. Vibrating reed meters and moving disk meters are primarily used to measure which of the following values?

1. The frequency of 60-Hz ac power
2. The rotational speed of synchronous motors
3. Frequencies between 1 kHz and 10 MHz
4. The frequencies of multiplexed signals

3-13. When using an oscilloscope to measure frequencies, which of the following formulas should you use?

1. $f = \frac{1}{t}$
2. $f = t$
3. $f = \frac{t}{1}$
4. $f = (N_x) \cdot \frac{AB}{A - B}$

3-14. Most oscilloscopes are limited in their frequency-measuring capability to which of the following upper frequency limits?

1. 50 kHz
2. 100 kHz
3. 500 kHz
4. 100 MHz

3-15. Which of the following indications should you observe when a frequency meter is adjusted to the resonant frequency of the signal under test?

1. An audible beat-frequency signal
2. A pronounced dip in output at resonance
3. A pronounced increase in output power
4. A bright glow of the frequency meter glow lamp

3-16. What is the purpose of the time interval measurement of a frequency counter?

1. It indicates the wave period
2. It indicates the time between two events
3. It indicates the time between two functions of an event
4. Both 2 and 3 above

3-17. What are the three basic categories of wavemeters?

1. Resonant, active, and passive
2. Absorption, active, and passive
3. Reaction, resonant, and absorption
4. Absorption, reaction, and transmission

3-18. In becoming a qualified technician, which of the following goals should you seek to achieve?

1. To be able to repair a specific piece of equipment
2. To be able to isolate faults in an entire system
3. To demonstrate a basic knowledge of system interconnections
4. To demonstrate minimum maintenance ability on a piece of equipment

3-19. When attempting to correct a technical problem, which of the following procedures should you follow?

1. Use short cuts
2. Do random testing
3. Use a logical approach
4. Do a self-test of the equipment

3-20. Efficient operation of equipment is assured by which of the following actions?

1. Using tricks of the trade
2. Making quick repairs when problems occur
3. Observing system quality figures during preventive maintenance
4. Monitoring all system test points continuously

3-21. The standing-wave ratio (swr) in a transmission line is figured by using which of the following ratios?

1. Maximum voltage to maximum current
2. Maximum voltage to minimum voltage
3. Maximum current to maximum voltage
4. Minimum voltage to minimum current

3-22. Swr measurements are taken for which of the following purposes?

1. To determine the output frequency of the system under test
2. To determine the matching quality of the transmission line termination
3. To determine the coupling quality of the transmission line
4. To determine system output power

3-23. Couplers containing slots are used with rf probes to provide access to which of the following components?

1. Wavemeters
2. Unidirectional couplers
3. Open transmission lines
4. Waveguides

3-24. The wavelength of a standing wave is measured on a short-circuited, terminated line using a magnetic or electric probe in which of the following ways?

1. By multiplying the average current by the peak current
2. By dividing the average voltage by the peak voltage
3. By measuring the distance between a maximum voltage point and a maximum current point
4. By measuring the distance between alternate maximum or minimum current points along the line

3-25. A neon lamp moved parallel to a two-wire parallel transmission line will glow at its brightest at which of the following points?

1. Maximum current points
2. Maximum voltage points
3. Maximum voltage and current points
4. Maximum and minimum current points

3-26. A milliammeter moved parallel to a two-wire transmission line will show its highest indication at which of the following points?

1. Maximum voltage points
2. Maximum current points
3. Maximum current and voltage points
4. Maximum and minimum voltage points

3-27. Which of the following devices may be used to measure swr without measuring the standing wave?

1. Bridge
2. Rf probe
3. Neon lamps
4. Milliammeter

3-28. When using an RC bridge to measure swr, which of the following factor(s) must you consider as the applied frequency increases?

1. Skin effect
2. Stray inductance
3. Stray capacitance
4. All of the above

3-29. Before a newly constructed bridge can be calibrated, adjustments must be made for which of the following reasons?

1. To determine the frequency range of the bridge
2. To keep stray effects at a minimum
3. To adjust the rf voltage amplitude
4. To determine the characteristic impedance of the circuit

3-30. Which of the following formulas apply(ies) when measuring swr with a bridge?

1. $Swr = \dfrac{R_L}{R_O}$
2. $Swr = \dfrac{R_O}{R_L}$
3. Both 1 and 2 above--use the one that yields an swr ratio greater than 1 to 1
4. $Swr = \dfrac{R_O \times R_L}{R_O + R_L}$

3-31. The ideal impedance match between transmitter and load is

1. 1 to 1
2. 2 to 1
3. 3 to 1
4. 4 to 1

3-32. When comparing vswr and iswr, which, if any, of the following is the correct ratio?

1. Vswr will exceed iswr by a minimum of 100%
2. Vswr will exceed iswr by a minimum of 50%
3. Vswr and iswr ratios will be equal
4. None of the above

3-33. Electrical losses caused by transmission line deterioration are best measured using which of the following pieces of equipment?

1. A signal generator and a power meter
2. A signal generator and a frequency counter
3. An swr meter and an oscilloscope
4. A frequency counter and a power meter

3-34. If a 9.5 GHz, 20 watt signal is inserted into a transmission line, approximately what signal should be measured at the other end of the transmission line?

1. 5 GHz, 10 watts
2. 5 GHz, 20 watts
3. 0 GHz, 10 watts
4. 0 GHz, 20 watts

3-35. To accurately determine transmission line losses, you should perform insertion losses at which of the following frequencies?

1. Midrange of the transmission line's frequency spectrum
2. At the upper and lower entrances of the transmission line's frequency spectrum
3. Across the entire frequency spectrum of the transmission line
4. Midrange of the transmission line's frequency spectrum, plus and minus 10 kHz

3-36. Which of the following transmission line specifications is/are considered important?

1. Frequency
2. Characteristic impedance
3. Power-handling capabilities
4. All of the above

3-37. Mixing two or more frequencies across a nonlinear device produces which of the following signals?

1. Crosstalk
2. Intermodulation distortion
3. Single sideband (ssb) transmission
4. Undesirable carrier frequency deviation

3-38. Which of the following statements describes cross modulation?

1. Degenerative feedback that causes a circuit to oscillate
2. Overmodulation that produces an echo
3. The signal from one channel that modulates the signal on an adjacent channel
4. Oscillation that is caused by system misalignment

3-39. Distortion caused by excessive regenerative feedback is called

1. echo
2. crosstalk
3. detected distortion
4. parasitic generation

3-40. When using a two-tone test to detect intermodulation distortion, what is the ideal indication you should see on a spectrum analyzer?

1. An exact reproduction of the input frequencies
2. The sum and difference of the input frequencies
3. A single frequency with the amplitude equal to the sum of the input frequencies
4. The beat frequency of the two inputs

3-41. Which of the following actions minimizes the effects of intermodulation distortion?

1. Using proper antenna spacing
2. Shielding components and circuitry
3. Using parasitic suppression circuits
4. All of the above

3-42. At what point does an amplitude-modulated signal begin to produce distortion?

1. Below 50% modulation
2. At 65% modulation
3. At 95% modulation
4. Above 100% modulation

3-43. To obtain 100% amplitude modulation of an rf carrier with a sine wave, the modulating power must equal what minimum percent of the rf carrier power?

1. 10%
2. 15%
3. 25%
4. 50%

3-44. The damping of a meter movement that is being used to measure modulation has which of the following disadvantages?

1. The frequency response of the meter is reduced
2. The accuracy of the meter movement is reduced
3. An average reading does not disclose transient overmodulation
4. The amount of current required to drive the meter is reduced

3-45. Which of the following modulation patterns can be observed on an oscilloscope?

1. Wave-envelope and trapezoidal
2. Lissajous and wave-envelope
3. Time division and frequency division
4. Lissajous and trapezoidal

3-46. The frequency response of most oscilloscopes limits the capability of measuring percentage of modulation to which of the following frequency bands?

1. Lf and hf
2. Slf and shf
3. Uhf
4. Vhf

3-47. When using the two-tone test (trapezoidal method) to check a transmitter, you should see what pattern on the oscilloscope?

1. A series of fully modulated sine waves
2. A 100% amplitude-modulated signal
3. Two pulses of equal amplitude and duration
4. Two opposing triangles that are mirror images of each other

3-48. Frequency deviation of an fm signal is usually expressed in which of the following units of measurements?

1. Kilohertz
2. dB
3. dBm
4. Volts

3-49. What limits an fm transmitter's maximum frequency deviation?

1. The width of the band assigned for station operation
2. The maximum power output rating of the transmitter
3. The distortion that occurs at 100% modulation
4. The transmitting antenna height

3-50. Spectrum analysis is a graphic plot of

1. amplitude versus time
2. time versus frequency
3. amplitude versus frequency
4. amplitude versus power

3-51. Time-domain plots are used by technicians to graphically view which of the following waveform parameters?

1. Amplitude versus time
2. Frequency versus time
3. Frequency versus distance
4. Amplitude versus power

3-52. Frequency-domain plots are used by technicians to graphically view which of the following waveform parameters?

1. Amplitude versus time
2. Amplitude versus frequency
3. Frequency versus distance
4. Amplitude versus power

3-53. Which of the following pieces of test equipment should you use to determine what signals make up a complex signal?

1. Oscilloscope
2. Sweep oscillator
3. Spectrum analyzer
4. Time-domain reflectometer

3-54. At 100% amplitude modulation, the total power in the sidebands equals what percentage of the carrier power?

1. 6%
2. 50%
3. 66%
4. 100%

3-55. When viewing a 100% amplitude-modulated signal with a spectrum analyzer, what type of display should you observe?

1. A center frequency and both the upper and lower sidebands 6 dB down from the center frequency
2. A center frequency and both the upper and lower sidebands of equal amplitude
3. A center frequency that is -6 dB down from both the upper and lower sidebands
4. A suppressed carrier with both the upper and lower sidebands of equal amplitude

3-56. Which of the following is/are an advantage of ssb transmission?

1. The voice quality of ssb transmissions is superior to both AM and fm transmissions
2. Ssb transmissions are not susceptible to interference caused by sun spots and atmospherics
3. Ssb requires one-sixth of the output power and less than half the bandwidth required by AM to transmit the same amount of intelligence power
4. All of the above

3-57. In fm, the AMOUNT of frequency deviation (shift) is proportional to

1. the frequency of the carrier
2. the amplitude of the modulating signal
3. the frequency of the modulating signal
4. the plate current of the transmitter's linear amplifier

3-58. In fm, the RATE of frequency deviation (shift) is proportional to

1. the impedance of the antenna
2. the power output of the transmitter
3. the amplitude of the modulating signal
4. the frequency of the modulating signal

3-59. When analyzing the composition of a rectangular wave with a spectrum analyzer, which of the following types of displays will you see?

1. A fundamental frequency and its odd harmonics only
2. A fundamental frequency and its even harmonics only
3. A fundamental frequency and its combined even and odd harmonics
4. An infinite number of fundamental frequencies

3-60. The ability of a spectrum analyzer to resolve signals refers to its ability to

1. distinguish one signal from other signals
2. shape signals through the use of filters
3. determine a receiver's minimum discernible signal
4. measure the frequency of a signal

3-61. The ability of a spectrum analyzer to resolve signals is limited by which of the following factors?

1. The amplitude of the signal under test
2. The narrowest bandwith of the spectrum analyzer
3. The upper frequency limits of the spectrum analyzer
4. The lower frequency limits of the spectrum analyzer

3-62. Which of the following characteristics of a transmission line fault can be observed using time-domain reflectometry?

1. Nature of the fault
2. Distance to the fault
3. Both 1 and 2 above
4. Figure of merit of the fault

3-63. What is the primary application of swept-frequency testing?

1. To determine the broadband frequency response of a device
2. To determine the characteristics of a device at a specific frequency
3. To determine the impedance of a transmission line
4. To determine the swr of a transmission line

3-64. You should perform an initial power check on a transmitting antenna before sweeping the antenna for which of the following reasons?

1. To prevent damage to the test equipment
2. To ensure the transmitter is deenergized
3. To ensure the transmitter is energized
4. To ensure the transmitter is keyed

Navy Electricity and Electronics Training Series

Module 22—Introduction to Digital Computers

NAVEDTRA 14194

Notice: NETPDTC is no longer responsible for the content accuracy of the NRTCs.

For content issues, contact the servicing Center of Excellence: Center for Surface Combat System (CSCS); (540) 284-1061 or DSN: 249-1061.

Although the words “he,” “him,” and “his” are used sparingly in this course to enhance communication, they are not intended to be gender driven or to affront or discriminate against anyone.

DISTRIBUTION STATEMENT A: Approved for public release; distribution is unlimited.

PREFACE

By enrolling in this self-study course, you have demonstrated a desire to improve yourself and the Navy. Remember, however, this self-study course is only one part of the total Navy training program. Practical experience, schools, selected reading, and your desire to succeed are also necessary to successfully round out a fully meaningful training program.

COURSE OVERVIEW: To introduce the student to the subject of Digital Computers who needs such a background in accomplishing daily work and/or in preparing for further study.

THE COURSE: This self-study course is organized into subject matter areas, each containing learning objectives to help you determine what you should learn along with text and illustrations to help you understand the information. The subject matter reflects day-to-day requirements and experiences of personnel in the rating or skill area. It also reflects guidance provided by Enlisted Community Managers (ECMs) and other senior personnel, technical references, instructions, etc., and either the occupational or naval standards, which are listed in the *Manual of Navy Enlisted Manpower Personnel Classifications and Occupational Standards,* NAVPERS 18068.

THE QUESTIONS: The questions that appear in this course are designed to help you understand the material in the text.

VALUE: In completing this course, you will improve your military and professional knowledge. Importantly, it can also help you study for the Navy-wide advancement in rate examination. If you are studying and discover a reference in the text to another publication for further information, look it up.

Sailor's Creed

"I am a United States Sailor.

I will support and defend the Constitution of the United States of America and I will obey the orders of those appointed over me.

I represent the fighting spirit of the Navy and those who have gone before me to defend freedom and democracy around the world.

I proudly serve my country's Navy combat team with honor, courage and commitment.

I am committed to excellence and the fair treatment of all."

TABLE OF CONTENTS

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

INSTRUCTIONS FOR TAKING THE COURSE

ASSIGNMENTS

The text pages that you are to study are listed at the beginning of each assignment. Study these pages carefully before attempting to answer the questions. Pay close attention to tables and illustrations and read the learning objectives. The learning objectives state what you should be able to do after studying the material. Answering the questions correctly helps you accomplish the objectives.

SELECTING YOUR ANSWERS

Read each question carefully, then select the BEST answer. You may refer freely to the text. The answers must be the result of your own work and decisions. You are prohibited from referring to or copying the answers of others and from giving answers to anyone else taking the course.

SUBMITTING YOUR ASSIGNMENTS

To have your assignments graded, you must be enrolled in the course with the Nonresident Training Course Administration Branch at the Naval Education and Training Professional Development and Technology Center (NETPDTC). Following enrollment, there are two ways of having your assignments graded: (1) use the Internet to submit your assignments as you complete them, or (2) send all the assignments at one time by mail to NETPDTC.

Grading on the Internet: Advantages to Internet grading are:

- you may submit your answers as soon as you complete an assignment, and
- you get your results faster; usually by the next working day (approximately 24 hours).

In addition to receiving grade results for each assignment, you will receive course completion confirmation once you have completed all the assignments. To submit your assignment answers via the Internet, go to:

https://courses.cnet.navy.mil

COMPLETION TIME

Courses must be completed within 12 months from the date of enrollment. This includes time required to resubmit failed assignments.

PASS/FAIL ASSIGNMENT PROCEDURES

If your overall course score is 3.2 or higher, you will pass the course and will not be required to resubmit assignments. Once your assignments have been graded you will receive course completion confirmation.

If you receive less than a 3.2 on any assignment and your overall course score is below 3.2, you will be given the opportunity to resubmit failed assignments. **You may resubmit failed assignments only once.** Internet students will receive notification when they have failed an assignment—they may then resubmit failed assignments on the web site. Internet students may view and print results for failed assignments from the web site. Students who submit by mail will receive a failing result letter and a new answer sheet for resubmission of each failed assignment.

COMPLETION CONFIRMATION

After successfully completing this course, you will receive a letter of completion.

STUDENT FEEDBACK QUESTIONS

We value your suggestions, questions, and criticisms on our courses. If you would like to communicate with us regarding this course, we encourage you, if possible, to use e-mail.

NAVAL RESERVE RETIREMENT CREDIT

If you are a member of the Naval Reserve, you may earn retirement points for successfully completing this course, if authorized under current directives governing retirement of Naval Reserve personnel. For Naval Reserve retirement, this course is evaluated at 4 points. (Refer to *Administrative Procedures for Naval Reservists on Inactive Duty,* BUPERSINST 1001.39, for more information about retirement points.)

Student Comments

Course Title: *NEETS Module 22*
Introduction to Digital Computers

NETPDTC 1550/41 (Rev 4-00)

CHAPTER 1

OPERATIONAL CONCEPTS

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions placed throughout the chapters are based on the objectives. By successfully completing the Nonresident Training Course (NRTC), you indicate that you have met the objectives and have learned the information. The learning objectives for this chapter are listed below.

Upon completion of this chapter, you will be able to do the following:

1. Describe the history of computers.
2. Describe how computers are classified.
3. Explain how digital computers have changed during each generation.
4. Describe the practical applications of digital computers in the Navy.
5. Describe the initial steps needed to use a microcomputer.
6. Explain storage media handling, backups, and the threats to storage media.

INTRODUCTION

Digital computers are used in many facets of today's Navy. It would be impossible for one *NEETS* module to cover all the ways they are used in any depth. A few of these ways are covered later in this chapter.

The purpose of this module is to acquaint you, the trainee, with the basic principles, techniques, and procedures associated with digital computers. We will use a desktop (personal) computer for most of the examples. Personal computers should be more familiar to you than the large mainframes, and the operating principles of personal computers relate directly to the operating principles of mainframe computers. You will learn the basic terminology used in the digital-computer world. When you have completed these chapters satisfactorily, you will have a better understanding of how computers are able to perform the demanding tasks assigned to them.

If we were to define the word computer, we would say a computer is an instrument for performing mathematical operations, such as addition, multiplication, division, subtraction, integration, vector resolution, coordinate conversion, and special function generation at very high speeds. But the usage of computers goes well beyond the mathematical-operations level.

Computers have made possible military, scientific, and commercial advances that before were considered impossible. The mathematics involved in orbiting a satellite around the earth, for example, would require several teams of mathematicians for a lifetime. Now, with the aid of electronic digital computers, the conquest of space has become reality.

Computers are employed when repetitious calculations or the processing of large amounts of data are necessary. The most frequent applications are found in the military, scientific, and commercial fields. They are used in many varied projects, ranging from mail sorting, through engineering design, to the identification and destruction of enemy targets. The advantages of digital computers include speed, accuracy, reliability, and man-power savings. Frequently computers are able to take over routine jobs, releasing people for more important work; work that cannot be handled by a computer.

HISTORY OF COMPUTERS

The ever increasing need for faster and more efficient computers has created technological advances that can be considered amazing. Ever since humans discovered that it was necessary to count objects, we have been looking for easier ways to do it. Contrary to popular belief, digital computers are not a new idea. The abacus is a manually operated digital computer used in ancient civilizations and used to this day in the Orient (see fig. 1-1). For those who consider the abacus outdated, in a contest between a person using a modern calculator and a person using an abacus, the person using the abacus won.

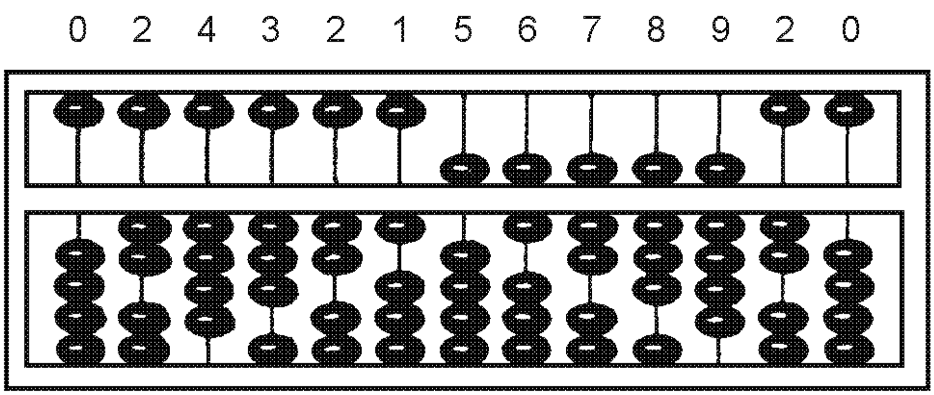

Figure 1-1.—Abacus.

The first mechanical adding machine (calculator) was invented by Blaise Pascal (French) in 1642. Twenty years later, an Englishman, Sir Samuel Morland, developed a more compact device that could multiply, add, and subtract. In 1682, Wilhelm Liebnitz (German) perfected a machine that could perform all the basic operations (addition, subtraction, division, and multiplication), as well as extract the square root. Liebnitz's principles are still in use today in our modern electronic digital computers.

As early as 1919, electronics entered the scene. An article by W. H. Eccles and F. W. Jordan described an electronic "trigger circuit" that could be used for automatic counting. It was the ECCLES-JORDAN multivibrator which was a little ahead of its time because a trigger circuit is one of many components required to make an electronic digital computer. Modern digital computers use these circuits, known as flip-flops, to store information, perform arithmetic operations, and control the timing sequences within the computer.

Under the pressure of military needs in World War II, the science of electronic data processing made giant strides forward. In 1944, Harvard University developed a computing system known as the Automatic Sequence Controlled Calculator. After the initial design and construction, several improved models were built.

Meanwhile, at the University of Pennsylvania, a second system was being developed. This system, completed in 1946, was named ENIAC (Electronic Numerical Integrator and Computer). ENIAC employed 18,000 vacuum tubes in its circuitry; and in spite of these bulky, hot tubes, it worked quite successfully. The first problem assigned to ENIAC was a calculation in nuclear physics that would have taken 100 human-years to solve by conventional methods. The ENIAC solved the problem in 2 weeks, only 2 hours of which were actually spent on the calculation. The remainder of the time was spent checking the results and operational details. All modern computers have their basics in these two early developments conducted at Harvard University and University of Pennsylvania.

In 1950, the UNIVAC I was developed. This machine was usually regarded as the most successful electronic data processor of its day. An outstanding feature of the UNIVAC I was that it checked its own results in each step of a problem; thus eliminating the need to run the problems more than once to ensure accuracy.

During the first outbreak of publicity about computers (especially when the UNIVAC predicted the outcome of the 1952 presidential election), the term "giant brain" caused much confusion and uneasiness. Many people assumed that science had created a thinking device superior to the human mind. Currently most people know better. By human standards the giant brain is nothing more than a talented idiot that is wholly dependent upon human instructions to perform even the simplest job. A computer is only a machine and definitely cannot think for itself. The field of artificial intelligence, however, is developing computer systems that can "think"; that is, mimic human thought in a specific area and improve performance with experience and operation. The field of digital computers is still in the growing stages. New types of circuitry and new ways of accomplishing things are continuing to be developed at a rapid rate.

In the military field, the accomplishments of digital computers are many and varied. One outstanding example is in weapons systems. Most of the controlling is done by digital computers.

CLASSIFICATIONS OF COMPUTERS

Computers can be classified in many different ways. They can be classified by the type of technology they use (mechanical, electromechanical, or electronic), the purpose for which they were designed (general purpose or special purpose), by the type of data they can handle (digital or analog), by the amount they cost (from $50 to $10 million and up), and even by their physical size (handheld to room size). We will briefly explain mechanical, electromechanical, and electronic computers; special-purpose and general-purpose computers; and analog and digital computers.

MECHANICAL COMPUTERS

Mechanical or analog computers are devices used for the computation of mathematical problems. They are made up of components, such as integrators, sliding racks, cams, gears, springs, and driveshafts. Figure 1-2 shows a typical mechanical computer used by the Navy. These computers are analog in nature, and their physical size depends on the number of functions the computer has to perform. In an analog computer, a continuing input will give a constantly updated output. This being perfect for target information, the Navy uses these analog computers primarily for gun fire control. As systems for naval weapons became more and more complex, the need for a different computer was apparent. The functions that had to be performed had increased the size of the computer to an unreasonable scale.

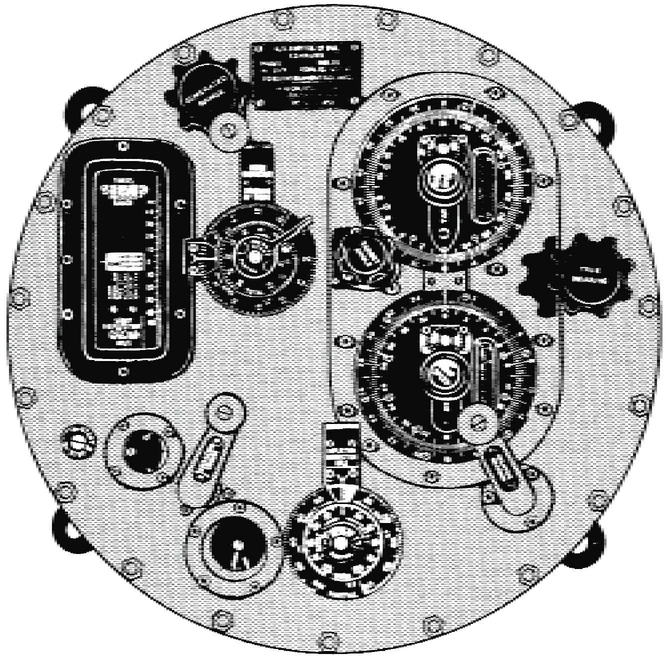

Figure 1-2.—Bulkhead-type mechanical computer

ELECTROMECHANICAL COMPUTERS

Electromechanical computers came next and differ from mechanical computers in that they use electrical components to perform some of the calculations and to increase the accuracy. Because the electrical components are smaller than their mechanical counterparts, the size of the computer was reduced, even though it performs more functions. The components used to perform the calculations are devices such as synchros, servos, resolvers, amplifiers, servo amplifiers, summing networks, potentiometers, and linear potentiometers. Figure 1-3 shows one of the Navy's electromechanical computers. These computers are used in gun fire control and missile fire control. Even though they are better than the mechanical computer, they still have their drawbacks. Of prime importance is that they are special-purpose computers. This means they can only be used for one job, dependent on their design characteristics. By today's Navy standards they are still too large, and the maintenance time on them is excessive. The need for a more accurate, reliable, versatile, and smaller computer was recognized.

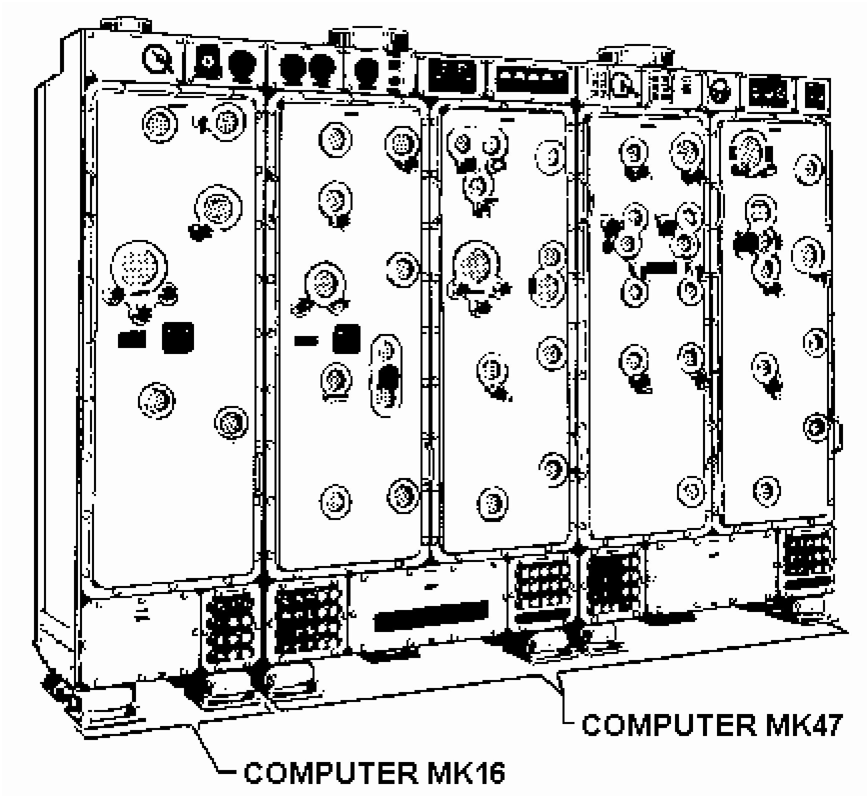

Figure 1-3.—Electromechanical computer.

ELECTRONIC COMPUTERS

Next came electronic computers. The early electronic computers' mathematical processes were solved by using electrical voltages only, applied to elements such as amplifiers, summing networks, differentiating, and integrating circuits. The weak link in this type of electrical computation was the vacuum tube. To correct this, transistors which consume less power and last longer than vacuum tubes were used in the amplifiers. Through technological research and development, we have progressed from tubes, to transistors, to miniaturized circuits, to integrated circuitry. These advances have made it possible to reduce the size and weight of our computers. Figure 1-4 is an example of one of our modern electronic digital computers.

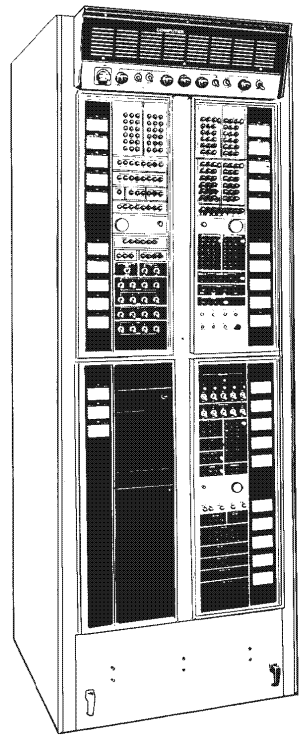

Figure 1-4.—Electronic digital computer.

SPECIAL-PURPOSE COMPUTERS

A special-purpose computer, as the name implies, is designed to perform a specific operation and usually satisfies the needs of a particular type of problem. Such a computer system would be useful in weather predictions, satellite tracking, or oil exploration. While a special-purpose computer may have many of the same features found in a general-purpose computer, its applicability to a particular problem is a function of its design rather than to a stored program. The instructions that control it are built directly into the computer, which makes for a more efficient and effective operation. A drawback of this specialization, however, is the computer's lack of versatility. It cannot be used to perform other operations.

GENERAL-PURPOSE COMPUTERS

General-purpose computers are designed to perform a wide variety of functions and operations. You will probably use this type of computer. A general-purpose computer is able to perform a wide variety of operations because it can store and execute different programs in its internal storage. Unfortunately, having this ability is often achieved at the expense of speed and efficiency. In most situations, however, you will find that having this flexibility makes this compromise a most acceptable one.

ANALOG COMPUTERS

All analog computers are special-purpose computers. They are designed to measure continuous electrical or physical conditions, such as current, voltage, flow, temperature, length, or pressure. They then convert these measurements into related mechanical or electrical quantities. The early analog computers were strictly mechanical or electromechanical devices. They did not operate on digits (in binary notation, either of the characters, 0 and 1). If digits were involved at all, they were obtained indirectly. Your wrist watch (if nondigital); your car's speedometer; and oil pressure, temperature, and fuel gauges are also considered analog computers. The output of an analog computer is often an adjustment to the control of a machine; such as, an adjustment to a valve that controls the flow of steam to a turbine generator or a temperature setting to control the ovens in the ship's galley for baking. Analog computers are also used for controlling processes. To do so, they must convert analog data to digital form, process it, and then convert the digital results back to analog form.

You should know that a digital computer can process data with greater accuracy than an analog computer, but an analog computer can process data faster than a digital computer, in some systems. Some computers combine the functions of both analog and digital computers. They are called hybrid computers.

DIGITAL COMPUTERS

Digital computers perform arithmetic and logic functions on separate discrete data, like numbers, or combinations of discrete data, such as name, rate, and division. This makes them different from analog computers that operate on continuous data, like measuring temperature changes. We generally use digital computers for business and scientific data processing. The following are examples:

Accounting—Computers are ideal for keeping payroll records, printing paychecks, billing customers, preparing tax returns, and taking care of many of the other accounting tasks in an organization.

Recordkeeping—Computers can record information like inventories and personnel files. They can also keep track of books checked out of a library. Airline ticket counters are much more efficient than they used to be, thanks to centralized reservation computers that can be reached over the telephone lines.

Industrial Uses—Industrial computers save considerable time and reduce waste by efficiently performing hundreds of industrial tasks, ranging from filling sales orders and routing parts to various locations on an assembly line, to designing earthquake-resistant structures, and controlling an entire oil refinery.

Science—The research and development applications are the most numerous. Digital computers are being used to do lengthy and complicated mathematical calculations millions of times faster than human beings. They are also used to collect, store, and evaluate data from experiments, analyze weather patterns, forecast crop statistics, and, believe it or not, design other computers.

Word Processing—Remember, these words were typed into a desktop computer! Word processing is among the most common applications for personal computers. If you have not discovered the advantages of computer writing, it's time to visit a computer dealer for a personalized demonstration.

None of this work could be performed by a computer without first instructing the computer how to do it by means of a list of instructions called a program. The instructions in the program must be written in one of the languages the computer understands. The most popular generic term for computer programs is software (this is covered in chapter 3). Hardware (covered in chapter 2), of course, refers to the computer and related equipment. It is easy to say that both computer hardware and software are interdependent because neither can perform useful work without the other. Digital computers may be either special or general purpose.

ACCURACY OF COMPUTERS

The fundamental difference between analog and digital computers is that digital computers deal with discrete quantities such as beads on an abacus, notches on a toothed wheel, or electrical pulses, while analog computers deal with continuous physical variables such as electrical voltages or mechanical shaft rotations. Computation with analog computers depends on the relation of information to a measurement of some physical quantity. For example, you can determine the number of boards in a picket fence by either a digital or an analog system as follows. In the digital method (fig. 1-5, view A), you use an adding machine and count the boards one by one. In the analog method (fig. 1-5, view B), you draw a string (marked off in inches for the width of each board including the gap) over the length of the fence, then measure the length of the string. The number of boards may then be determined by dividing the length of string by the number of inches per board.

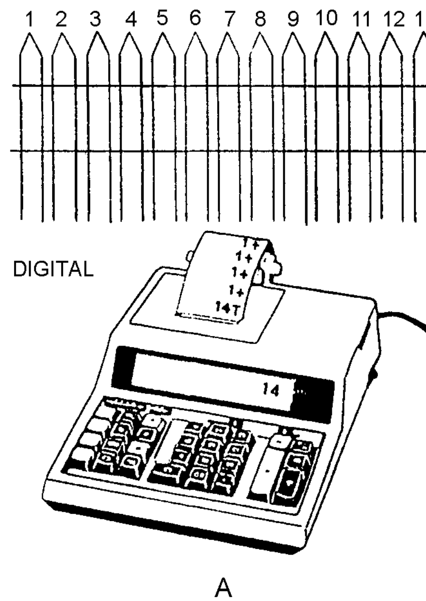

Figure 1-5A.—Digital computation.

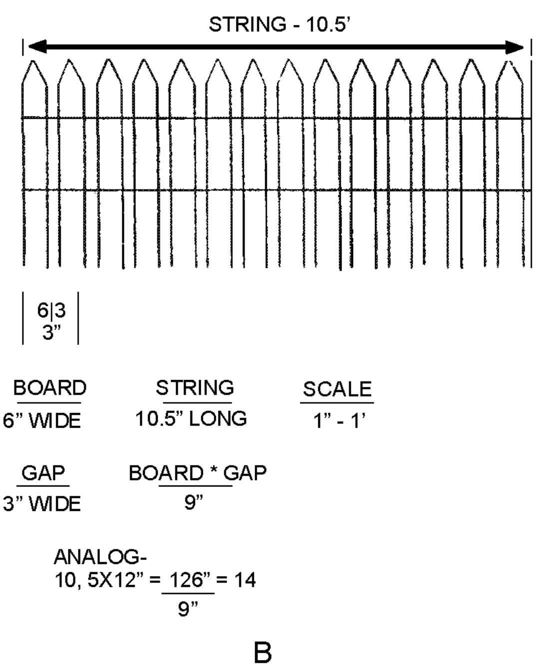

Figure 1-5B.—Analog computation.

The accuracy of an analog computer is restricted to the accuracy with which physical quantities can be sensed and displayed. This, in turn, is related to the quality of the components used in constructing the computer; for example, the tolerance of electrical resistors or mechanical shafts and the quality of the output equipment. In an analog computer, for example, if the constant is represented by a voltage, it probably could be read only to the third decimal place.

On the other hand, the accuracy of a digital computer is governed by the number of significant figures carried in the computations. This, in turn, is determined by the computer's design. In a digital computer, the number of decimal places in the constant could be many, depending on the design of the computer processing unit. The digital computer is, therefore, capable of higher precision and accuracy. However, a computer, regardless of its accuracy, would do you no good if the wrong one were chosen for a given task.

Most of the computer systems you will work with will be general-purpose digital computers. The remainder of this module will be about general-purpose digital computers.

Q-1. How are computers classified?

Q-2. Mechanical computers are considered to be of what type?

Q-3. The Navy uses analog computers primarily for what purpose?

Q-4. How do electromechanical computers differ from the mechanical computers?

Q-5. In electronic computers, vacuum tubes were replaced by transistors and transistors have been replaced by what device?

Q-6. A computer that is designed to perform a specific operation and usually satisfies the needs of a particular type of problem, is said to be what type of computer?

Q-7. Rather than using a stored program, a special-purpose computer's applicability to a particular problem is a function of what?

Q-8. What is a drawback to the special-purpose computer?

Q-9. A general-purpose computer is designed for what purpose?

Q-10. How is a general-purpose computer able to perform different operations?

Q-11. In a general-purpose computer, the ability to perform a wide variety of operations is achieved at the expense of what capabilities?

Q-12. All analog computers are what type of computers?

Q-13. What are analog computers designed to measure?

Q-14. Early analog computers were what type of devices?

Q-15. What are computers called that combine the functions of both analog and digital computers?

Q-16. Digital computers are generally used for what purposes?

Q-17. What is the fundamental difference between analog and digital computers?

Q-18. How is the accuracy of an analog computer restricted?

Q-19. A constant represented by a voltage can be read to what decimal place?

Q-20. The accuracy of a digital computer is governed by what factor?

Q-21. In a digital computer, what does the number of decimal places in the constant depend on?

Q-22. You will most likely be working with what type of computer?

DIGITAL COMPUTER GENERATIONS

In the electronic computer world, we measure technological advancement by generations. A specific system is said to belong to a specific "generation." Each generation indicates a significant change in computer design. The UNIVAC I represents the first generation. Currently we are moving toward the fourth generation.

FIRST GENERATION

The computers of the first generation (1951-1958) were physically very large machines characterized by the vacuum tube (fig. 1-6). Because they used vacuum tubes, they were very unreliable, required a lot of power to run, and produced so much heat that adequate air conditioning was critical to protect the computer parts. Compared to today's computers, they had slow input and output devices, were slow in processing, and had small storage capacities. Many of the internal processing functions were measured in thousandths of a second (millisecond). The software (computer program) used on first generation computers was unsophisticated and machine oriented. This meant that the programmers had to code all computer instructions and data in actual machine language. They also had to keep track of where instructions and data were stored in memory. Using such a machine language (see chapter 3) was efficient for the computer but difficult for the programmer.

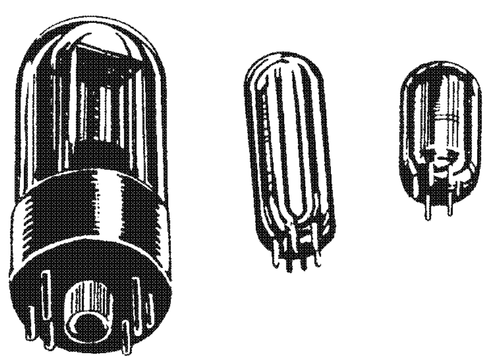

Figure 1-6.—First generation computers used vacuum tubes.

SECOND GENERATION

The computers of the second generation (1959-1963), were characterized by transistors (fig. 1-7) instead of vacuum tubes. Transistors were smaller, less expensive, generated almost no heat, and required very little power. Thus second generation computers were smaller, required less power, and produced a lot less heat. The use of small, long lasting transistors also increased processing speeds and reliability. Cost performance also improved. The storage capacity was greatly increased with the introduction of magnetic disk storage and the use of magnetic cores for main storage. High speed card readers, printers, and magnetic tape units were also introduced. Internal processing speeds increased. Functions were measured in millionths of a second (microseconds). Like the first generation, a particular computer of the second generation was designed to process either scientific or business oriented problems but not both. The software was also improved. Symbolic machine languages or assembly languages were used instead of actual machine languages. This allowed the programmer to use mnemonic operation codes for instruction operations and symbolic names for storage locations or stored variables. Compiler languages were also developed for the second generation computers (see chapter 3).

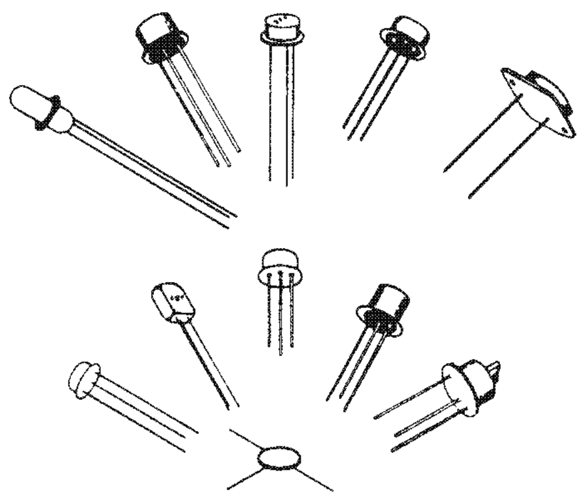

Figure 1-7.—Second generation computers used transistors.

THIRD GENERATION

The computers of this generation (1964-1970), many of which are still in use, are characterized by miniaturized circuits. This reduces the physical size of computers even more and increases their durability and internal processing speeds. One design employs solid-state logic microcircuits (fig. 1-8) for which conductors, resistors, diodes, and transistors have been miniaturized and combined on half-inch ceramic squares. Another smaller design uses silicon wafers on which the circuit and its components are etched. The smaller circuits allow for faster internal processing speeds resulting in faster execution of instructions. Internal processing speeds are measured in billionths of a second (nanoseconds). The faster computers make it possible to run jobs that were considered impractical or impossible on first or second generation equipment. Because the miniature components are more reliable, maintenance is reduced. New mass storage, such as the data cell, was introduced during this generation, giving a storage capacity of over 100 million characters. Drum and disk capacities and speed have been increased, the portable disk pack has been developed, and faster, higher density magnetic tapes have come into use. Considerable improvements were made to card readers and printers, while the overall cost has been greatly reduced. Applications using online processing, real-time processing, time sharing, multiprogramming, multiprocessing, and teleprocessing have become widely accepted. More on this in later chapters.

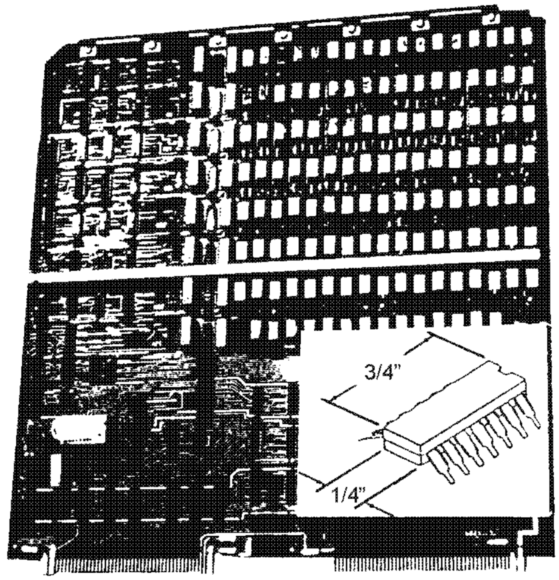

Figure 1-8.—Third generation computers used microcircuits.

Manufacturers of third generation computers are producing a series of similar and compatible computers. This allows programs written for one computer model to run on most larger models of the same series. Most third generation systems are designed to handle both scientific and business data processing applications. Improved program and operating software has been designed to provide better control, resulting in faster processing. These enhancements are of significant importance to the computer operator. They simplify system initialization (booting) and minimize the need for inputs to the program from a keyboard (console intervention) by the operator.

FOURTH GENERATION AND BEYOND

The computers of the fourth generation are not easily distinguished from earlier generations, yet there are some striking and important differences. The manufacturing of integrated circuits has advanced to the point where thousands of circuits (active components) can be placed on a silicon wafer only a fraction of an inch in size (the computer on a chip). This has led to what is called large scale integration (LSI) and very large scale integration (VLSI). As a result of this technology, computers are significantly smaller in physical size and lower in cost. Yet they have retained large memory capacities and are ultra fast. Large mainframe computers are increasingly complex. Medium sized computers can perform the same tasks as large third generation computers. An entirely new breed of computers called microcomputers (fig. 1-9) and minicomputers are small and inexpensive, and yet they provide a large amount of computing power.

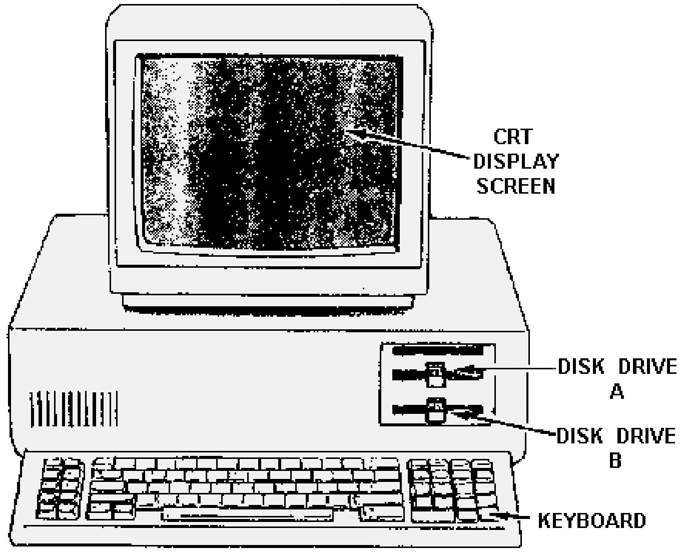

Figure 1-9.—Fourth generation desktop (personal) computer.

What is in store for the future? The computer industry still has a long way to go in the field of miniaturization. You can expect to see the power of large mainframe computers on a single super chip. Massive data bases, such as the Navy's supply system, may be written into read-only memory (ROM) on a piece of equipment no bigger than a desktop calculator (more about ROM in chapter 2). The future challenge will not be in increasing the storage or increasing the computer's power, but rather in properly and effectively using the computing power available. This is where software (programs such as assemblers, report generators, subroutine libraries, compilers, operating systems, and applications programs) will come into play (see chapter 3). Some believe developments in software and in learning how to use these extraordinary, powerful machines we already possess will be far more important than further developments in hardware over the next 10 to 20 years. As a result, the next 20 years (during your career) may be even more interesting and surprising than the last 20 years.

Q-23. Technological advancement is measured by what, in the electronic computer world?

Q-24. What does each generation of computer systems indicate?

Q-25. What were computers of the first generation characterized by?

Q-26. How did vacuum tubes cause a problem for first generation computers?

Q-27. In first generation computers, internal processing functions were measured by what division of time?

Q-28. The software (computer program) used on first generation computers was what type?

Q-29. How were processing speed and reliability increased in second generation computers?

Q-30. In second generation computers, how was the storage capacity greatly increased?

Q-31. With improvements in software, what kind of computer languages could be used on second generation computers?

Q-32. What do the smaller circuits in third generation computers allow for?

Q-33. On third generation computers, what results are gained by faster internal processing speeds?

Q-34. The data cell had a storage capacity of how many characters?

Q-35. What type of applications were most third generation computer systems designed to accomplish?

Q-36. What type of computers are small and inexpensive yet provide a lot of computing power?

Q-37. What does the acronym ROM stand for?

Q-38. What will be one of the future challenges involving computer power?

Q-39. What term is used for programs such as assemblers, compilers, and operating systems?

USES OF A DIGITAL COMPUTER

In the modern computer world of today, the uses of the digital computer are almost as limitless as a person's imagination. New and better programs are being written everyday for easier and greater uses. Consider how many mathematicians it would take to put an astronaut in orbit around the moon, but it only takes one computer. Think back to the days without word processing when a document had to be retyped entirely when any changes were needed. Think back to the days of using an adding machine to prepare and revise budgets and accounting reports. Let's look at three of the primary uses of general-purpose digital computers in the Navy: word processing, accounting/recordkeeping, and work center uses.

WORD PROCESSING

One of the more widespread uses of the computer is word processing. The word processor can be considered a typewriter with a display screen. To the hundreds of thousands of word processor users, the computer is nothing more than a typewriter. Both have keyboards, and both have a mechanism for making the image of the character you strike on the keyboard appear on some type of visual medium. When using an electric typewriter, the process is strictly mechanical. When you press the key, it causes the type face to strike the paper, and in so doing, it leaves an impression. In the computer, the process is more indirect. A program stored in the computer's memory causes a visual representation to appear on a crt (cathode-ray tube) or at a printer. However, from the view point of the user, the result is the same, a printed document.

The great advantage of computers over typewriters is in correcting errors. In the past, correcting a document with a typewriter has meant typing it all over again. Since computers allow the movement of information from one part of memory to another, it is possible to make many changes on a document, and print the result. If the document is still not correct, only the changes need to be entered. The use of computers in this particular way came to be known as word processing.

A further breakthrough came with the development of word-processing application programs for microcomputers. These programs cost a fraction of their office machine counterparts, and could be run on general-purpose microcomputers. This was unique because general-purpose microcomputers could be used for functions such as spreadsheets, data base management systems, and programming in common computer languages.

The Navy saw the obvious uses to which microcomputers using the word processing programs could be put. Some of these are manuscript writing, memorandum writing, identification-card application filing, and recordkeeping.

ACCOUNTING AND RECORDKEEPING

There are virtually unlimited applications for the computer in today's modern business world, from basic accounting functions to controlling the manufacture of products, and of course, keeping records of these actions. Six standard systems dealing with accounting applications are widely accepted. These systems are (1) order entry; (2) inventory control; (3) accounts receivable; (4) accounts payable; (5) general ledger; and (6) payroll. (Figure 1-10 shows a simplified flowchart of payroll.) The area of recordkeeping has two requirements, legal and audit. The Navy has included similar functions in its Shipboard Non-Tactical ADP Program for work center use.

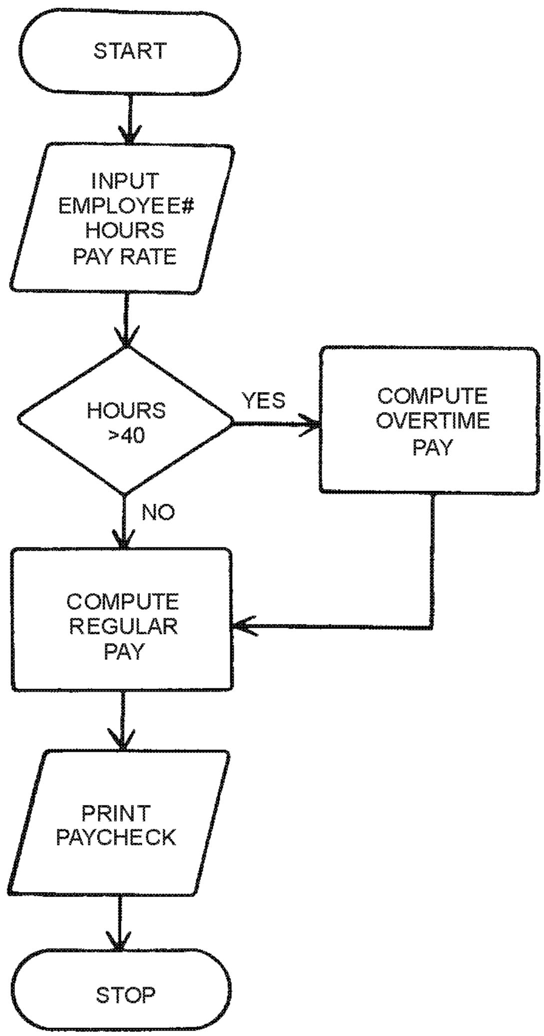

Figure 1-10.—Programming flowchart used to build a payroll program.

WORK CENTER USES (SNAP II)

Every Navy rating has the responsibility for some element of ship's maintenance. And for every rate, recordkeeping has been a "tough nut to turn," an administrative chore that goes along with the work to be done, but takes a "back burner" position to the physical maintenance of the ship and equipment. Today, aboard some ships and soon aboard most, much of that hassle will be done with a SNAP.

The Navy has looked at the paperwork blizzard of recordkeeping responsibility of the essential records and reports that must be generated, and has offered relief to the fleet. This is in the form of S-N-A-P, which stands for Shipboard Non-Tactical ADP Program.

SNAP II is a modern shipboard computer system designed to support shipboard and intermediate-level maintenance, supply, financial, and administrative functions. If this sounds confusing, it really isn't, for the systems are designed to be user-friendly; that is, operating instructions are written in everyday English. Figure 1-11 shows the AN/UYK-62 (V) Data Processing Set. This is the SNAP II computer and its associated hardware.

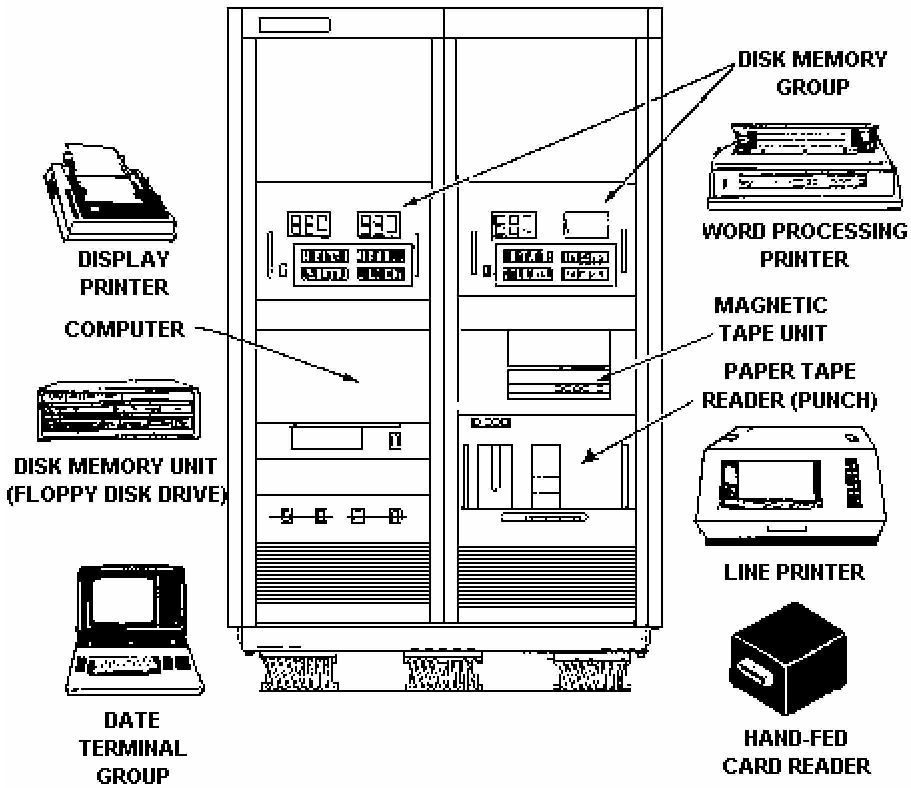

Figure 1-11.—AN/UYK-62 (V) Data Processing Set (SNAP II).

Over the next 3 years, new functions will be added to SNAP to support more of the ship's administrative workload. Pay, personnel, food service, ship's store, PMS, training, medical and dental data are all to be added to SNAP systems.

The SNAP concept is to take the power of the modern computer, the ability to process information, and put that power in the hands of the work center sailors. The sailors can use the system to reduce the labor associated with the paperwork function. User terminals are placed in the different work centers for use by the work center supervisor. Each work center has a different access code. This access code or password prevents unauthorized entry into the main computer's program. Different levels of entry are also defined. The levels depend on a work center's need.

Information stored in the computer for a typical work center normally has the following items that can be updated by the work center supervisor. COSAL (coordinated onboard ship/shore allowance list) is a listing of the repair parts that are allowed to be kept onboard ship, at all times. APL (allowance parts list) is the reference for stock numbers, part numbers, and quantity allowed onboard for a specific system. EIC (equipment identification code) identifies a system, sub-system, or equipment. SHIP'S FORCE WORK LIST is a listing of all work to be performed by a certain work center during a given time period. CSMP (current ship's maintenance projects) provides shipboard maintenance managers with a consolidated listing of deferred maintenance to manage and control its accomplishment. These are but a few of the uses of SNAP II that can be updated by the work center supervisor.

Although the information is usually viewed on a display screen (cathode-ray tube), printed (hard) copies can be obtained. Today, hard copy output from SNAP can be sent to higher authorities in lieu of written reports. In the future, these hard copy transmittals may be replaced by disks or tapes containing the same data. In some cases, the shipboard computers will have an extra telephone wire to the pier or tender, and information can be exchanged electronically.

And there are other important benefits. In practice, the system expedites the storage and retrieval of information the Navy has about its ships. In turn, information that is more accessible means a more timely supply of parts, an improved aid to planners on when and how long to schedule ships' overhauls, and updated information for making decisions whether to place additional or remove unnecessary shipboard equipment. These decisions are now made by laboriously using stacks of printed files. SNAP can sort through these files electronically so Navy planners can make more effective and timely decisions.

SNAP II is a system for unclassified use only at present. This cuts the costs of the installation and many of the physical and electronic security requirements.

Q-40. What is one of the more widespread uses of the computer?

Q-41. What is the great advantage of computers over typewriters?

Q-42. How are word processing programs used by the Navy?

Q-43. How many systems dealing with accounting applications have been widely accepted?

Q-44. What does the acronym S-N-A-P stand for?

Q-45. For what purposes is the SNAP II system designed?

Q-46. What does user friendly mean in computer terms?

Q-47. What does a password prevent?

Q-48. In the SNAP II system, how are the different levels of entry defined?

Q-49. The work center supervisor can update what items from a user terminal?

Q-50. At present what type of classified use is allowed for SNAP II?

USING A DESKTOP COMPUTER

To use a desktop (personal) computer effectively, you'll need to learn about the hardware (the equipment) and the software (the programs). You will also need to know how to handle disks and how to back up programs and data files. So let's assume you have a desktop computer system to use. Its hardware consists of a display screen, a keyboard, a computer, two floppy disk drives (A & B), and a printer. Look at the example in figure 1-12. You need software (computer programs) to make the computer operate. The first program you need is the operating system. The operating system manages the computer and allows you to run application programs like word processing or recordkeeping programs. So let's begin with the operating system.

Figure 1-12.—Typical microcomputer system with display, keyboard, floppy disk drives, and printer.

OPERATING SYSTEM

An operating system is simply a set of programs and routines that lets you and other programs use the computer. A digital computer uses one central set of programs called the operating system to manage execution of other programs and to perform common functions like read, write, or print. Other programs, or you the user, can order the operating system to perform these common functions. These orders are called system calls when other programs use them, or simply commands when you put them through the keyboard.

First, you must load the operating system into the computer so we, and our programs, can use the computer. Remember, in our example, we have a desktop computer with two floppy disk drives, named A and B.

Booting the System

Each desktop computer has a built-in program called "bootstrap loader." When you turn the computer on, this program tries to load, or "boot," an external operating system from disk, usually from drive A, into the computer's internal memory. Disk drive B is usually used for data file disks. The term boot comes from the idea of pulling yourself up by your bootstraps. The computer loads a little program from the disk that tells it how to load a second, bigger program (the operating system). The operating system then tells it how to load another program (an applications program or utility program) to perform a specific job or function. The first thing you need to learn about using a computer is that computers and their programs are very particular. They require complete accuracy and attention to detail on your part. They are not good at guessing what you meant. You'll quickly learn there are a few things that can go wrong at this point, in which case the computer will give you an error message on the display screen similar to this:

Device Error

This means the computer is not reading anything in A drive. Check for:

1. No floppy disk in drive A

2. Floppy disk inserted incorrectly in drive

3. Lock handle on drive A not lowered

Another error message you might receive at this time is:

No System

This means the computer is reading a properly inserted floppy disk, but the disk does not have an operating system on it. Replace the disk with one that does contain the operating system.

Once the operating system is properly booted (loaded), you will see a display similar to this:

A>

You now have what is called a prompt. At this point you can tell the computer what to do next, such as run an application program for example: word processing, accounting, or recordkeeping.

Running an Application Program

To load an application program into the computer from drive A, you put the disk with the application program in disk drive A. Next you type the name of the program following the operating system prompt (A>).

A>**WORDPROC**

This tells the system what program to load and run; in this case Word Processing. The computer then does what the application program tells it. If the application is word processing, the system is ready for you to type a new document, correct an existing document, print a document, and so on. You'll learn more about both the operating system and application programs in chapter 3.

Each application program will have its own set of instructions to follow. In addition to printed documentation, many will include online HELP screens you can display while you are working. These will tell you how to perform a given function or operation.

Another area that needs your constant attention relates to handling floppy disks and making backup copies to be sure your work is not lost.

STORAGE MEDIA HANDLING AND BACKUP

Floppy disks (fig. 1-13) are one means by which you will store data (files that you create) either directly or in backing up the data you store on hard (or fixed) disk. For this reason, and because floppy disks are extremely fragile, you should follow certain guidelines to ensure their proper care and handling. This includes properly labeling and backing up disks.

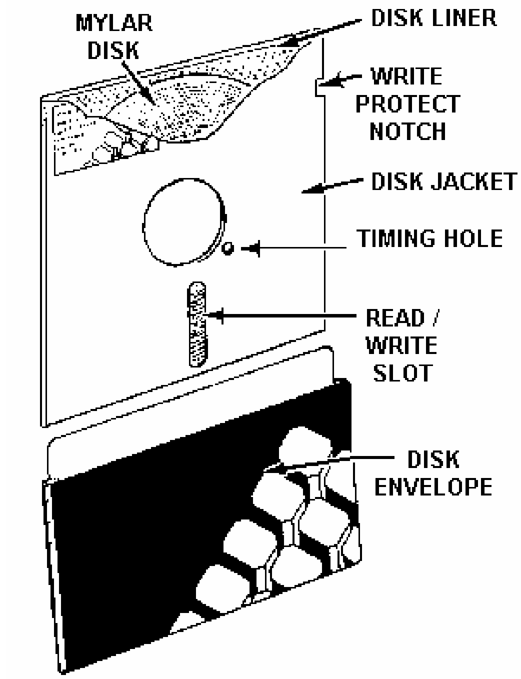

Figure 1-13.—Floppy disk.

Handling

Never touch the exposed surface of a disk. As you know (or will learn), most of the surface of the actual disk is protected most of the time; however, there are areas that are exposed. These areas are the timing hole and the read/write slots. Touching an exposed area can ruin that particular area. If you are familiar with Murphy's Law, you will realize the area you ruin will invariably contain the most important data on that disk.

Storage

Never bend, fold, or otherwise distort the shape of a disk. Never place heavy objects such as books on top of disks. Store disks in the box they came in, or in filing containers that are specifically designed for storing disks. Try to store disks vertically, but if you do store disks horizontally, do not stack more than 10 disks.

Exposure

Disks are subject to exposure from magnetic fields, smoke, heat, and sunlight. X-rays may also have a negative effect.

MAGNETIC FIELDS.—Disks should never be exposed to anything that could be the source of a magnetic field. Exposure of a disk to a magnetic field could cause the destruction of some or all of the data contained on that disk. Some common sources of magnetic energy are crt's, disk drives, and perhaps the most common, the telephone.

SMOKE.—Smoke can cause buildup on disks and on disk drives. DO NOT SMOKE while you work at a terminal or computer.

HEAT AND SUNLIGHT.—Never expose disks to excessive heat or direct sunlight. Either can cause the disks to become warped or distorted so they cannot be used. Disks are made of a plastic material, and if you have ever seen a phonograph record that has been exposed to heat or sunlight, you have some idea of the damage that can result from exposure. Typically, disks will operate only between 10 and 50 degrees Celsius (50 to 120 degrees Fahrenheit). They will accept a relative humidity of 10% to 80%.

X-RAYS.—There is some question about the effect that airport x-ray machines have on disks. It has been the normal experience that the walk-through x-ray machines at airports have no effect on floppy disks; however, this is not to say there will be no effect. It is up to you because these disks contain the data you work with and need. You may not want to take the chance the disks will be affected.

Labeling

When labeling the outside of a floppy disk, write the label before attaching it to the disk. Never use a pencil or ballpoint pen to write on a label once that label has been attached to a disk. When you use an instrument with a sharp point to write on the label, you can actually etch into the surface of the disk underneath the protective sheath, thereby destroying that disk. If you must write on a label once it has been attached to a disk, use a felt-tip marker.

Data Backup

In virtually all computer systems, the possibility exists for errors to occur that accidentally alter or destroy the data stored in the data bases or files. This may occur because of natural disasters, such as fire, flood, or power outages. It may occur through operator error. It may occur through equipment malfunction.

It is essential, therefore, to provide a means to ensure that any data lost can be recovered. The most common method is backup files. A backup file is merely a copy of a file. If for some reason the file or data base is destroyed or becomes unusable, the backup file can be used to recreate the file or data base. Two media are commonly used for backup: disk or tape.

Disk—The most common method of creating a backup for a microcomputer is to use a floppy disk and the diskcopy procedure. This is accomplished by using the original data base or file and copying the information onto a blank floppy disk. The instructions for this procedure will be provided with the particular computer and program you are using.

Tape—Another method of creating a backup is to use magnetic tape. The information contained on your disk, whether it is a data base or file, can be copied onto a tape. The instructions for this procedure will also be provided with the particular computer and program you are using.

Q-51. What is a central set of programs called that manages the execution of other programs and performs common functions like read, write, and print?

Q-52. What is the function of a built-in program called a bootstrap loader?

Q-53. When you see the error message NO SYSTEM, what does it mean?

Q-54. When an operating system prompt (A>) is displayed on the screen, what do you enter from the keyboard to load an application program?

Q-55. If disks are stored horizontally, how many can be stacked?

Q-56. What can exposure to a magnetic field do to the data on a disk?

Q-57. What is the temperature range within which a disk will operate?

Q-58. What is the most common method to ensure that any stored data lost can be recovered?

Q-59. The most common method of creating a backup for a microcomputer is what?

Q-60. Other than disk, what is another media used for backup files?

SUMMARY

This chapter has presented information on the history and classification of computers. It introduced you to electronic digital computers, their uses and operation. The information that follows summarizes the important points of this chapter.

Early computers were **MECHANICAL** or **ELECTROMECHANICAL**. **ELECTRONIC COMPUTERS** came into use in the 1940s.

ANALOG COMPUTERS are special-purpose computers designed to measure continuous electrical or physical conditions.

DIGITAL COMPUTERS are special- or general-purpose computers designed to perform arithmetic and logic functions on separate discrete data. They are generally used for business and scientific data processing.

Digital computers have evolved through four generations: vacuum tubes, transistors, miniaturized circuits, and integrated circuits.

WORD PROCESSING is one of the most widespread uses of desktop computers.

ACCOUNTING AND RECORDKEEPING are also major uses of computers. Included are order entry, inventory control, accounts receivable, accounts payable, general ledger, and payroll.

The Navy's **SHIPBOARD NON-TACTICAL ADP PROGRAM (SNAP)** consists of computers used by work center supervisors for logistic and administrative support. This system expedites the storage and retrieval of information the Navy has about its ships.

A **DESKTOP (PERSONAL) COMPUTER** is a microcomputer with at least a display screen, keyboard, floppy disk drive, and printer. It may also have additional devices such as a second floppy or a hard disk drive.

An **OPERATING SYSTEM** is loaded into the computer to let you and other programs use the computer. It also provides common functions like read, write, and print.

You can direct the computer to run an **APPLICATION PROGRAM** by telling the operating system the name of program to run. Common application programs are word processing, accounting, and recordkeeping.

You will probably be using **FLOPPY DISKS** for data storage and backup. To ensure you don't damage a disk, use care in handling, labeling and storing the disks.

ANSWERS TO QUESTIONS Q1. THROUGH Q60.

A-1. *Technology (mechanical, electromechanical, electronic), purpose (special or general), type of data they handle (analog or digital), cost, physical size (handheld to room size).*

A-2. *Analog.*

A-3. *Gun fire control.*

A-4. *Electromechanical computers use electrical components to perform some of the calculations.*

A-5. *Integrated circuits.*

A-6. *Special-purpose.*

A-7. *Its design.*

A-8. *Lack of versatility.*

A-9. *To perform a wide variety of functions and operations.*

A-10. *By storing different programs in its internal storage.*

A-11. *Speed and efficiency.*

A-12. *Special-purpose.*

A-13. *Continuous electrical or physical conditions.*

A-14. *Mechanical or electromechanical.*

A-15. *Hybrid computers.*

A-16. *Business and scientific data processing.*

A-17. *Digital computers deal with discrete quantities, while analog computers deal with continuous physical variables.*

A-18. *By the accuracy with which physical quantities can be sensed and displayed.*

A-19. *Third.*

A-20. *The number of significant figures carried in the computations.*

A-21. *Design of the computer processing unit.*

A-22. *General-purpose digital computer.*

A-23. *Generations.*

A-24. *Significant change in computer design.*

A-25. *The vacuum tube.*

A-26. *They were unreliable, required a lot of power to run, and produced so much heat that air conditioning was needed to protect computer parts.*

A-27. Thousandths of a second (millisecond).

A-28. Unsophisticated and machine oriented.

A-29. By the use of small, long lasting transistors.

A-30. With the introduction of magnetic disk storage and the use of core for main storage.

A-31. Symbolic machine languages or assembly languages.

A-32. Faster internal processing speeds.

A-33. Faster execution of instructions.

A-34. Over 100 million.

A-35. Both scientific and business data processing applications.

A-36. Microcomputers and minicomputers.

A-37. Read-only memory.

A-38. How to properly and effectively use the computing power available.

A-39. Software.

A-40. Word processing.

A-41. Correcting errors.

A-42. For manuscript writing, memorandum writing, identification-card application filing, and recordkeeping.

A-43. Six.

A-44. Shipboard Non-tactical ADP Program.

A-45. To support shipboard and intermediate level maintenance, supply, financial, and administrative functions.

A-46. Operating instructions are written in everyday English.

A-47. Unauthorized entry into the main computer's program.

A-48. Dependent on a work center's need.

A-49. COSAL, APL, EIC, SHIP'S FORCE WORK LIST, and CSMP.

A-50. Unclassified.

A-51. Operating system.

A-52. To load an external operating system into the computer's internal memory.

A-53. The computer is reading a properly inserted floppy disk, but it does not have an operating system on it.

A-54. The program name.

A-55. No more than ten.

A-56. Destroy some or all of it.

A-57. 10 to 50 degrees Celsius or 50 to 120 degrees Fahrenheit.

A-58. Backup files.

A-59. Use a floppy disk and the diskcopy procedure.

A-60. Magnetic tape.

CHAPTER 2

HARDWARE

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to do the following:

1. Explain the cpu and describe the functions of the different sections.
2. Categorize the types of storage and their functions.
3. Describe how storage is classified.
4. Analyze and compare the input/output devices and explain their functions.

INTRODUCTION

Components or tools of a computer system are grouped into one of two categories, hardware or software. We refer to the machines that compose a computer system as hardware. This hardware includes all the mechanical, electrical, electronic, and magnetic devices within the computer itself (the central processing unit) and all related peripheral devices (printers, magnetic tape units, magnetic disk drive units, and so on). These devices will be covered in this chapter to show you how they function and how they relate to one another. Take a few minutes to study figure 2-1. It shows the functional units of a computer system: the inputs, the central processing unit (cpu), and the outputs. The inputs can be on any storage medium from punched cards, paper tape, or magnetic ink to magnetic tape, disk, or drum; or they can be entries from a console keyboard or a cathode-ray tube (crt) terminal. The data from one or more of these inputs will be processed by the central processing unit to produce output. The output may be in punched cards or paper tape, on magnetic tape, disk, or drum, or it may be printed reports or information displayed on a console typewriter or crt terminal. The figure also shows the data flow, instruction flow, and flow of control. We'll start our hardware discussion with the cpu and then move into storage media (disk, tape, and drum). We'll end the chapter with a discussion of input/output devices and how they work.

CENTRAL PROCESSING UNIT (CPU)

The brain of a computer system is the central processing unit, which we generally refer to as the cpu or mainframe. The central processing unit IS THE COMPUTER. It is the cpu that processes the data transferred to it from one of the various input devices, and then transfers either the intermediate or final results of the processing to one of many output devices. A central control section and work areas are required to perform calculations or manipulate data. The cpu is the computing center of the system. It consists of a control section, internal storage section (main or primary memory), and arithmetic-logic section (fig. 2-1). Each of the sections within the cpu serves a specific function and has a particular relationship to the other sections within the cpu.

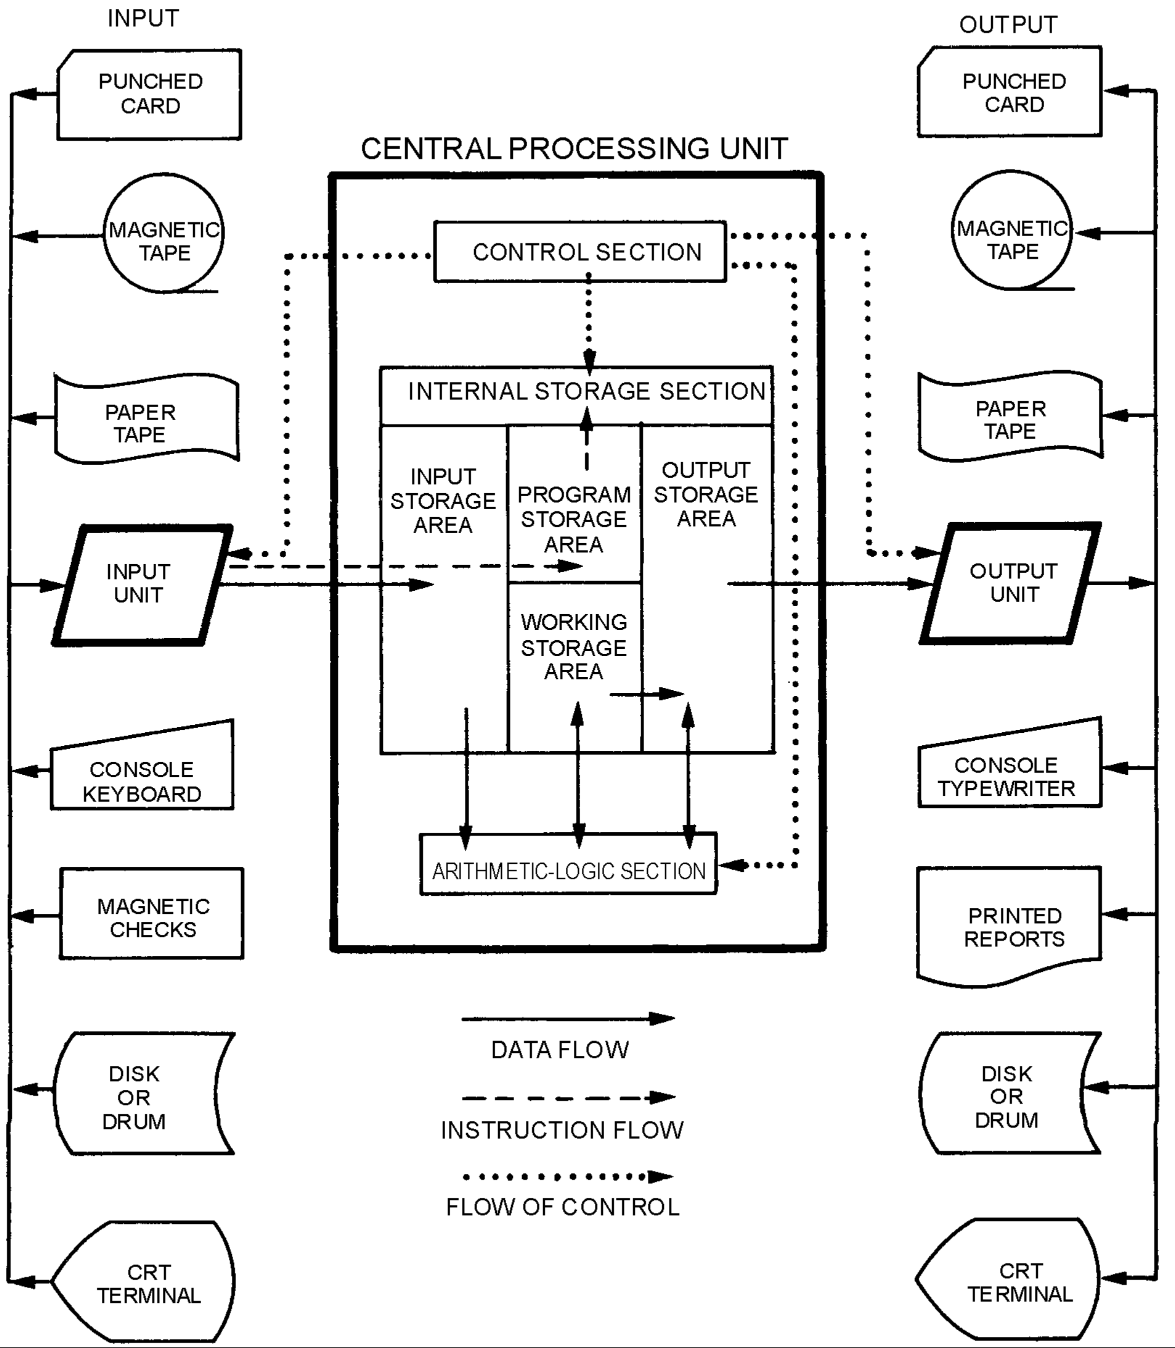

Figure 2-1.—Functional units of a computer system.

CONTROL SECTION

The control section may be compared to a telephone exchange because it uses the instructions contained in the program in much the same manner as the telephone exchange uses telephone numbers. When a telephone number is dialed, it causes the telephone exchange to energize certain switches and control lines to connect the dialing phone with the phone having the number dialed. In a similar manner, each programmed instruction, when executed, causes the control section to energize certain control lines, enabling the computer to perform the function or operation indicated by the instruction.

The program may be stored in the internal circuits of the computer (computer memory), or it may be read instruction-by-instruction from external media. The internally stored program type of computer, generally referred to only as a stored-program computer, is the most practical type to use when speed and fully automatic operation are desired.

Computer programs may be so complex that the number of instructions plus the parameters necessary for program execution will exceed the memory capacity of a stored-program computer. When this occurs, the program may be sectionalized; that is, broken down into modules. One or more modules are then stored in computer memory and the rest in an easily accessible auxiliary memory. Then as each module is executed producing the desired results, it is swapped out of internal memory and the next succeeding module read in.

In addition to the commands that tell the computer what to do, the control unit also dictates how and when each specific operation is to be performed. It is also active in initiating circuits that locate any information stored within the computer or in an auxiliary storage device and in moving this information to the point where the actual manipulation or modification is to be accomplished.

The four major types of instructions are (1) transfer, (2) arithmetic, (3) logic, and (4) control. Transfer instructions are those whose basic function is to transfer (move) data from one location to another. Arithmetic instructions are those that combine two pieces of data to form a single piece of data using one of the arithmetic operations.

Logic instructions transform the digital computer into a system that is more than a high-speed adding machine. Using logic instructions, the programmer may construct a program with any number of alternate sequences. For example, through the use of logic instructions, a computer being used for maintenance inventory will have one sequence to follow if the number of a given item on hand is greater than the order amount and another sequence if it is smaller. The choice of which sequence to use will be made by the control section under the influence of the logic instruction. Logic instructions, thereby, provide the computer with the ability to make decisions based on the results of previously generated data. That is, the logic instructions permit the computer to select the proper program sequence to be executed from among the alternatives provided by the programmer.

Control instructions are used to send commands to devices not under direct command of the control section, such as input/output units or devices.

ARITHMETIC-LOGIC SECTION

The arithmetic-logic section performs all arithmetic operations-adding, subtracting, multiplying, and dividing. Through its logic capability, it tests various conditions encountered during processing and takes action based on the result. As indicated by the solid arrows in figure 2-1, data flows between the arithmetic-logic section and the internal storage section during processing. Specifically, data is transferred as needed from the internal storage section to the arithmetic-logic section, processed, and returned to the internal storage section. At no time does processing take place in the storage section. Data may be transferred back and forth between these two sections several times before processing is completed. The results are then transferred from internal storage to an output unit, as indicated by the solid arrow (fig. 2-1).

MEMORY (INTERNAL STORAGE) SECTION

All memory (internal storage) sections must contain facilities to store computer data or instructions (that are intelligible to the computer) until these instructions or data are needed in the performance of the computer calculations. Before the stored-program computer can begin to process input data, it is first necessary to store in its memory a sequence of instructions, and tables of constants and other data it will use in its computations. The process by which these instructions and data are read into the computer is called loading.

Actually, the first step in loading instructions and data into a computer is to manually place enough instructions into memory using the keyboard or electronically using an operating system (discussed in chapter 1), so that these instructions can be used to bring in more instructions as desired. In this manner a few instructions are used to bootstrap more instructions. Some computers make use of an auxiliary (wired) memory that permanently stores the bootstrap program, thereby making manual loading unnecessary.

The memory (internal storage) section of a computer is essentially an electronically operated file cabinet. It has a large number (usually several hundred thousand) of storage locations; each referred to as a storage address or register. Every item of data and program instruction read into the computer during the loading process is stored or filed in a specific storage address and is almost instantly accessible.

Q-1. What is the brain of a computer system?

Q-2. How many sections make up the central processing unit?

Q-3. What are the names of the sections that make up the cpu?

Q-4. The control section can be compared to what?

Q-5. What are the four major types of instructions in the control section?

Q-6. What capability allows the arithmetic/logic section to test various conditions encountered during processing and take action based on the result?

Q-7. In the arithmetic/logic section, data is returned to what section after processing?

Q-8. What is the process by which instructions and data are read into a computer?

TYPES OF INTERNAL STORAGE

You already know that the internal storage section is the holding area in which instructions and data are kept. For the control section to control and coordinate all processing activity, it must be able to locate each instruction and data item in storage. About now, you are probably wondering how the control section is able to find these instructions and data items. To understand this, let's look at storage as nothing more than a collection of mailboxes. Each mailbox has a unique address and represents a location in memory as shown in figure 2-2. Like the mail in your mailbox, the contents of a storage location can change, but the number on your mailbox or memory address always remains the same. In this manner, a particular program instruction or data item that is held in storage can be located by knowing its address. Some computers can address each character of data in memory directly. Others address computer words which contain a group of characters at a single address. Each computer word contains a group of characters at a single address. Some of the more common types of internal storage media used in today's computers are as follows: magnetic core, semiconductor, and bubble.

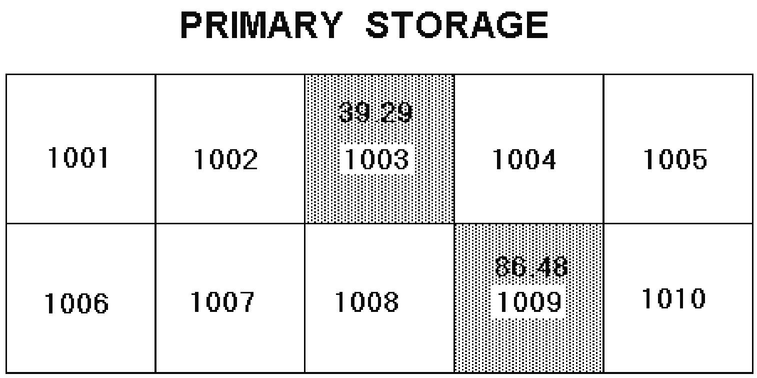

Figure 2-2.—Memory locations.

MAGNETIC CORE STORAGE

Although magnetic core storage is no longer as popular as it once was, we will cover it in some detail because its concepts are easily understood and apply generally to the more integrated semiconductor and bubble-type memories. Magnetic core storage is made up of tiny doughnut-shaped rings made of ferrite (iron), that are strung on a grid of very thin wires (fig. 2-3). Since data in computers is stored in binary form (refer to *NEETS*, module 13), a two-state device is needed to represent the two binary digits (bits), 0 for off and 1 for on. In core storage, each ferrite ring can represent a 0 or 1 bit, depending on its magnetic state. If magnetized in one direction, it represents a 1 bit, and if magnetized in the opposite direction, it represents a 0 bit. These cores are magnetized by sending an electric current through the wires on which the core is strung. It is this direction of current that determines the state of each core.

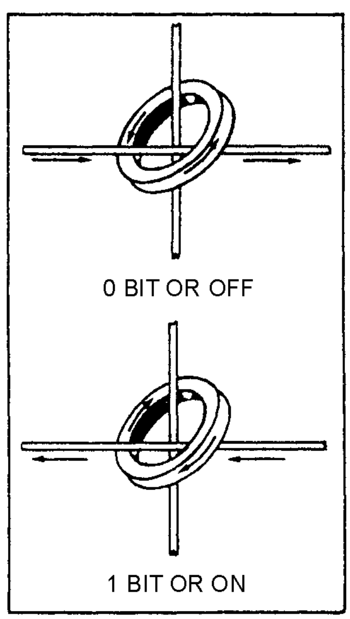

Figure 2-3.—Two-state principle of magnetic storage.

SEMICONDUCTOR STORAGE (THE SILICON CHIP)

Semiconductor memory consists of hundreds of thousands of tiny electronic circuits etched on a silicon chip (fig. 2-4). Each of these electronic circuits is called a bit cell and can be in either an off or on state to represent a 0 or 1 bit, depending on whether or not current is flowing in that cell. Another name you will hear used for semiconductor memory chips is integrated circuits (ICs). Developments in technology have led to large scale integration (LSI), which means that more and more circuits can be squeezed onto the same silicon chip. Companies are even manufacturing very large scale integrated circuits (VLSI), which means even further miniaturization.

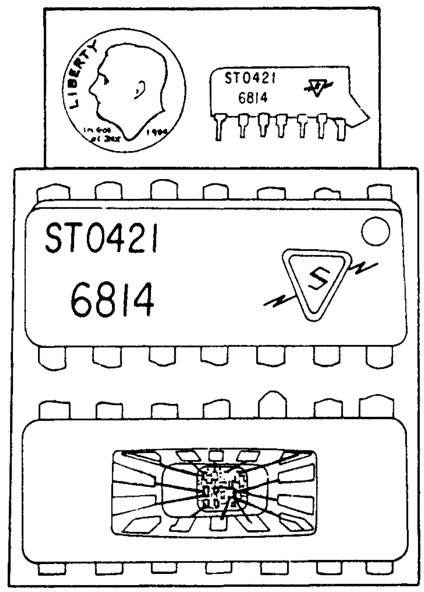

Figure 2-4.—A semiconductor memory chip (integrated circuit).

Some of the advantages of semiconductor storage are fast internal processing speeds, high reliability, low power consumption, high density (many circuits), and low cost. However, there is a drawback to this type of storage. It is volatile, which means all data in memory is lost when the power supply is removed. Should the power on your computer fail and you have no backup power supply, all the stored data is lost. This is not the case with magnetic core storage. Core storage is nonvolatile. This means the data is retained even if there is a power failure or breakdown, since the cores store data in the form of magnetic charges rather than electric current.

BUBBLE STORAGE

One of the latest technological developments in storage media is the introduction of bubble memory. Bubble memory consists of a very thin crystal made of semiconductor material. The molecules of this special crystal act as tiny magnets (fig. 2-5). The polarity of these molecules or "magnetic domains" can be switched in an opposite direction by passing a current through a control circuit imprinted on top of the crystal. In this manner, data can be stored by changing the polarity of the magnetic domains. Since the principle is the same as for magnetic core storage, bubble memory is considered nonvolatile. The data is retained even if there is a power failure. Furthermore, the process of reading from bubble memory is nondestructive, meaning that the data is still present after being read. This is not the case with core storage, which must be regenerated after being read. If we were to view these magnetic domains under a microscope, they would look like tiny bubbles; hence the name, bubble memory.

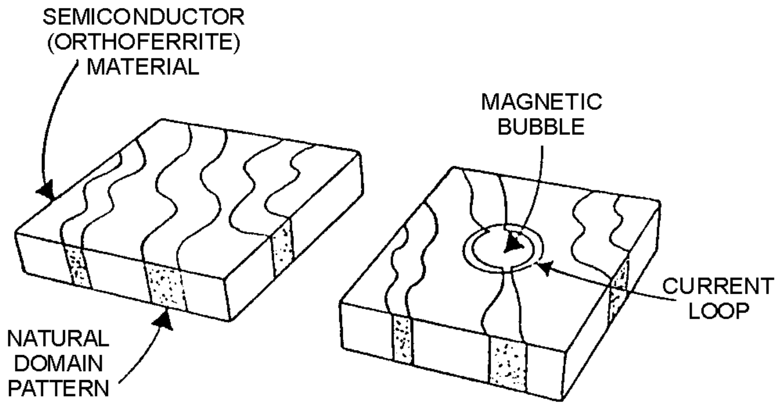

Figure 2-5.—Bubble memory.

Q-9. Magnetic core storage is made up of what?

Q-10. A semiconductor memory consists of what?

Q-11. What is another name for semiconductor memory chips?

Q-12. In computer storage, what does volatile mean?

Q-13. What type of storage can retain its data even if there is a power failure or breakdown?

Q-14. Bubble memory consists of what?

Q-15. How are the magnetic domains of a bubble memory switched?

Q-16. What do we mean when we say that reading from bubble memory is nondestructive?

CLASSIFICATIONS OF INTERNAL STORAGE

Up to this point, you have learned some of the general functions of the cpu, the physical characteristics of memory, and how data is stored in the internal storage section. Now, we will explain yet another way to classify internal (primary or main) storage. This is by the different kinds of memories used within the cpu: read-only memory, random-access memory, programmable read-only memory, and erasable programmable read-only memory.

READ-ONLY MEMORY (ROM)

In most computers, it is useful to have often used instructions, such as those used to bootstrap (initial system load) the computer or other specialized programs, permanently stored inside the computer. Memory that enables us to do this without the programs and data being lost (even when the computer is powered down) is called read-only memory. Only the computer manufacturer can provide these programs in ROM and once done, they cannot be changed. Consequently, you cannot put any of your own data or programs in ROM. Many complex functions such as routines to extract square roots, translators for programming languages, and operating systems can be placed in ROM memory. Since these instructions are hard wired (permanent), they can be performed quickly and accurately. Another advantage of ROM is that your computer facility can order programs tailored for its needs and have them permanently installed in ROM by the manufacturer. Such programs are called microprograms or firmware.

RANDOM-ACCESS MEMORY (RAM)

Another kind of memory used inside computers is called random-access memory (RAM) or read/write memory. RAM memory is rather like a blackboard on which you can scribble down notes, read them, and rub them out when you are finished with them. In the computer, RAM is the working memory. Data can be read (retrieved) from or written (stored) into RAM just by giving the computer the address of the location where the data is stored or is to be stored. When the data is no longer needed, you can simply write over it. This allows you to use the storage again for something else. Core, semiconductor, and bubble storage all have random access capabilities.

PROGRAMMABLE READ-ONLY MEMORY (PROM)

An alternative to ROM is programmable read only memory (PROM) that can be purchased already programmed by the manufacturer or in a blank state. By using a blank PROM, you can enter any program into the memory. However, once the PROM has been written into, it can never be altered or changed. Thus you have the advantage of ROM with the additional flexibility to program the memory to meet a unique need. The main disadvantage of PROM is that if a mistake is made and entered into PROM, it cannot be corrected or erased. Also, a special device is needed to "burn" the program into PROM.

ERASABLE PROGRAMMABLE READ-ONLY MEMORY (EPROM)

The erasable programmable read-only memory (EPROM) was developed to overcome the drawback of PROM. EPROMs can also be purchased blank from the manufacturer and programmed locally at your command/activity. Again, this requires special equipment. The big difference with EPROM is that it can be erased if and when the need arises. Data and programs can be retrieved over and over again without destroying the contents of the EPROM. They will stay there quite safely until you want to reprogram it by first erasing the EPROM with a burst of ultra-violet light. This is to your advantage, because if a mistake is made while programming the EPROM, it is not considered fatal. The EPROM can be erased and corrected. Also, it allows you the flexibility to change programs to include improvements or modifications in the future.

Q-17. In what type of memory are often used instructions and programs permanently stored inside the computer?

Q-18. Who provides the programs stored in ROM?

Q-19. Can programs in ROM be changed?

Q-20. What is another name for random-access memory (RAM)?

Q-21. How is data read from or written into RAM?

Q-22. In what two states can programmable read-only memory (PROM) be purchased?

Q-23. What is the main disadvantage of PROM?

Q-24. What does EPROM stand for?

Q-25. How is EPROM erased?

SECONDARY STORAGE

The last kind of memory we will briefly introduce here is called secondary storage or auxiliary storage. This is memory outside the main body of the computer (cpu) where we store programs and data for future use. When the computer is ready to use these programs and data, they are read into internal storage. Secondary (auxiliary) storage media extends the storage capabilities of the computer system. We need it for two reasons. First, because the computer's internal storage is limited in size, it cannot always hold all the data we need. Second, in secondary storage, data and programs do not disappear when power is turned off. Secondary storage is nonvolatile. This means information is lost only if you, the user, intentionally erase it. The three types of secondary storage we most commonly use are magnetic disk, tape, and drum.

MAGNETIC DISK

The popularity of disk storage devices is largely because of their direct-access capabilities. Most every system (micro, mini, and mainframe) will have disk capability. Magnetic disks resemble phonograph records (round platters), coated with a magnetizable recording material (iron oxide), but their similarities end there. Magnetic disks come in many different sizes and storage capacities. They range from 3 inches to 4 feet in diameter and can store from 2.5 million to 600 million characters (bytes) of data. They can be portable in that they are removable, or they can be permanently mounted in the storage devices called disk drive units or disk drives. They can be made of rigid metal (hard disks) or flexible plastic (floppy disks or diskettes) as shown in figure 2-6.

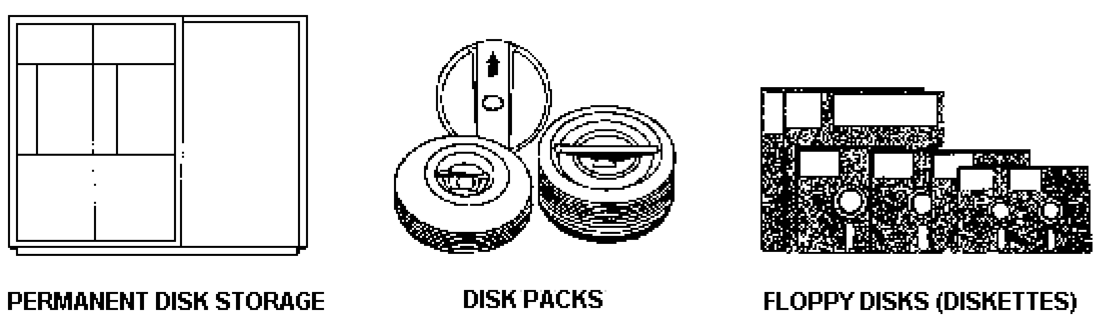

Figure 2-6.—Various types and sizes of magnetic disk storage.

Music is stored on a phonograph record in a continuous groove that spirals into the center of the record. But there are no grooves on a magnetic disk. Instead, data is stored on all disks in a number of invisible concentric circles called tracks. Each track has a designated number beginning with track 000 at the outer edge of the disk. The numbering continues sequentially toward the center to track 199, 800, or whatever the highest track number is. No track ever touches another (fig. 2-7). The number of tracks can vary from 35 to 77 on a floppy disk surface and from 200 to over 800 on hard disk surfaces.

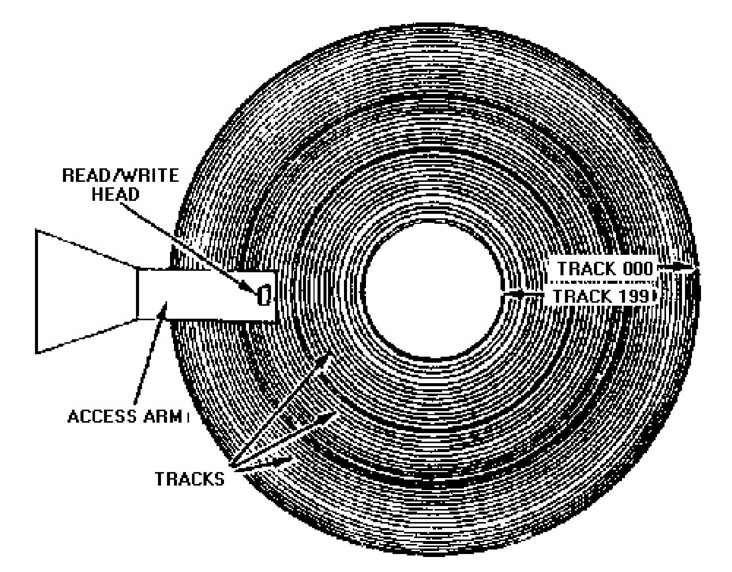

Figure 2-7.—Location of tracks on the disk's recording surface.

Data is written as tiny magnetic bits (or spots) on the disk surface. Eight-bit codes are generally used to represent data. Each code represents a different number, letter, or special character. In chapter 4, you'll learn how the codes are formed. When data is read from the disk, the data on the disk remains unchanged. When data is written on the disk, it replaces any data previously stored on the same area of the disk.

Characters are stored on a single track as strings of magnetized bits (0's and 1's) as shown in figure 2-8. The 1 bits indicate magnetized spots or ON bits. The 0 bits represent unmagnetized portions of the track or OFF bits. Although the tracks get smaller as they get closer to the center of the disk platter, each track can hold the same amount of data because the data density is greater on tracks near the center.

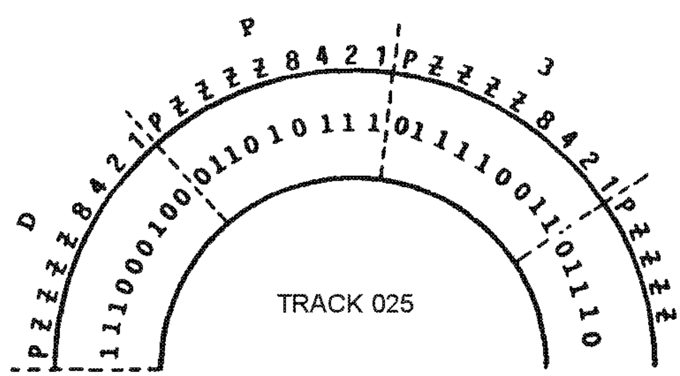

Figure 2-8.—A string of bits written to disk on a single track.

A track can hold one or more records. A record is a set of related data treated as a unit. The records on a track are separated by gaps in which no data is recorded, and each of the records is preceded by a disk address. This address indicates the unique position of the record on the track and is used to directly access the record. Figure 2-9 shows a track on which five records have been recorded. Because of the gaps and addresses, the amount of data we can store on a track is reduced as the number of records per track is increased. Records on disk can be blocked (grouped together). Only one disk address is needed per block, and as a result, fewer gaps occur. We can use the blocking technique to increase the amount of data we can store on one track.

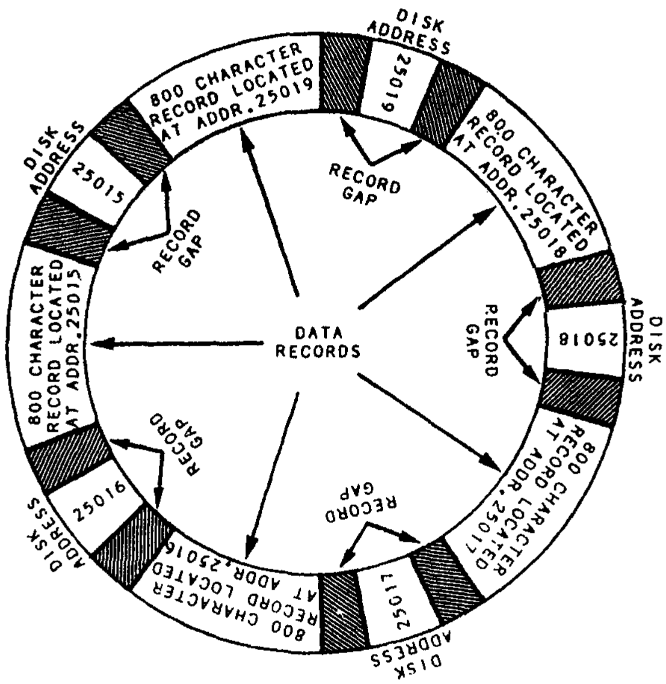

Figure 2-9.—Data records as they are written to disk on a single track.

The storage capacity of a disk depends on the bits per inch of track and the tracks per inch of surface. Using Winchester technology, the designers of disk drive units were able to increase the data density of a disk by increasing the number of tracks. Winchester was the code name used by IBM during the development of this technology. The designers originally planned to use dual disk drives to introduce the new concept. Each drive was to have a storage capacity of 30 million characters, and thus was expected to be a "30-30." Since that was the caliber of a famous rifle, the new product was nicknamed "Winchester." The designers found that data density could be improved and storage capacity increased by reducing the flying height, the distance of the read/write heads over the disk surfaces when reading and writing. By doing this, smaller magnetized spots could be precisely written and then read. The read/write heads were moved so close to the disk that a human hair looked like a mountain in the path of the flying head. Winchester technology reduces this potential problem by sealing the disks in a contamination-free container. This eliminates foreign objects from coming in contact with the read/write heads.

Data can be physically organized in one of two ways on a disk pack, depending on the manufacturer and the model of disk drive you are using. One way uses the cylinder method, and the other uses the sector method. On diskettes, data is organized using the sector method.

The cylinder method uses a cylinder as the basic reference point. When you look at figure 2-10, view A, you will see a disk pack containing six disk platters with 10 recording surfaces. Imagine you are looking down through the disk pack from the top. All the tracks with the same number line up vertically. Together they are called a cylinder. These 10 tracks, one on each recording surface, can be referenced by the 10 read/write heads on the five access arms at each discrete location where the access arms can be positioned.

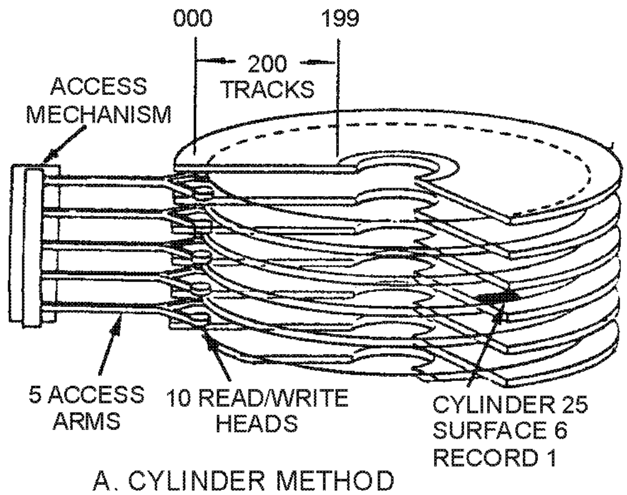

Figure 2-10A.—Physical organization of data on a disk. CYLINDER METHOD.

Therefore, to physically reference a record stored using the cylinder method, a computer program must specify the cylinder number, the recording surface number, and the record number as shown in figure 2-10, view A. Here, the record is stored in cylinder 25 of recording surface 6 and is the first record on that track. Special data stored on each track specifies the beginning of the track so that the first record, second record, third record, and so on, can be identified.

Another way to physically organize data on the disk pack (and on diskettes) is to use the sector method. This requires that each of the tracks be divided into individual storage areas called sectors (shown in figure 2-10, view B). The number of sectors varies with the disk system used; however, there are usually eight or more. Each sector holds a specific number of characters. Before a record can be accessed, a computer program must again give the disk drive the record's address specifying the track number, the surface number, and the sector number of the record. One or more read/write heads are then moved to the proper track, the head over the specified surface is activated, and the data is read from or written to the designated sector as it spins under the head.

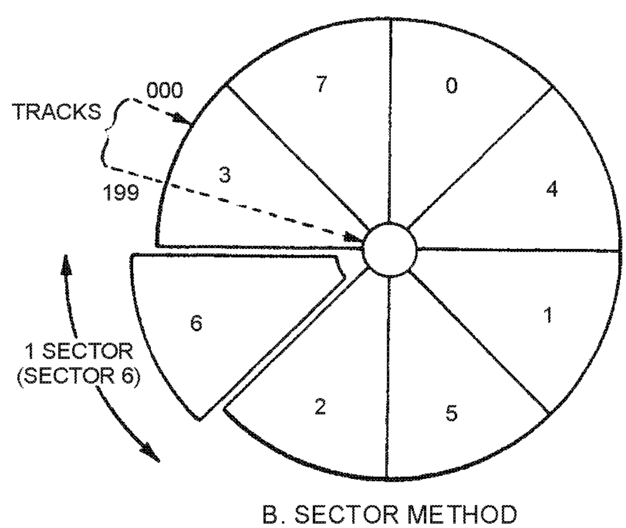

Figure 2-10B.—Physical organization of data on a disk. SECTOR METHOD.

MAGNETIC TAPE

Another type of storage device is magnetic tape which is similar to the tape used with commercial tape recorders. It is used mainly for secondary storage. It differs from commercial tape in that it is usually wider (ranging from one-half inch to an inch), and it is manufactured to more rigid quality specifications. It is made of a MYLAR® base coated with a magnetic oxide that can be magnetized to store data. Magnetic tape comes in a variety of lengths (from 600 to 3,000 feet), and is packaged in one of three ways: open reel, cartridge, or cassette, as shown in figure 2-11. Large computers use standard open reels, 1/2-inch wide tape, 2,400 feet in length. Magnetic tape units are categorized by the type of packaging used for the tape. The tape unit (or drive) shown in figure 2-12 uses open reels, while cartridge tape units use tape cartridges and cassette units use tape cassettes. Cartridge tape units are often used on personal computers to provide backup for hard disk.

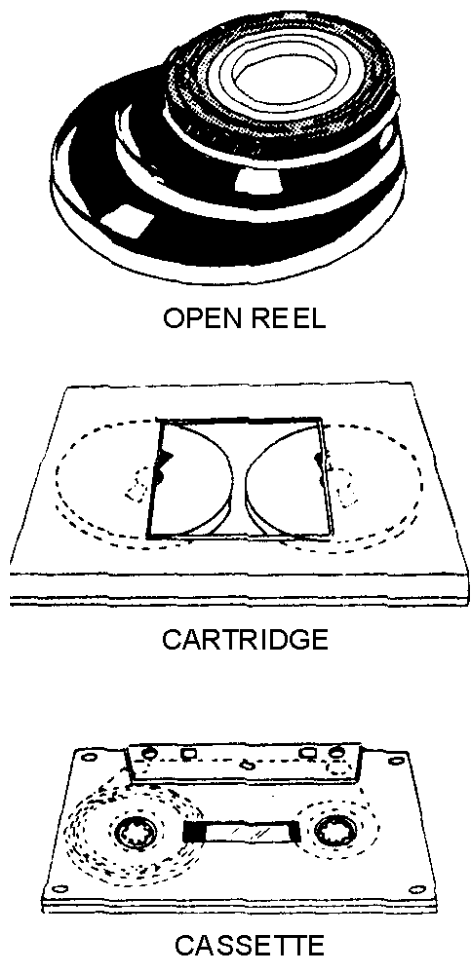

Figure 2-11.—Various types of magnetic tape storage.

Figure 2-12.—Mounting a magnetic tape

A standard 1/2-inch tape may have either seven (fig. 2-13, view A) or nine tracks (fig. 2-13, view B) of data stored on it, depending upon the particular read/write heads installed in the tape unit. Read/write heads are usually designed to read (or write) data (in the form of bits) concurrently across the width of the tape.

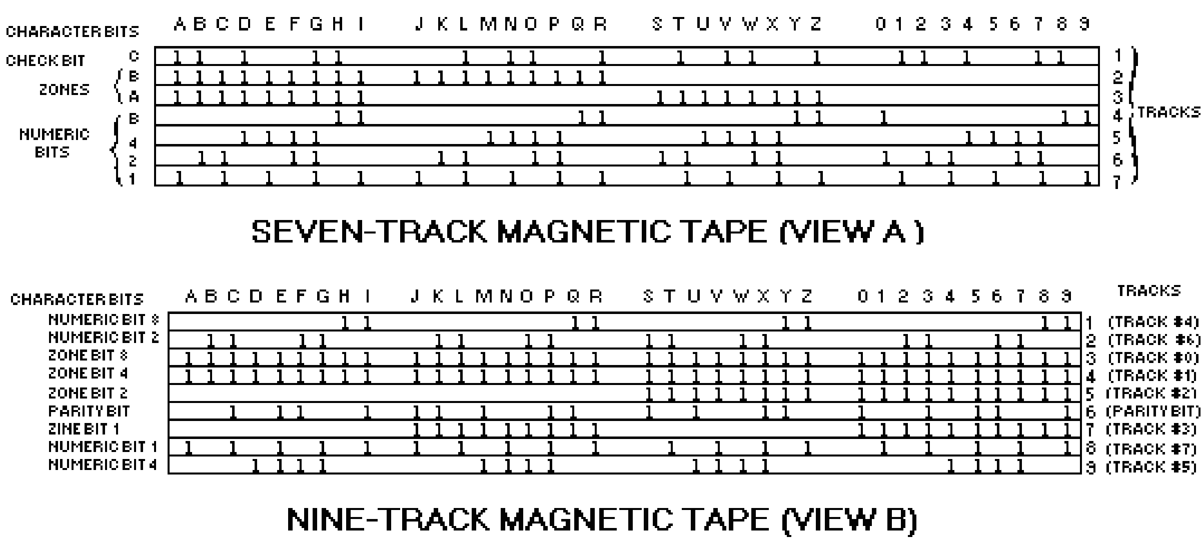

Figure 2-13.—Multi-track magnetic tape.

The amount of data or the number of binary digits (0 and 1 bits) that can be written (stored) on a linear inch of tape is known as the tape's recording density. Common recording densities for multitrack tapes range from 200 to 6,250 bits/bytes per inch (BPI). Also note that sometimes the density of a tape is referred to as the number of frames per inch (FPI) or characters per inch (CPI) rather than BPI. Regardless of which term is used, a frame or byte is a group of related bits that make up a single character written across the width of the tape. Most magnetic tape units are capable of reading and writing in several different densities.

Magnetic tapes have many common features and data recording formats. Each tape is physically marked in some manner to indicate where reading and writing on tape is to begin (known as the beginning-of-tape [BOT]), and where it ends (known as the end-of-tape [EOT]). The length of tape between the BOT and EOT is referred to as the usable recording (reading/writing) surface or usable storage area. BOT/EOT markers are usually made of short silver strips of reflective tape (1/4-inch wide by 1/2-inch long) as shown in figure 2-14. The BOT marker is normally placed toward the front edge of the tape (the side nearest you when the tape is mounted on the tape unit). The EOT marker is placed toward the back edge (the side farthest from you when the tape is mounted on the tape unit). They are placed approximately 15 to 20 feet in from each end on the shiny side of the tape. Sometimes, holes or clear plastic inserts are used as markers in place of reflective strips. Regardless of the method used, the BOT/EOT markers are sensed by an arrangement of lamps and/or photodiode sensors to indicate where reading and writing is to begin and end.

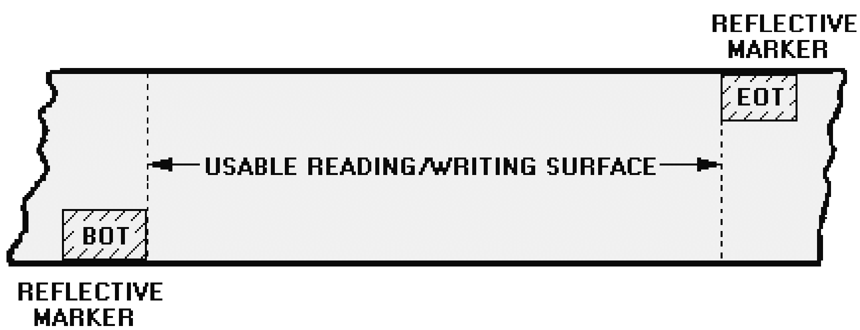

Figure 2-14.—Beginning-of-tape (BOT) and end-of-tape (EOT) markers.

We can make records on magnetic tape any size we need to hold the data. We are restricted only by the length of the tape or the capacity of internal storage. For example, a record can be one character, several characters, or thousands of characters in length. The collection of records is called a file. A file containing payroll records is called a payroll file; a file containing supply inventory records is called a supply inventory file.

Records can be placed on tape either separately as single records (unblocked) as shown in figure 2-15, view A, or multiple records can be grouped together (blocked) as shown in figure 2-15, view B, to form a record block. The number of records stored in a record block is the blocking factor. In this example, the blocking factor is five.

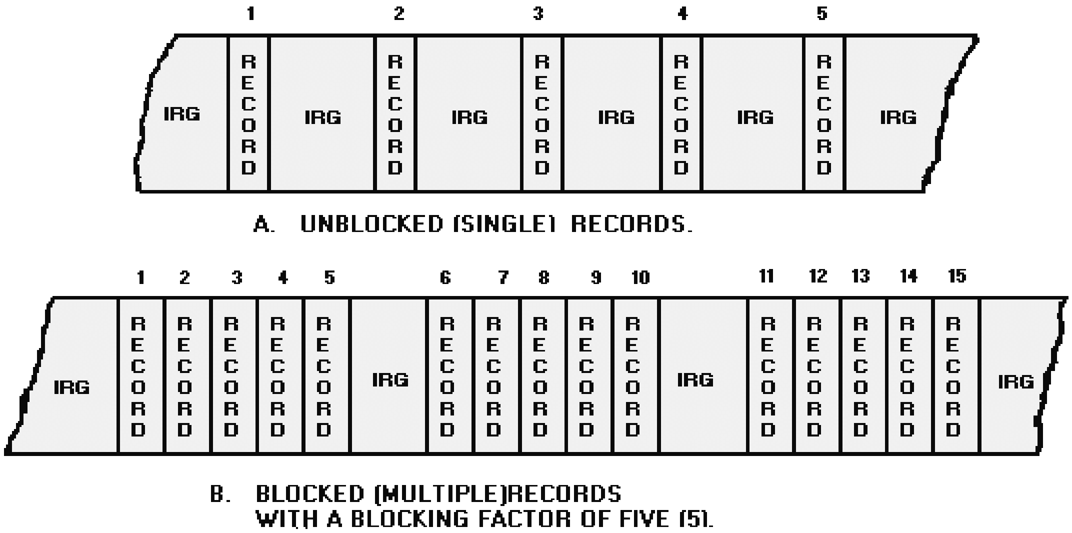

Figure 2-15.—Record formats on magnetic tape.

All magnetic tape must be moving at a predetermined speed for data to be read from or written on the tape. Data cannot be read or written while the tape is coming up to speed, slowing down, or stopped. During this time delay, the tape moves a short distance creating a blank spot on the tape. This interrecord gap or interblock gap separates each single record or block of records on the tape. The length of the gap varies, depending upon the particular system and method of recording, but is approximately 2/5 to 3/4 inch in length. If single records are stored on the tape, the interrecord gap may be longer than the portion of tape used to store the record. Therefore, much of the tape's recording surface is wasted.

To overcome the inefficiency of storing single data records, we normally block records. In figure 2-15, view B, you will notice the tape is used more efficiently than the tape in figure 2-15, view A. Blocking allows more data to be stored on a reel of tape.

During reading, the record begins with the first character sensed following an interrecord or interblock gap and continues until the next gap is reached. All input records read are internally stored in accordance with the amount of storage area set aside by the applications program.

Magnetic tape, as a storage media, offers several useful features. We can store large amounts of data in a variety of convenient package sizes (open reels, cartridges, or cassettes). Magnetic tapes are easily interchangeable between similar tape units of different computer systems, and tapes are less prone to damage than other types of storage media.

MAGNETIC DRUM

Like the magnetic disk, the magnetic drum is another example of a direct-access storage device. Although the magnetic drum was once used as main (or primary) storage, it is now used as secondary (or auxiliary) storage. Unlike some disk packs, the magnetic drum cannot be physically removed. The drum is permanently mounted in the device.

Magnetic drum storage devices consist of either a hollow cylinder (thus, the name drum) or a solid cylinder that rotates at a constant velocity (from 600 to 6,000 rpm). The outer surface is coated with an iron-oxide material capable of being magnetized.

A magnetic drum differs from a magnetic disk in that the tracks in which the data is stored are assigned to channels located around the circumference of the drum as shown in figure 2-16. That is, the channels form circular bands around the drum. The coded representation of data in figure 2-16 is similar to that used on 9-track magnetic tape, 8-bit code. The basic functions of the read/write heads are to place magnetized spots (those little binary 0's and 1's) on the drum during a writing operation and to sense these spots during a reading operation. The read/write heads of a drum perform in a manner similar to the read/write heads of a magnetic tape unit or disk drive unit.

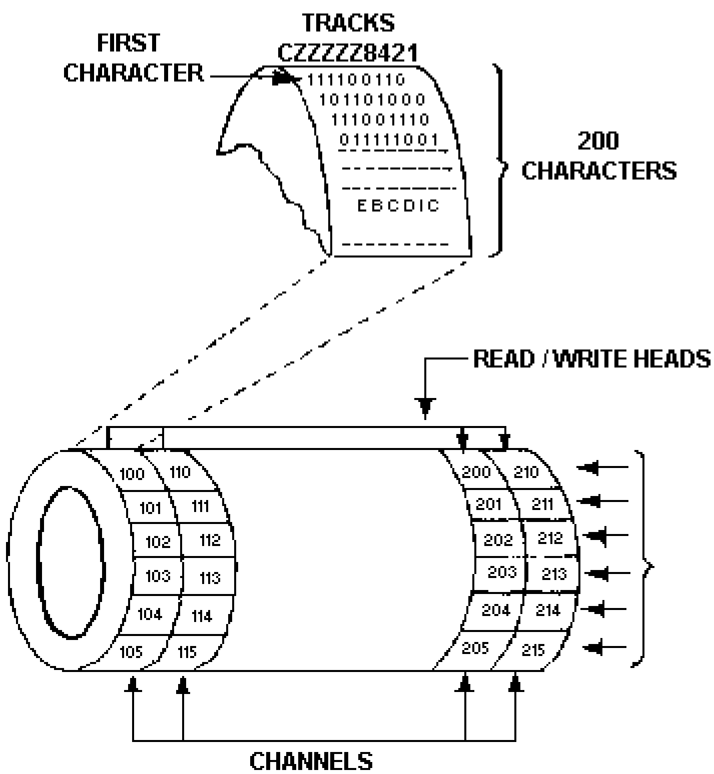

Figure 2-16.—Magnetic drum.

The tracks on each channel are grouped into sectors as illustrated in figure 2-16. Does this sound familiar to you? It sounds almost like the format used on disk packs when referring to tracks (or cylinders) and sectors. As the drum rotates, the reading or writing occurs when the specified sector of a given channel passes under the read/write head for that channel.

Some drums are mounted in a horizontal position, such as the one shown in figure 2-16, while others are mounted in a vertical position. Another major difference in the design is the number of read/write heads. Some drums use only one read/write head, which services all channels on the drum. In this case, the head moves back and forth (or up and down) over the surface of the drum as required. Other drums, using multiple read/write heads, have one principal advantage over drums with the single-head type. Since one read/write head is assigned to each channel, no read/write head movement is required. That is, the time required for head positioning is zero. The only significant time required when reading or writing is the rotational delay that occurs in reaching a desired record location.

To give you some idea of speed and storage capacities, some high-speed drums are capable of transferring over one million characters of data per second, which is roughly equivalent to reading a stack of punched cards 8 feet high in one second. The storage capacities of magnetic drums range from 20 million to more than 150,000 million characters (or bytes) of data.

Q-26. Why are disk storage devices popular?

Q-27. How is data stored on all disks?

Q-28. What precedes each record on a disk?

Q-29. How is the storage capacity of a disk determined?

Q-30. What two ways can data be physically organized on a disk pack?

Q-31. The amount of data that can be stored on a linear inch of tape is known by what term?

Q-32. The length of tape between BOT and EOT is referred to by what term?

Q-33. How does a magnetic drum differ from a magnetic disk?

Q-34. Tracks on each channel of a magnetic drum are grouped into what?

INPUT/OUTPUT DEVICES (EXTERNAL)

Input and output devices are similar in operation but perform opposite functions. It is through the use of these devices that the computer is able to communicate with the outside world. Input data may be in any one of three forms:

1. Manual inputs from a keyboard or console
2. Analog inputs from instruments or sensors
3. Inputs from a source on or in which data has previously been stored in a form intelligible to the computer

Computers can process hundreds of thousands of computer words or characters per second. Thus, a study of the first method (manual input) reflects the inability of human-operated keyboards or keypunches to supply data at a speed that matches the speed of digital computers. A high average speed for keyboard operation is two or three characters per second, that, when coded to form computer words, would reduce the data input rate to the computer to less than a computer word per second. Since mainframe computers are capable of reading several thousand times this amount of information per second, it is clear that manual inputs should be minimized to make more efficient use of computer time. However, as a rule, the keyboard is the normal input media for microcomputers.

Input data that has previously been recorded on paper tapes, magnetic tapes, magnetic disks, or floppy disks in a form understood by the program may also be entered into the computer. These are much faster methods than entering data manually from a keyboard. The most commonly used input devices in this category are magnetic tape units, magnetic disk drive units, and floppy disk drive units.

Output information is also made available in three forms:

1. Displayed information: codes, numbers, words, or symbols presented on a display device like a cathode-ray screen

2. Control signals: information that operates a control device, such as a lever, aileron, or actuator

3. Recordings: information that is stored in a machine language or human language on tapes, disks, or printed media

Devices that display, store, or read information include magnetic tape units, magnetic disk drive units, floppy disk drive units, printers, and display devices.

MAGNETIC TAPE UNITS (INPUT/OUTPUT)

The purpose of any magnetic tape unit (drive or device) is to write data on or read data from a magnetic tape (fig. 2-17). Tape stores data in a sequential manner. In sequential processing, the computer must begin searching at the beginning and check each record until the desired data is found. Like a tape cassette with recorded music, to play the fifth song recorded, you must play or fast forward the tape past the first four songs before you can play the fifth.

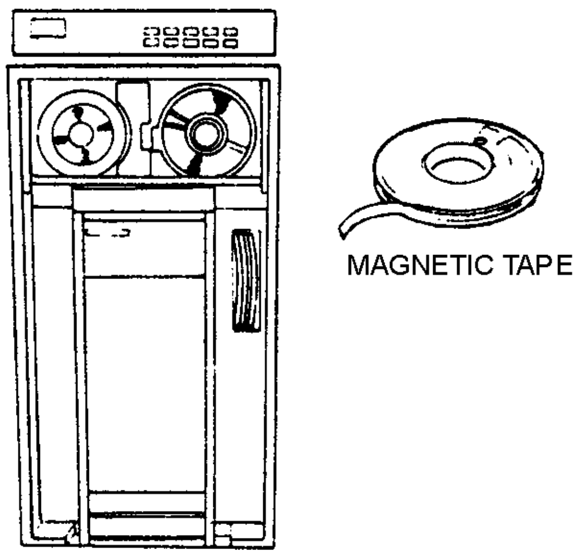

Figure 2-17.—Magnetic tape unit.

Two reels are used, tape moves from a supply reel to a take-up reel (both are mounted on hubs). Figure 2-18 shows the basic tape drive mechanism. The magnetic oxide coated side of the tape passes directly over the read/write head assembly, making contact with the heads. The magnetic tape unit reads and writes data in parallel channels or tracks along the length of the tape as shown in figure 2-19, view A. Each channel or track is used by a read/write head (one for each channel), as the tape moves across the magnetic gap of the head. Read/write heads may be either one gap or two gap as shown in figure 2-19, views B and C. The one-gap head has only one magnetic gap at which both reading and writing occur. The two-gap head has one gap for reading and another for writing. Although the one gap is satisfactory, the two-gap head gives increased speed by checking while writing. For example, a tape being written on passes over the write gap where the data is recorded, and then the data is read as it passes over the read gap to make a comparison. With this method, errors are detected almost instantly. When you look closely at figure 2-19, view B (top view), you will notice that there is one read/write coil in the write head for each channel (or track). In this particular case, there are seven. It is the electrical current flowing through these coils that magnetizes the iron-oxide coating on the surface of the tape.

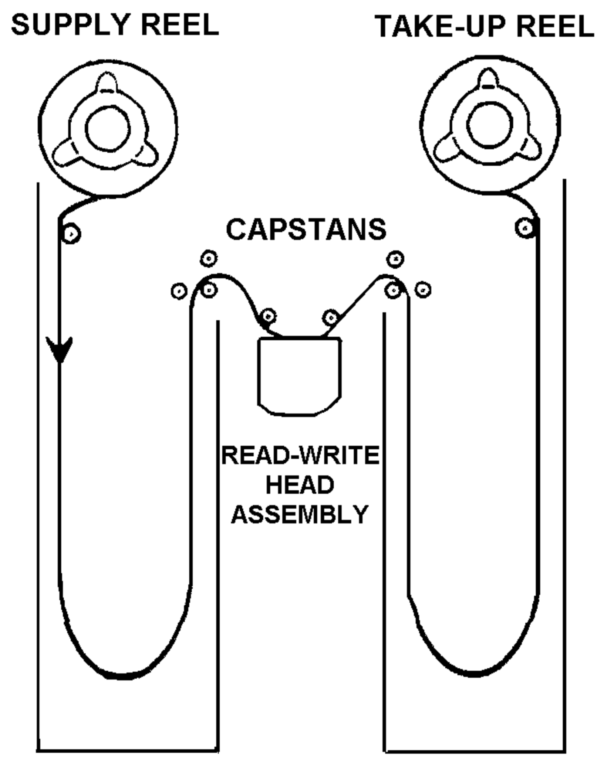

Figure 2-18.—A basic tape drive mechanism.

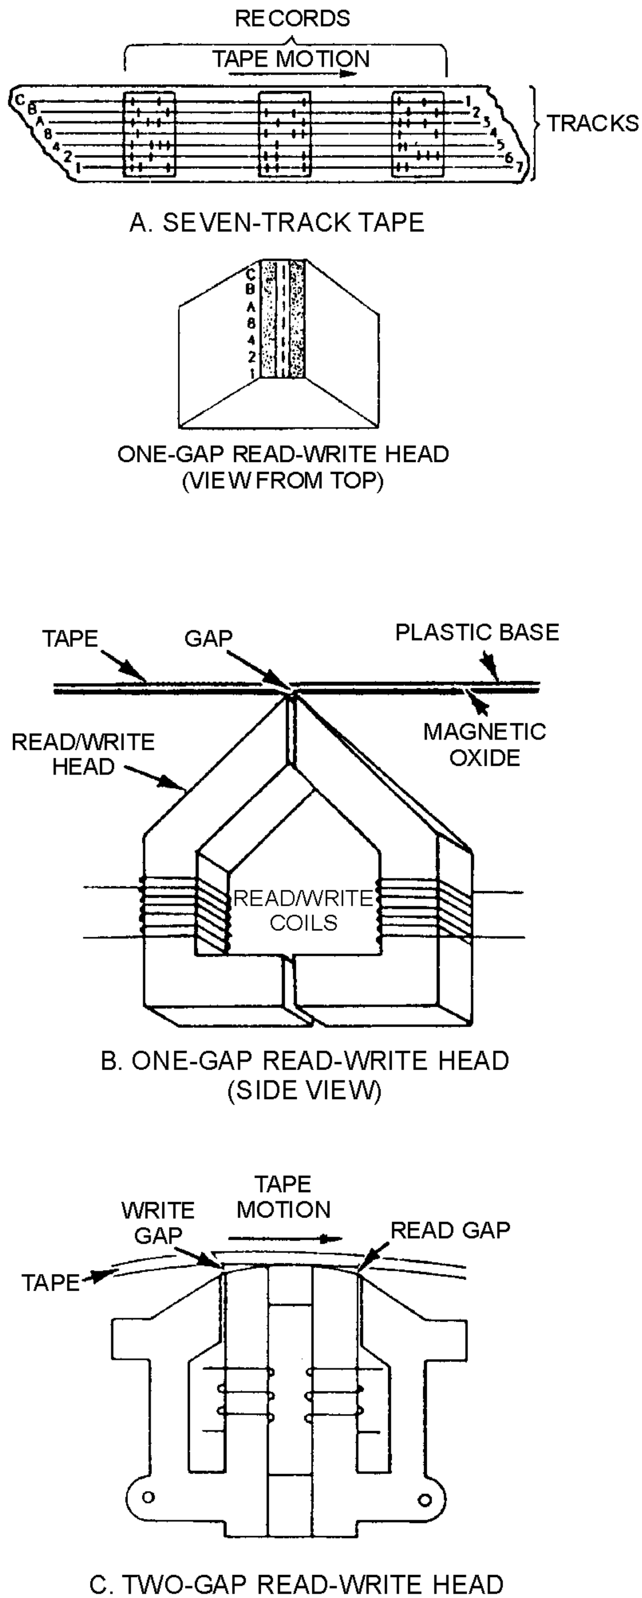

Figure 2-19.—Read/write head assemblies.

The major differences between magnetic tape units are the speed at which the tape is moved past the read/write head and the density of the recorded information. You know that density describes the number of binary digits, bytes, or frames we can record on an inch of tape. The most common tape densities are 800 and 1,600 BPI (or FPI). Tape speed (or tape movement) varies to a great extent, from less than 50 inches per second to more than 100 inches per second. How fast a tape unit reads and writes is specified as the character transfer rate which is calculated by multiplying the speed of the magnetic tape unit by the character density.

MAGNETIC DISK DRIVE UNITS (INPUT/OUTPUT)

Magnetic disk drive units are storage devices that read and write information on the magnetized surfaces of rotating disks (fig. 2-20). The disks are made of thin metal, coated on each side so that data can be recorded in the form of magnetized spots. As the disks spin around like music records, characters can be stored on them or retrieved in a direct manner. This direct accessing of data has a big advantage over the sequential accessing of data. It gives us fast, immediate access to specific data without having to examine each and every record from the beginning. You can direct the disk drive to begin reading at any point. This is like the phonograph record, you can place the needle at any point and begin playing at any point.

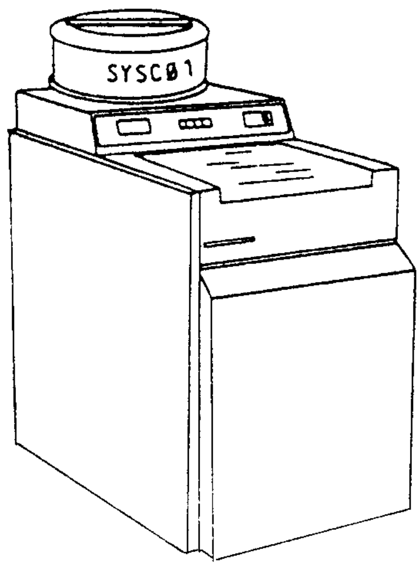

Figure 2-20.—Magnetic disk drive unit.

Located within each disk drive unit is a drive motor that rotates the disk at a constant speed, normally 3,600 revolutions per minute (rpm); or, if you prefer, 60 revolutions per second. The rotational speed for floppy disks is usually between 300 and 400 rpm because of their plastic base. Data is written on the tracks of a spinning disk surface and read from the surface by one or more (multiple) read/write heads. When reading from and writing to hard disks (rigid disks), the read/write heads float on a cushion of air and do not actually touch the surface of the disk. The distance between the head and the surface varies from a millionth of an inch to one-half millionth of an inch. This distance is called the flying height. When multiple disks (platters) are packaged together as a unit in a disk pack, a number of access arms and read/write heads are used to access both surfaces of each platter (fig. 2-21). The disk pack shown consists of six metal disks mounted on a central spindle. Data can be recorded on all surfaces except the top surface of the top disk, and the bottom surface of the bottom disk. These two surfaces are intentionally left blank for protection.

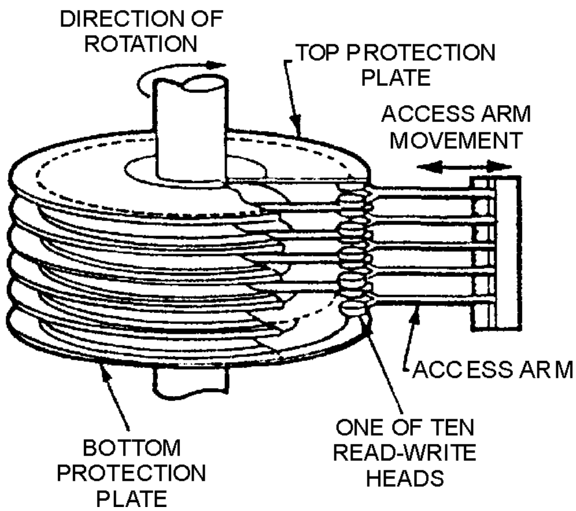

Figure 2-21.—Multiple access arms, read/write heads used with disk packs.

FLOPPY DISK DRIVE UNITS (INPUT/OUTPUT)

Floppy disk drive units are physically smaller than magnetic disk drive units and are typically used with personal (desktop) computers (fig. 2-22). The unit consists of a disk drive in which the disk rotates and a controller containing the electronic circuitry that feeds signals onto and from the disk. The disk (diskette) is a thin, flexible platter (floppy disk) coated with magnetic material so characters can be recorded on the surface in the form of magnetized spots. Floppy disks come in several sizes from 3 to 8 inches in diameter. The most common are the 8-inch disk, the 5 1/4-inch disk, and the 3 1/2-inch disk.

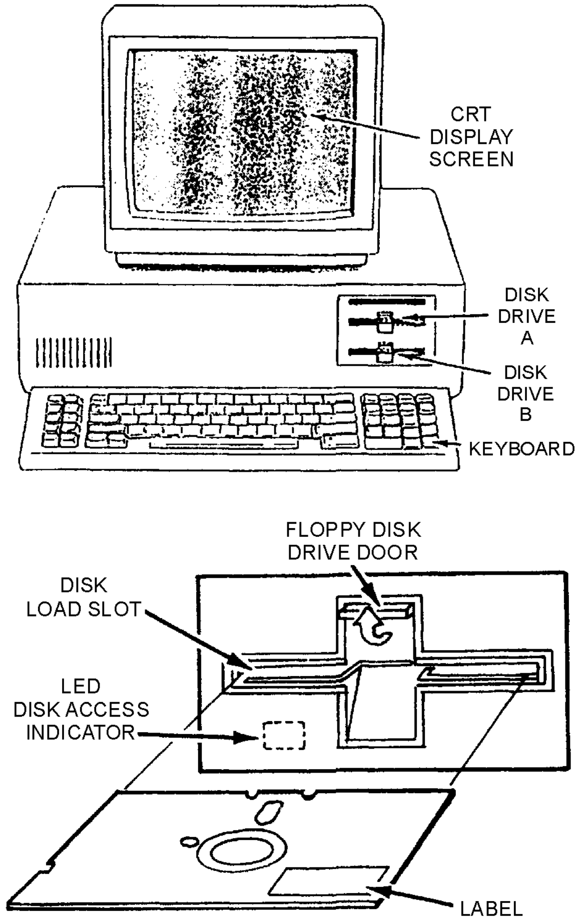

Figure 2-22.—Floppy disk drive unit.

PRINTERS (OUTPUT)

Printers are widely used output devices that express coded characters on hard (paper document) copy (fig. 2-23). They print out computer program results as numbers, letters, words, symbols, graphics, or drawings. Printers range from electronic typewriters to high-speed printers. High-speed printers are usually used on mainframes and minis to prepare supply requisitions, pay checks, inventory, or financial reports at 10 lines per second and faster. The types of printers we'll discuss are daisy-wheel, dot matrix, ink jet, and laser. These are the ones commonly used with personal computers.

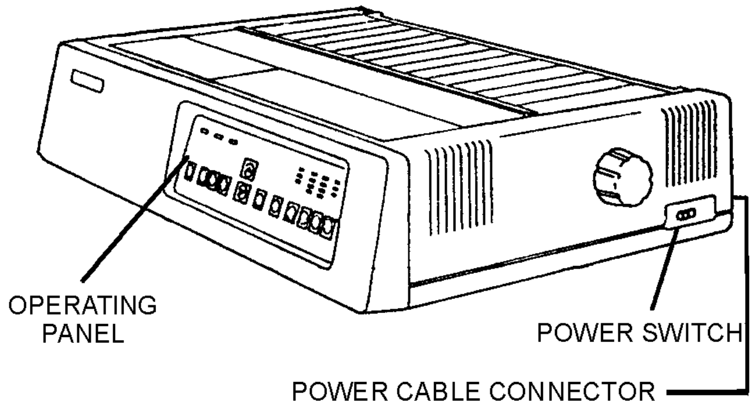

Figure 2-23.—Printer.

Daisy-Wheel Printers

Daisy-wheel printers have the most professional-looking, pleasing-to-the-eye print of all the printers in the character-at-a-time impact printer class. Daisy-wheel printers are often used in an office or word processing environment, where crisp, sharp, high-quality (letter quality) characters are a must. The daisy-wheel printer uses a round disk, with embossed characters located at the end of each petal-like projection (one character per petal), similar to the petals of a daisy, as shown in figure 2-24. A drive motor spins the wheel at a high rate of speed. When the desired character spins to the correct position, the print hammer strikes that character causing it to be printed on the paper. Once printed, the daisy wheel continues to move, searching out the next character to be printed, until the line is completed. The speeds of daisy-wheel printers range from 30 to 60 characters per second (cps).

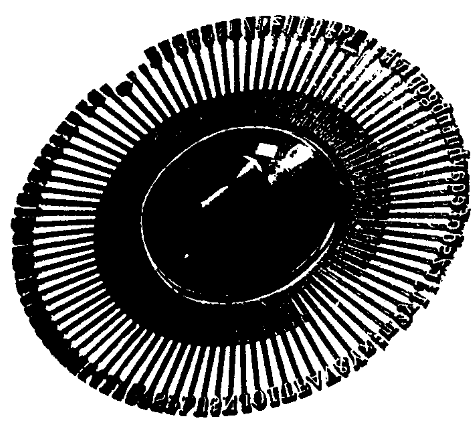

Figure 2-24.—A daisy-wheel print wheel.

Dot-Matrix Printers

Dot-matrix printers, (also known as the wire matrix printers) create characters in much the same way you see numbers on the scoreboard at a baseball or football game. In contrast to the daisy-wheel printers, dot-matrix printers use an arrangement of tiny pins or hammers, called a dot matrix, to generate characters a dot-at-a-time. A dot-matrix print head builds characters out of the dots created by the pins in the matrix. Figure 2-25, view A, shows what dot matrix characters look like when printed.

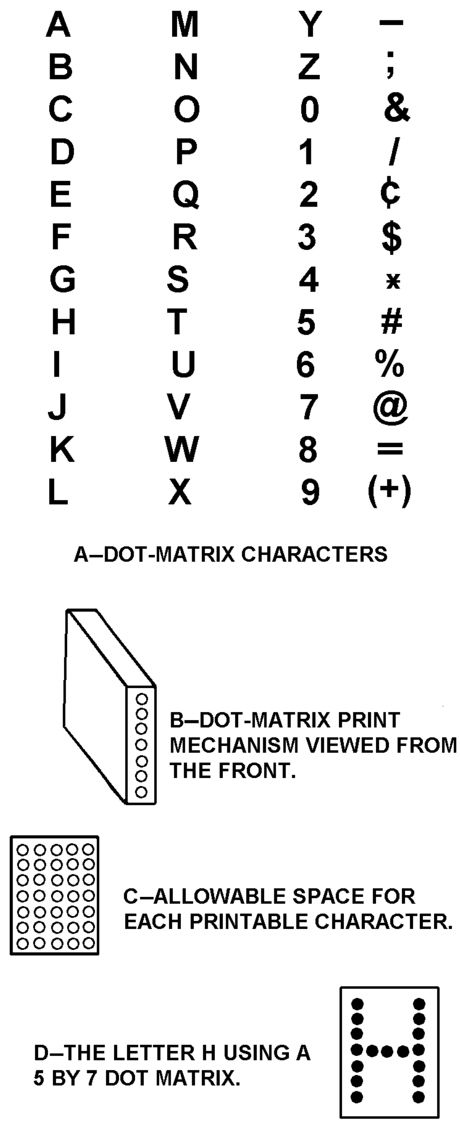

Figure 2-25.—Dot-matrix printing.

The dot matrix is defined in terms of rows and columns of dots. A 5 by 7 matrix uses up to five vertical columns of seven dots to create a character. An example of a 5 by 7 matrix printing the letter H is shown in figure 2-25, view D. The size of dot matrixes varies from a 5 by 7 matrix to as large as a 58 by 18 matrix. A number of dot-matrix printers use a single vertical column of pins to print characters, as shown in figure 2-25, view B. The characters are printed by moving (stepping) the print head a small amount and printing the vertical columns one at a time until the character is printed as shown in figure 2-25, views C and D.

The size of the matrix determines the quality of the printed character. In other words, the more dots used to print a character, the better the character is filled in and the higher its print quality. Dot-matrix printers are faster than the daisy-wheel printers with speeds ranging from 60 to 350 cps, but their print quality is not as good.

Ink Jet Printers

Ink jet printers employ a technique very similar to the way we use a can of spray paint and a stencil. A spray of electrically charged ink is shot (under pressure) toward the paper. Before reaching the paper, the ink is passed through an electrical field which forms the letters in a matrix form. The print resulting from this process consists of easy to read, high-quality characters. Some manufacturers use large droplets of ink for faster printing, while others use small droplets for better clarity but with slightly reduced printing speeds. These printers can print up to 300 cps (characters per second).

Laser Printers

Laser printers direct a beam of light through a rotating disk containing the full range of print characters. The appropriate character image is directed onto photographic paper, which is then put through a toner, developed, and used to make additional copies. The print resulting from this process consists of sharp, clean images that are easy on the eyes. These printers can print up to 20,000 plus lines per minute, or 26,666 cps (characters per second).

KEYBOARDS (INPUT)

A keyboard is nothing more than an array of switches called keyswitches. Keyboards are designed to input a code to the computer when a keyswitch is depressed. Each keyswitch, or key, on the keyboard is assigned a particular code value; and it is usually imprinted with a legend to identify its function. Figure 2-26 shows a keyboard combined with a crt on a microcomputer.

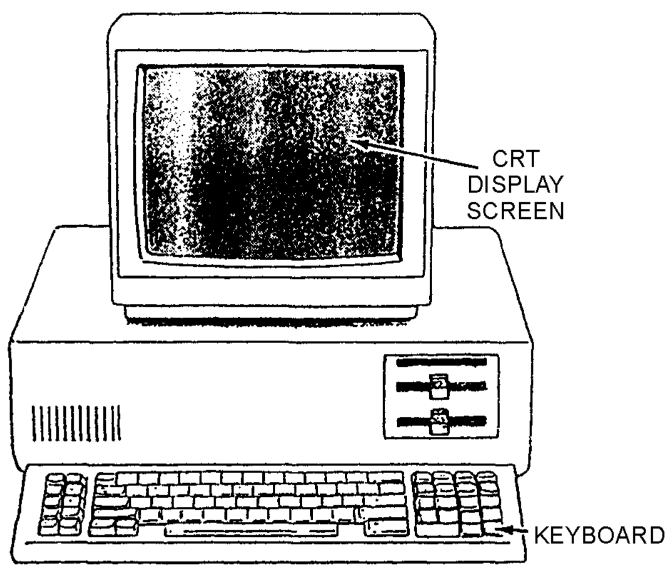

Figure 2-26.—Keyboard combined with a crt and microcomputer.

The primary purpose of a keyboard is to enter or input alphanumeric (numbers, letters, and special characters) character codes. The major grouping of keyswitches on a keyboard will be in one of the two styles of a typewriter keyboard arrangement (QWERTY or DVORAK). The typewriter keyswitches are arranged in 4 rows of 10 or more switches. The keyboard arrangement shown in figure 2-27 is QWERTY. The rows are usually offset to the row above to make it easier to reach all the keys when typing. The tops of the individual keyswitches are sculptured to conform to the shape of the human finger.

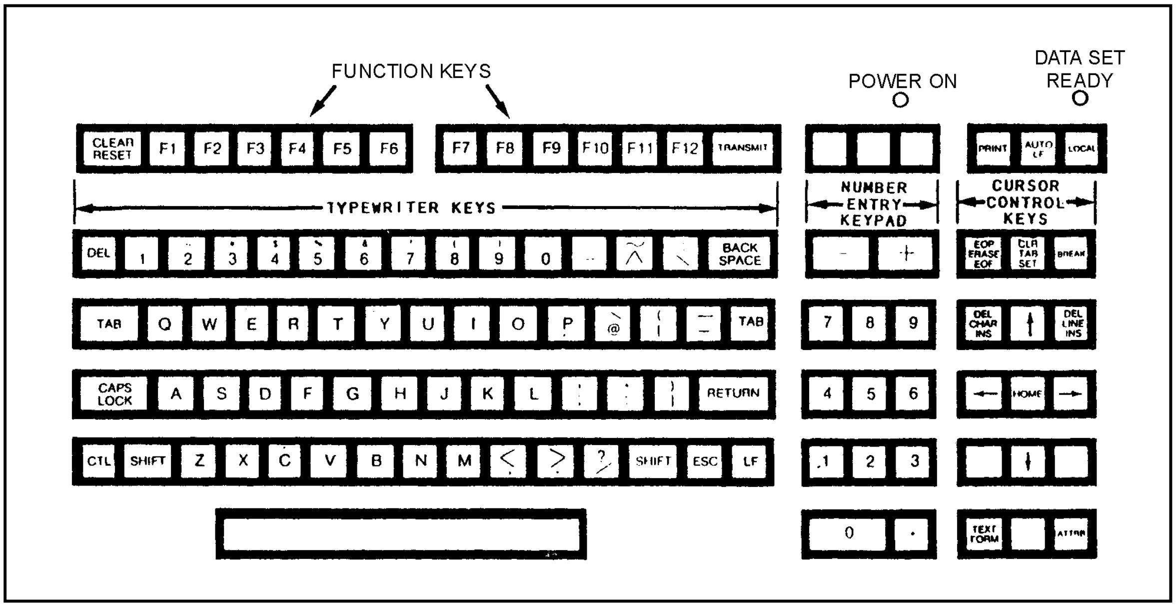

Figure 2-27.—Keyboard layout.

Other groupings of keyswitches are used for special purposes, such as number entry (calculator) keypads, special function switches (F1-F12), and cursor control keys. The special function switches allow an operator to use the special functions designed in the software. For example, in a word processing program, you can use them to spell check a document, search for a particular portion of text, move text from one place to another, and to print hard copies of a document. These are but a few of the functions allowed; however, as you become more familiar with computers you will learn them all. The cursor control key allows you to move to different locations on the screen.

The design of keyboards varies from device to device and is dependent on the requirements of the system in which the keyboards are installed.

Keyboards are generally used with nontactical computer systems. However, the newer tactical display system consoles have optional keyboards for data entry. A keyboard may be built into the display device, or it may be a separate component connected only by a communication cable.

DISPLAY DEVICES

Display devices are the crts and other displays that are part of computer terminals, computer consoles, and microcomputers. They are designed to project, show, exhibit, or display softcopy information (alphanumerics or graphic symbology).

The information displayed on a display device screen is not permanent. That is where the term soft-copy comes from. The information is available for viewing only as long as it is on the display screen. Two types of display devices used with personal/microcomputers are the raster scan crt's and the flat panel displays.

Raster Scan Crts

Raster scan crts (tv scan video monitors or display monitors) are used extensively in the display of alphanumeric data and graphics. They are used primarily in nontactical display applications such as SNAP II user terminals and desktop computers.

The raster is a series of horizontal lines crossing the face of the crt screen (fig. 2-28). Each horizontal line is made up of one trace of the electron beam from left to right. The raster starts at the top left corner of the crt screen. As each horizontal line is completed, the blanked electron beam is rapidly returned or retraced to the left of the screen.

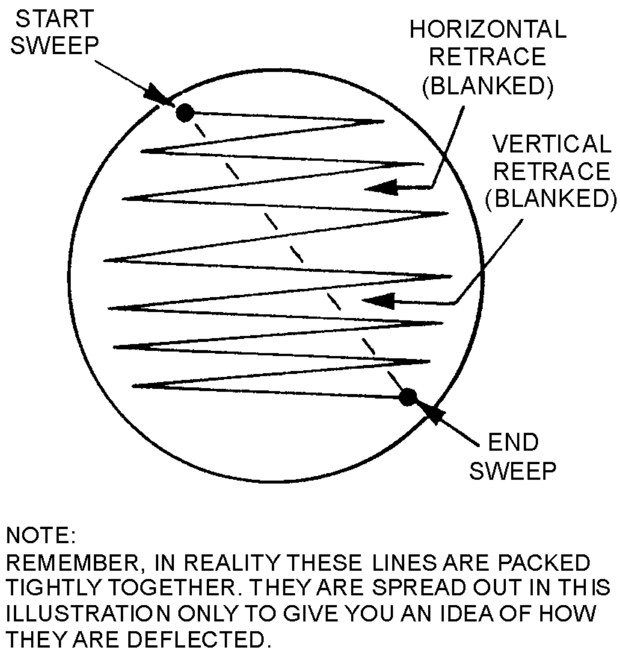

Figure 2-28.—Raster or TV scan.

Vertical deflection moves the beam down, and the horizontal sweep repeats. When the vertical sweep reaches the bottom line of the raster, a vertical blanked retrace returns the sweep to the starting position of the raster, and the process is repeated.

Each completed raster scan is referred to as a field; two fields make up a frame. The display rate of fields and frames determines the amount of flicker in the display that is perceived by the human eye. Each field is made up of approximately 525 horizontal lines. The actual number of horizontal lines varies from device to device. A frame consists of the interlaced lines of two fields. The horizontal lines of the two fields are interlaced to smooth out the display. A display rate of 30 frames per second produces a smooth, flicker-free raster and corresponding display on the screen.

PICTURE ELEMENTS.—The actual display of data results from the use of picture elements. A picture element is a variable dot of light derived from video signals input to the display monitor. The picture elements, often called pixels or pels, are contained in the horizontal scan lines crossing the face of the crt screen. The horizontal and vertical sweeps are continuous and repetitive in nature.

Pictures with alphanumeric characters and graphics can be created and displayed by varying the intensity or brightness of the picture element dots. This is done in conjunction with the phosphor coating on the face of the crt.

The number of picture elements in each horizontal line varies from device to device. The actual number of picture elements is dependent on the frequency bandwidth of the video monitor, the number of characters to be displayed on a line, and the physical size of the screen.

Each picture element is addressable by a row and column address. Picture elements are numbered from left to right on each horizontal line (column number). Each horizontal line has a row number. Picture elements, at a minimum, will have off (blanked) or on (full intensity) states. Many display devices have the capability to display picture elements at varying degrees of intensity for the display of graphics.

Characters are assembled on the screen in much the same way as a dot-matrix print head prints a character. It takes several horizontal lines and picture elements on each line to create a character. Figure 2-29 shows the generation of the character A, 7 picture elements wide and 9 horizontal lines high. The character is built using what is, in effect, a 7 by 9 dot matrix. The picture elements used to build the character would be at full intensity; the remaining picture elements in the matrix would be blanked. If dark characters on a lighted screen were desired, then the character picture elements would be blanked and the remainder displayed at full intensity.

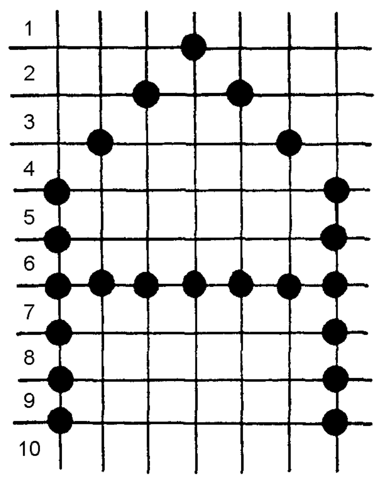

Figure 2-29.—A 7 by 9 picture element character.

Approximately 640 picture elements per horizontal line are required for the display of an 80 character line. Therefore, you can expect 140,000 picture elements on a raster scan display screen (80 alphanumeric characters per line and 25 lines).

HORIZONTAL AND VERTICAL RESOLUTION.—Horizontal resolution is defined in terms of the number of picture elements that can be displayed on the horizontal line without overlapping or running into each other. It is often stated in terms of lines of resolution. In other words, a monitor with a horizontal resolution of 1,000 lines can display 1,000 vertical lines using 1,000 picture elements per line.

Vertical resolution depends on the number of horizontal scan lines used by the particular display raster. Generally, the greater the number of scan lines, the easier it is to resolve a horizontal line of display. This characteristic remains true up to a point, called the merge point, where the variation between the lines cannot be detected by the human eye.

DISPLAYING DATA ON RASTER SCAN SCREENS.—Raster scan displays are repetitive in nature. The raster frame is displayed approximately 30 times a second.

The basic video monitor does nothing more than display the video signals it receives. If no video signals are received, then all the picture elements remain blanked, and the screen is blank in each frame. For data to be displayed accurately, each and every frame must blank and unblank the same picture elements.

The digital logic that drives video monitors is designed to take advantage of the repetitive nature of frames. There can only be a fixed number of picture elements on the screen of a display; therefore, the contents of the display screen are organized into a data unit called a page.

The page contains the status of every picture element on the display screen. The page is usually stored in some form of random-access memory, RAM chips being the most common. The contents of page memory, or, as it is sometimes called, video memory, are continually scanned by the video generation logic and used to develop the video signals for the picture element display. The picture element locations in page memory are read in time to develop the video signals for the picture element display on the horizontal lines.

If the display is to be changed, the contents of page memory must be changed. The display on the screen changes as new data is stored in page memory. Two addressing methods are used with page memory.

Unformatted Displays.—Displays that reference page memory by picture element address are called unformatted or fully populated displays. These displays are more commonly used for graphics rather than alphanumeric characters.

Formatted Displays.—Often displays are organized by character position and line number. These displays are known as formatted displays. This display method is used with devices displaying alphanumeric characters only or those with an alternate graphic capability.

The video generation logic of these types of displays scans the entire page memory, as before, to generate the display picture elements. The difference is in the way the new data is written into the page memory. Individual picture element addresses are not used. Character addresses are used to reference page memory.

The screen is organized into character lines. Each line is made up of a fixed number of character positions or columns. A fixed number of character lines can be displayed. A common arrangement found on display screens is twenty five 80-character lines, or 2,000 characters.

The character set that can be displayed on a device's formatted screen is stored in ROMs or PROMS. That is, the dot-matrix (picture element) patterns for each individual character to be displayed are stored. Different character sets may be displayed by simply replacing the appropriate ROM or PROM chips with new chips containing different character patterns.

Upon receipt of a character code and a row and column address, the device logic reads the picture element pattern (dot matrix) from the ROM and writes the pattern into the appropriate character position in the page memory. The desired character is then displayed at the correct position. Other display devices store the codes in page memory and convert the codes to picture element dots when scanning memory to refresh or redisplay the characters on the screen. The use of formatted displays greatly simplifies the programming requirements for the display of alphanumeric data.

Flat Panel Displays

A number of display methods are in use that are designed to reduce the depth of the crt display caused by the length of the tube. These devices are collectively known as flat panel displays. Three types of flat panel displays commonly in use with computer systems are liquid crystal displays (LCDs), gas plasma displays (GPDs), and electroluminescent displays (ELDs).

The screens of these flat panel displays are made up of pairs of electrodes. Each pair of electrodes is used to generate one picture element.

The liquid crystal display differs from the gas plasma and electroluminescent displays in that it does not generate its own light for the picture elements. The LCD requires an external light source, often called a backlight, for computer applications. The liquid crystal material between the charged electrodes becomes translucent when voltage is applied and allows the backlight to shine through as a picture element.

In the gas plasma and electroluminescent displays, the picture element light is generated by ionizing a gas (neon or neon argon) between the charged electrodes (gas plasma display) or by stimulating a luminescent material in the same manner (electroluminescent display). In either case, the picture element only emits light when the electrodes have voltage applied to them.

One of the advantages of flat panel displays is that smaller voltages are required for their operation than for a crt. Gas plasma displays use approximately 200 volts to charge the electrodes, and electroluminescent displays require only 20 volts.

The picture elements in these displays are addressed by the row and column method. Displays with as many as 737,280 picture elements (960 rows by 768 columns) have been developed.

The picture elements on flat panel displays are not lighted continually. This would require a large amount of power and generate excessive heat. A sequential scan similar to a crt raster is used. Once again a page memory is required. The picture element electrodes are on and off as the scan sequentially addresses page memory.

Those picture elements that are to display a dot are momentarily turned on and off starting with the first picture element in the top row, or line, and ending with the last picture element on the bottom row. The picture elements are turned on and off at a high enough frequency that the human eye cannot detect the flicker of the off-on-off cycle.

The sequential scan used to light the picture elements is continuous and repetitive. Once again, the page memory must be changed to change the display. Flat panel displays may be formatted or unformatted in the same manner as crt displays.

Q-35. What is the purpose of any magnetic tape unit?

Q-36. What are the major differences between magnetic tape units?

Q-37. Why is direct accessing of data a big advantage over the sequential accessing of data?

Q-38. What is a floppy disk?

Q-39. What are the three most common sizes of floppy disks?

Q-40. What output device expresses coded characters as hard copy (paper documents)?

Q-41. What four types of printers are commonly used with personal computers?

Q-42. What is the primary purpose of a keyboard?

Q-43. Raster scan or tv scan video monitors are used extensively for what purpose?

Q-44. How many fields make up a frame?

Q-45. A field is approximately how many horizontal lines?

Q-46. What are picture elements often called?

Q-47. Vertical resolution depends on what?

Q-48. Flat panel displays are designed to reduce what problem of a crt display?

Q-49. What does the liquid crystal display require for computer applications?

SUMMARY

Now that you have finished chapter 2, you should be feeling more at ease with digital computers. You should realize by now that they are not so hard to understand, once you have the terminology down. The information that follows summarizes the important points of this chapter.

The **CENTRAL PROCESSING UNIT** is the brain of the computer. We generally refer to it as the cpu or mainframe.

The **CONTROL SECTION** directs the flow of traffic (operations) and data, and maintains order within the computer.

The **ARITHMETIC-LOGIC SECTION** performs all arithmetic operations-adding, subtracting, multiplying, and dividing. It also tests various conditions during processing and takes action based on the result.

INTERNAL STORAGE is sometimes referred to as primary storage, main storage, or main memory (because its functions are similar to our own human memory). It stores the programs and data.

MAGNETIC CORE STORAGE is made up of tiny doughnut-shaped rings made of ferrite (iron) that are strung on a grid of very thin wires.

SEMICONDUCTOR STORAGE consists of hundreds of thousands of tiny electronic circuits etched on a silicon chip.

BUBBLE STORAGE is made of semiconductor material in the form of a very thin crystal.

READ-ONLY MEMORY (ROM) allows us to permanently store programs that will not be lost even when the computer is powered down.

RANDOM-ACCESS MEMORY (RAM) is read/ write memory. It is the working memory, rather like a blackboard, that you can scribble down notes, read them, and rub them out when you are finished with them.

SECONDARY STORAGE is the memory outside the main body of the computer (cpu) where we store programs and data for future use.

MAGNETIC TAPE is a sequential access storage device.

MAGNETIC DISK is a direct access storage device.

INPUT/OUTPUT DEVICES are the means by which the computer communicates with the outside world. These include magnetic tape units, magnetic disk drive units, floppy disk drive units, printers (daisy-wheel, dot-matrix, ink jet, and laser), and display devices (raster scan crt and flat panel).

ANSWERS TO QUESTIONS Q1. AND Q49.

A-1. The central processing unit.

A-2. Three.

A-3. Control section, internal storage section, and arithmetic-logic section.

A-4. A telephone exchange.

A-5. Transfer, arithmetic, logic, and control.

A-6. Logic.

A-7. Internal storage.

A-8. Loading.

A-9. Tiny doughnut-shaped rings made of ferrite iron.

A-10. Hundreds of thousands of tiny electronic circuits etched on a silicon chip.

A-11. Integrated circuits.

A-12. All data in memory is lost when the power source is removed.

A-13. Nonvolatile (magnetic core storage and bubble memory are examples).

A-14. A very thin crystal made of semiconductor material.

A-15. By passing a current through a control circuit imprinted on top of the crystal.

A-16. The data is still present after being read.

A-17. Read-only memory (ROM).

A-18. Only the manufacturer.

A-19. No.

A-20. Read/write memory.

A-21. By giving the computer the address of the location where the data is stored or is to be stored.

A-22. Already programmed by the manufacturer or in a blank state.

A-23. If a mistake is made and entered, it cannot be corrected or erased.

A-24. Erasable programmable read-only memory.

A-25. With a burst of ultra-violet light.

A-26. Largely because of their direct access capabilities.

A-27. In a number of invisible concentric circles called tracks.

A-28. A disk address.

A-29. By the bits per inch of track and the tracks per inch of surface.

A-30. By cylinder or sector.

A-31. Recording density.

A-32. The usable recording (reading/writing) surface or usable storage area.

A-33. The tracks in which the data is stored are assigned to channels that form circular bands around the drum.

A-34. Sectors.

A-35. To write data on or read data from a magnetic tape.

A-36. The speed at which the tape is moved past the read/write head and the density of the recorded information.

A-37. It gives us fast, immediate access to specific data without having to examine each and every record from the beginning.

A-38. A thin, flexible platter coated with magnetic material so characters can be recorded.

A-39. 8 inch, 5 1/4 inch, and 3 1/2 inch.

A-40. Printers.

A-41. Daisy-wheel, dot-matrix, ink jet, and laser.

A-42. To enter or input alphanumeric character codes.

A-43. The display of alphanumeric data and graphics.

A-44. Two.

A-45. 525.

A-46. Pixels or pels.

A-47. The number of horizontal scan lines used.

A-48. Reduce the depth of the crt display caused by the length of the tube.

A-49. An external light source, called a backlight.

CHAPTER 3
SOFTWARE

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to do the following:

1. Recognize and compare the different types and functions of operating systems.
2. Identify the types of utilities and explain their functions.
3. Describe the different types and functions of programming languages.
4. Explain the steps necessary to develop a program and describe the tools used.
5. Compare and describe the types and functions of applications packages.

INTRODUCTION

Up to now we have been discussing computer OPERATIONAL CONCEPTS and HARDWARE (the computer and its peripheral devices), and how these devices work and communicate with each other. What about this thing called SOFTWARE? Do we really need it? We most certainly do! Software plays a major role in computer data processing. For example, without software, the computer could not perform simple addition. It's the software that makes everything happen. Or putting it another way, software brings the computer to life.

You already know it takes a program to make the computer function. You load an operating system into the computer to manage the computer's resources and operations. You give job information to the operating system to tell it what you want the computer to do. You may tell it to assemble or compile a COBOL program. You may tell it to run the payroll or print inventory reports. You may tell it to copy a tape using a utility program. You may tell it to print the data from a disk file, also using a utility program. You may tell it to test a program. This job information may be entered through the console or read into the computer from tape or disk. It also may be entered by the programmer or user from a remote computer terminal. The operating system receives and processes the job information and executes the programs according to that job information.

Software can be defined as all the stored programs and routines (operating aids) needed to fully use the capabilities of a computer. Generally speaking, we say, "If it is not hardware then it must be software."

OPERATING SYSTEMS

The operating system is the heart of any computer system. Through it, everything else is done. Basically, operating systems are designed to provide the operator with the most efficient way of executing many user programs.

An operating system is a collection of many programs used by the computer to manage its own resources and operations. These programs control the execution of other programs. They schedule, assign resources, monitor, and control the work of the computer. There are several types.

TYPES OF OPERATING SYSTEMS

Operating systems are designed to provide various operating modes. Some systems can only do one task at a time, while others can perform several at a time. Some systems allow only one person to use the system, and others allow multiple users. Single user/single tasking operating systems are the simplest and most common on microcomputers. CP/M®-80[1], CP/M-86®[1], and MS-DOS®[2] are examples. Single user/multitasking operating systems allow you to do more than one task as long as the tasks don't use the same type of resources. For example, you can print one job while you run another, as long as the second job does not require the printer. Examples are Concurrent CP/M® -86 [3], Concurrent® DOS [3], and MS-DOS®; (3.0 and above). Multiuser/multitasking operating systems let more than one user access the same resources at the same time. This is especially useful for sharing common data. These are only feasible on processors (the functional unit in a computer that interprets and executes instructions) of 16 bits or more and with large memories. UNIX [4] is an example. There are also multiprocessor systems, shared resource systems. This means each user (or operator) has a dedicated microprocessor (cpu), which shares common resources (disks, printers, etc.).

1. CP/M and CP/M-86 are registered trademarks of Digital Research Inc.

2. MS-DOS is a registered trademark of Microsoft Corporation.

3. Concurrent CP/M and Concurrent DOS are trademarks of Digital Research Inc.

4. UNIX is a trademark of AT&T.

COMPATIBILITY WITH APPLICATIONS SOFTWARE

To use an applications program, it must be compatible with the operating system. Therefore, the availability of application software for a particular operating system is critical. Because of this, several operating systems have become the most popular. For 8-bit microcomputers, CP/M (Control Program for Microprocessors) is widely used because many hardware manufacturers have adopted it. MS-DOS (MicroSoft Disk Operating System) designed from CP/M dominates in lower performance 16-bit systems. UNIX, an operating system for larger computers, is being used on the more powerful 16-bit and 32-bit microcomputers. Other operating systems are offered by microcomputer manufacturers.

To overcome the applications software compatibility problem, some software comes in several versions so it can be run under several different operating systems. The point to remember is that not all applications software will run on all systems. You have to check to see that compatibility exists. You need the right version.

OPERATING SYSTEM FUNCTIONS

To give you a better idea of what you can expect to see on your microcomputer display screen, we will show a few fundamental disk operating system commands and messages. Again, the functions of each operating system are about the same, but each may use a different command to do about the same thing. For example, try not to get confused because CP/M uses the command PIP (peripheral interchange program) to copy a file, while MS-DOS uses the command COPY.

Remember, the first thing you need to do is boot (initial program load) the system. There are many ways this can be done. Here is an example. When you turn on the power, a prompt may appear on the screen. You then insert the operating system floppy disk into the drive A. Type a B (for boot) and press the RETURN key. The operating system will load from the disk. If you are using a system set up for automatic booting, you won't have to type the B. The system automatically loads the operating system when you insert the disk that contains it. Some systems will then ask for date and time. Enter these. You will next see a prompt, usually A> (or A:). The system is ready and drive A is assigned as your primary drive. One thing you might want to do is to display the disk directory to see what is on the disk. To do this, enter DIR following the A>. This will list your files.

COMMAND	.COM
CONFIGUR	.COM
DATDBL	.BAK
DATDBL	.DOC
FINANCE	.BAS
MASTER	.DOC

It may also give you file size and the date and time of the file. Let's take an example. Let's say you are to copy the file "MASTER.DOC" from the floppy disk in drive A to the floppy disk in drive B and then delete the file on the floppy disk in drive A. You have just displayed the directory of the floppy disk in drive A. Check to see that the file you want is on the floppy disk in drive A. It is. You then insert the floppy disk on which you want the copy into drive B. Be sure it is formatted with the track and sector information so it is ready to receive data. Also, be sure the disk is not write-protected. On a 5-1/4 inch floppy disk that means the write protect notch is uncovered. Following the A> type

COPY MASTER.DOC B:

and press RETURN. The system will copy the file and give it the same name. Next you might want to display the directory on drive B to see that the file was copied. You can do this by entering DIR B: following the A> prompt. To delete the file on the floppy disk in drive A, type

DEL MASTER.DOC

following the A> prompt on the screen and press RETURN.

You probably noticed each entry in the directory is followed by three characters. These are called extensions, and we use them to tell us the type of file we are working with. For example,

.BAK	Means backup file.
.BAS	Means BASIC source program.
.TMP	Means temporary file.
.DOC	Means ASCII document file.
.BIN	Means binary file, and so on.

Other typical built-in operating system commands you can use might include:

RENAME	to change the name of a file
DISKCOPY	to copy a whole floppy disk
FORMAT	to initialize a floppy disk, get it ready to receive data and programs from the system
TIME	to display or set the time

You will learn to use these and many other system commands as you operate a specific computer.

We won't go into any more detail here. You will have documentation and reference manuals for the specific version of the operating system you will be using.

Q-1. What is the heart of any computer system?

Q-2. Which types of operating systems are the simplest and most common on microcomputers?

Q-3. What types of operating systems let more than one user access the same resources at the same time?

Q-4. Why is the availability of applications software for a particular operating system critical?

Q-5. How is the applications software compatibility problem overcome?

UTILITY PROGRAMS

Now that you have learned about operating systems, let's go into another type of program, utilities. In addition to the utility commands (like diskcopy and rename), which are built into the operating system, you will probably have some independent utility programs. These are standard programs that run under control of the operating system just like your applications programs. They are called utilities because they perform general types of functions that have little relationship to the content of the data. Utility programs eliminate the need for programmers to write new programs when all they want to do is copy, print, or sort a data file. Although a new program is not needed, we do have to tell the program what we want it to do. We do this by providing information about files, data fields, and the process to be used. For example, a sort program arranges data records in a specified order. You will have to tell the sort program what fields to sort on and whether to sort in ascending or descending sequence.

Let's examine two types of utility programs to give you some idea of how a utility program works. The first will be sort-merge and the second the report program generator (RPG).

SORT-MERGE PROGRAMS

Sorting is the term given to arranging data records in a predefined sequence or order. Merging is the combining of two or more ordered files into one file. For example, we normally think of putting a list of people's names in alphabetical order arranging them in sequence by last name. We arrange those with the same last name in order by first name.

If we do this ourselves, we know the alphabetic sequence —B comes after A, C after B, and so on, and it is easy to arrange the list, even if it is a time consuming job. On a computer, the sequence of characters is also defined. It is called the collating sequence. Every coding system has a collating sequence. The capability of a computer to compare two values and determine which is greater (B is greater than A, C is greater than B, and so on) makes sorting possible. What about numbers and special characters? They are also part of the collating sequence. In EBCDIC, (EBCDIC is a computer code that is discussed in detail in chapter 4) special characters, such as #, $, &, and *, come in front of the alphabetic characters, and numbers follow. When you sort records in the defined sequence, they are in ascending sequence. Most sort programs also allow you to sort in reverse order. This is called descending sequence. In EBCDIC, it is 9-0, Z-A, then special characters.

To sort a data file, you must tell the sort program what data field or fields to sort on. These fields are called sort (or sorting) keys. In our example, the last name is the major sort key and the first name is the minor sort key.

Sorting is needed in many applications. For example, for mailing we need addresses in ZIP Code order; personnel records may be kept in service number order; and inventory records may be kept in stock number order. We could go on and on. Because many of our files are large, sorting is very time consuming, and it is one of the processes most used on computer systems. As a user, you will become very familiar with this process.

Sort-merge programs usually have phases. First they initialize: read the parameters, produce the program code for the sort, allocate the memory space, and set up other functions. The sort-merge program then reads in as many input data records as the memory space allocated can hold, arranges (sorts) them in sequence, and writes them out to an intermediate sort-work file. It continues reading input, sorting and writing intermediate sort-work files until all the input is processed. It then merges (combines) the ordered intermediate sort-work files to produce one output file in the sequence specified. The merging process can be accomplished with less memory than the sort process since the intermediate sort work files are all in the same sequence. Records from each work file can be read, the sort keys compared based on the collating sequence and sort parameters, and records written to the output file maintaining the specified sequence.

REPORT PROGRAM GENERATORS

Report program generators (RPG) are used to generate programs to print detail and summary reports of data files. Figure 3-1 is an example of a printed report. RPGs were designed to save programming time. Rather than writing procedural steps in a language like BASIC or COBOL, the RPG programmer writes the printed report requirements on specially designed forms.

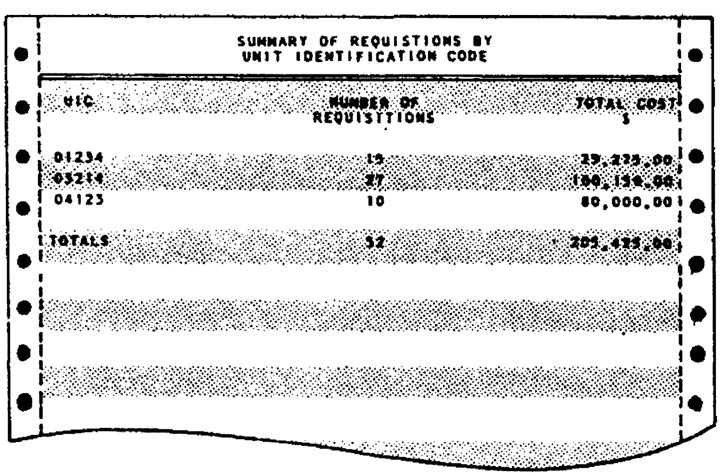

Figure 3-1.—Printed report using a report program generator (RPG) program.

Included in the requirements are an input file description, the report heading information lines, the input data record fields, the calculations to be done, and the data fields to be printed and summarized. The RPG program takes this information and generates a program for the specific problem. You then run that program with the specified input data file to produce the printed report. The input data file must be in the sequence in which you want the report to summarize the data.

In our example (fig. 3-1), we summarized requisitions based on unit identification codes (UIC). We first sorted the input data file on the field that contains the UIC. We provided specifications to the RPG program to tell it to accumulate totals from the detail (individual) data records until the UIC changed. We then told it to print the total number of requisitions and total cost for that UIC. We did not have it print each detail record, although we could have. The UIC is called the control field. Each time the control field changes, there is a control break. Each time there is a control break, the program prints the summary information. After all records are read and processed, it prints a summary line (TOTALS) for all UICs. You can also use RPGs to generate a program to update data files.

Q-6. What programs eliminate the need for programmers to write new programs when all they want to do is copy, print, or sort a data file?

Q-7. How do we tell a utility program what we want it to do?

Q-8. What is the term given to arranging data records in a predefined sequence or order?

Q-9. To sort a data file, what must you tell the sort program?

Q-10. What are report program generators used for?

PROGRAMMING LANGUAGES

Programmers must use a language that can be understood by the computer. Several methods can achieve human-computer communication. For example, let us assume the computer only understands French and the programmer speaks English. The question arises: How are we to communicate with the computer? One approach is for the programmer to code the instructions with the help of a translating dictionary before giving them to the processor. This would be fine so far as the computer is concerned; however, it would be very awkward for the programmer.

Another approach is a compromise between the programmer and computer. The programmer first writes instructions in a code that is easier to relate to English. This code is not the computer's language; therefore, the computer does not understand the orders. The programmer solves this problem by giving the computer another program, one that enables it to translate the instruction codes into its own language. This translation program, for example, would be equivalent to an English-to-French dictionary, leaving the translating job to be done by the computer.

The third and most desirable approach from an individual's standpoint is for the computer to accept and interpret instructions written in everyday English terms. Each of these approaches has its place in the evolution of programming languages and is used in computers today.

MACHINE LANGUAGES

With early computers, the programmer had to translate instructions into the machine language form that the computers understood. This language was a string of numbers that represented the instruction code and operand address(es).

In addition to remembering dozens of code numbers for the instructions in the computer's instruction set, the programmer also had to keep track of the storage locations of data and instructions. This process was very time consuming, quite expensive, and often resulted in errors. Correcting errors or making modifications to these programs was a very tedious process.

SYMBOLIC LANGUAGES

In the early 1950s, mnemonic instruction codes and symbolic addresses were developed. This improved the program preparation process by substituting letter symbols (mnemonic codes) for basic machine language instruction codes. Each computer has mnemonic codes, although the symbols vary among the different makes and models of computers. The computer still uses machine language in actual processing, but it translates the symbolic language into machine language equivalent. Symbolic languages have many advantages over machine language coding. Less time is required to write a program. Detail is reduced. Fewer errors are made. Errors which are made are easier to find, and programs are easier to modify.

PROCEDURE-ORIENTED LANGUAGES

The development of mnemonic techniques and macroinstructions led to the development of procedure-oriented languages. Macroinstructions allow the programmer to write a single instruction that is equivalent to a specified sequence of machine instructions. These procedure-oriented languages are oriented toward a specific class of processing problems. A class of similar problems is isolated, and a language is developed to process these types of applications. Several languages have been designed to process problems of a scientific-mathematical nature and others that emphasize file processing.

Procedure-oriented languages were developed to allow a programmer to work in a language that is close to English or mathematical notation. This improves overall efficiency and simplifies the communications process between the programmer and the computer. These languages have allowed us to be more concerned with the problems to be solved rather than with the details of computer operation. For example:

COBOL (COmmon Business Oriented Language) was developed for business applications. It uses statements of everyday English and is good for handling large data files.

FORTRAN (FORmula TRANslator) was developed for mathematical work. It is used by engineers, scientists, statisticians, and others where mathematical operations are most important.

BASIC (Beginner's All-Purpose Symbolic Instruction Code) was designed as a teaching language to help beginning programmers write programs. Therefore, it is a general-purpose, introductory language that is fairly easy to learn and to use. With the increase in the use of microcomputers, BASIC has regained popularity and is available on most microcomputer systems.

Other languages gaining in popularity are PASCAL and Ada. PASCAL is being used by many colleges and universities to teach programming because it is fairly easy to learn; yet is a more powerful language than BASIC. Although PASCAL is not yet a standardized language, it is still used rather extensively on microcomputers. It has greater programming capabilities on small computers than are possible with BASIC.

Ada's development was initiated by the U.S. Department of Defense (DOD). Ada is a modern general-purpose language designed with the professional programmer in mind and has many unique features to aid in the implementation of large scale applications and real-time systems. Because Ada is so strongly supported by the DOD and other advocates, it will become an important language like those previously mentioned. Its primary disadvantage relates to its size and complexity, which will require considerable adjustment on the part of most programmers.

The most familiar of the procedure-oriented languages are BASIC and FORTRAN for scientific or mathematical problems, and COBOL for file processing.

Programs written in procedure-oriented languages, unlike those in symbolic languages, may be used with a number of different computer makes and models. This feature greatly reduces reprogramming expenses when changing from one computer system to another. Other advantages to procedure-oriented languages are (1) they are easier to learn than symbolic languages; (2) they require less time to write; (3) they provide better documentation; and (4) they are easier to maintain. However, there are some disadvantages of procedure-oriented languages. They require more space in memory, and they process data at a slower rate than symbolic languages.

Q-11. With early computers, the programmer had to translate instructions into what type of language form?

Q-12. When were mnemonic instruction codes and symbolic addresses developed?

Q-13. What led to the development of procedure oriented languages?

Q-14. What computer language was developed for mathematical work?

Q-15. What are two disadvantages of procedure oriented languages?

PROGRAMMING

Programming is, simply, the process of planning the computer solution to a problem. Thus, by writing:

1. Take the reciprocal of the resistance of all resistors (expressed in ohms);
2. Sum the values obtained in step 1;
3. Take the reciprocal of the sum derived in step 2.

A generalized process or program for finding the total resistance of a parallel resistance circuit has now been derived.

To progress from this example to preparing a program for a computer is not difficult. However, one basic characteristic of the computer must be kept in mind. It cannot think. It can only follow certain commands, and these commands must be correctly expressed and must cover all possibilities. Thus, if a program is to be useful in a computer, it must be broken down into specifically defined operations or steps. Then the instructions, along with other data necessary for performing these operations or steps, must be communicated to the computer in the form of a language or code that is acceptable to the machine. In broad terms, the computer follows certain steps in executing a program. It must first read the instructions (sequentially unless otherwise programmed), and then in accordance with these instructions, it executes the following procedures:

1. Locates the parameters (constants) and such other data as may be necessary for problem solution
2. Transfers the parameters and data to the point of manipulation

3. Manipulates the parameters and data in accordance with certain rules of logic

4. Stores the results of such manipulations in a specific location

5. Provides the operator (user) with a useful output

Even in a program of elementary character such as the one above, this would involve breaking each of the steps down into a series of machine operations. Then these instructions, parameters, and the data necessary for problem solution must be translated into a language or code that the computer can accept.

Next, we'll provide an introduction to the problem solving concepts and flow charting necessary to develop a program.

OVERVIEW OF PROGRAMMING

Before learning to program in any language, it is helpful to establish some context for the productive part of the entire programming effort. This context comprises the understanding and agreement that there are four fundamental and discrete steps involved in solving a problem on a computer.

The four steps are as follows:

1. State, analyze, and define the problem.

2. Develop the program logic and prepare a program flowchart or decision table.

3. Code the program, prepare the code in machine readable form, prepare test data, and perform debug and test runs.

4. Complete the documentation and prepare operator procedures for implementation and production.

Figure 3-2 depicts the evolution of a program. Programming can be complicated, and advance preparation is required before you can actually start to write or code the program. The first two steps, problem understanding/definition and flowcharting, fall into the advance planning phase of programming. It is important at this point to develop correct habits and procedures, since this will prevent later difficulties in program preparation.

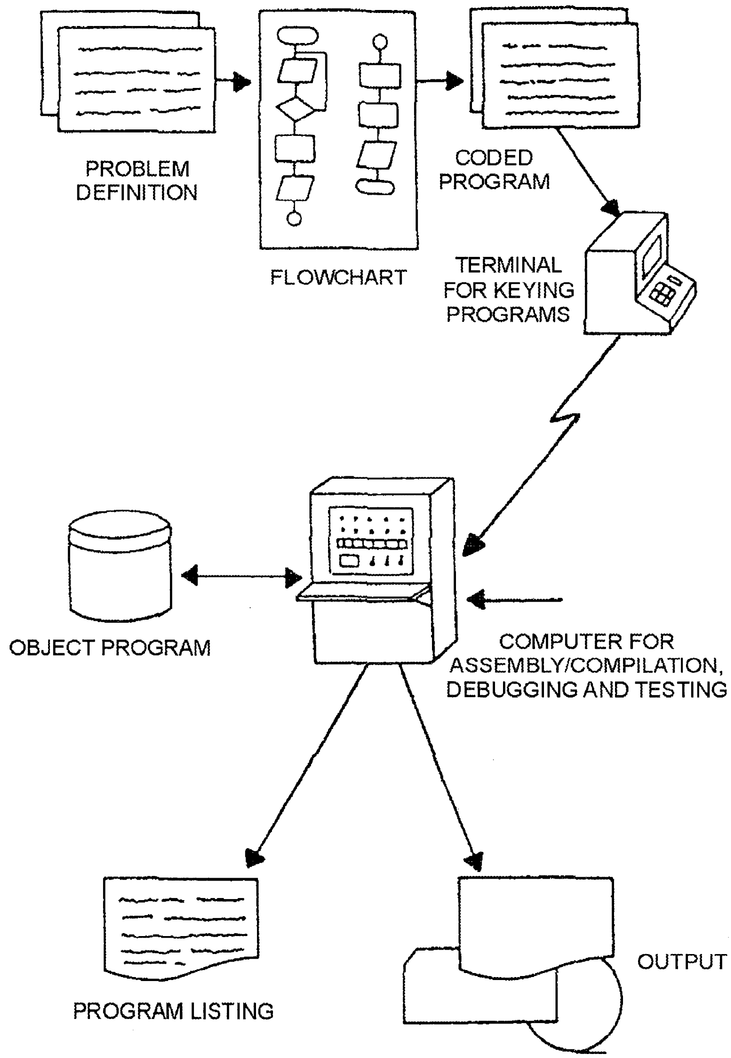

Figure 3-2.—Evolution of a program.

Whether you are working with a systems analyst, a customer, or solving a problem of your own, it is extremely important that you have a thorough understanding of the problem.

Every aspect of the problem must be defined:

- What is the problem?
- What information (or data) is needed?
- Where and how will the information be obtained?
- What is the desired output?

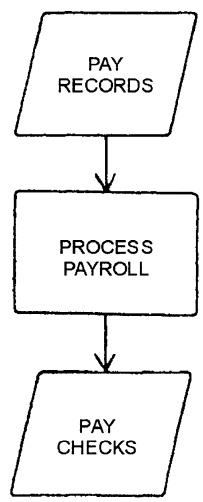
Starting with only a portion of the information, or an incomplete definition, will result in having to constantly alter what has been done to accommodate the additional facts as they become available. It is easier and more efficient to begin programming after all of the necessary information is understood. Once you have a thorough understanding of the problem, the next step is flowcharting.

FLOWCHARTING

Flowcharting is one method of pictorially representing a procedural (step-by-step) solution to a problem before you actually start to write the computer instructions required to produce the desired results. Flowcharts use different shaped symbols connected by one-way arrows to represent operations, data flow, equipment, and so forth.

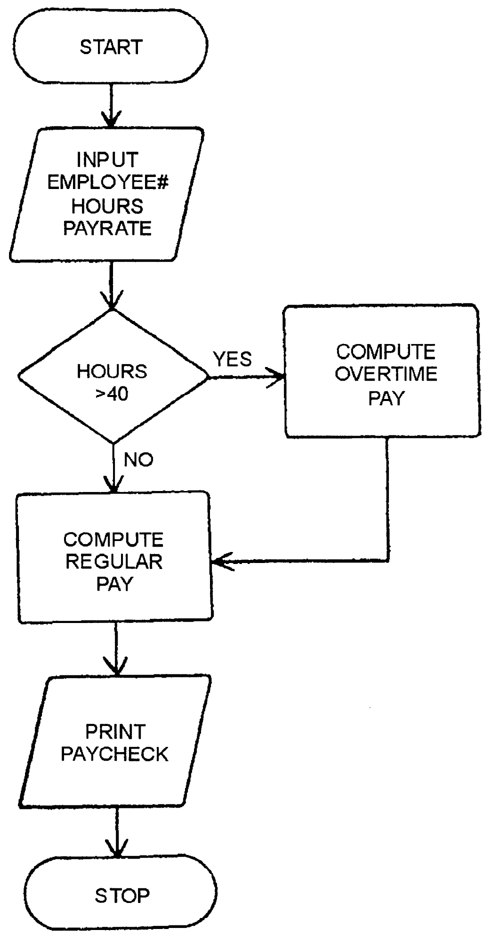
There are two types of flowcharts, system (data) flowcharts and programming flowcharts. A system (data) flowchart defines the major phases of the processing, as well as the various data media used. It shows the relationship of numerous jobs that make up an entire system. In the system (data) flowchart, an entire program run or phase is always represented by a single processing symbol, together with the input/output symbols showing the path of data through a problem solution. For example:

SYSTEM FLOWCHART



The second type of flowchart, and the one we will talk about in this section is the programming flowchart. It is constructed by the programmer to represent the sequence of operations the computer is to perform to solve a specific problem. It graphically describes what is to take place in the program. It displays specific operations and decisions, and their sequence within the program. For example:

PROGRAMMING FLOWCHART



Tools of Flowcharting

Next we will take a look at the tools used in flowcharting. These tools are the fundamental symbols, graphic symbols, flowcharting template, and the flowcharting worksheet.

FUNDAMENTAL SYMBOLS.—To construct a flowchart, you must know the symbols and their related meanings. They are standard for the military, as directed by *Department of the Navy Automated Data Systems Documentation Standards*, SECNAVINST 5233.

Symbols are used to represent functions. These fundamental functions are processing, decision, input/output, terminal, flow lines, and connector symbol. All flowcharts may be initially constructed using only these fundamental symbols as a rough outline to work from. Each symbol corresponds to one of the functions of a computer and specifies the instruction(s) to be performed by the computer. The contents of these symbols are called statements. Samples of these fundamental symbols, definitions, examples, and explanations of their uses are shown in figure 3-3.

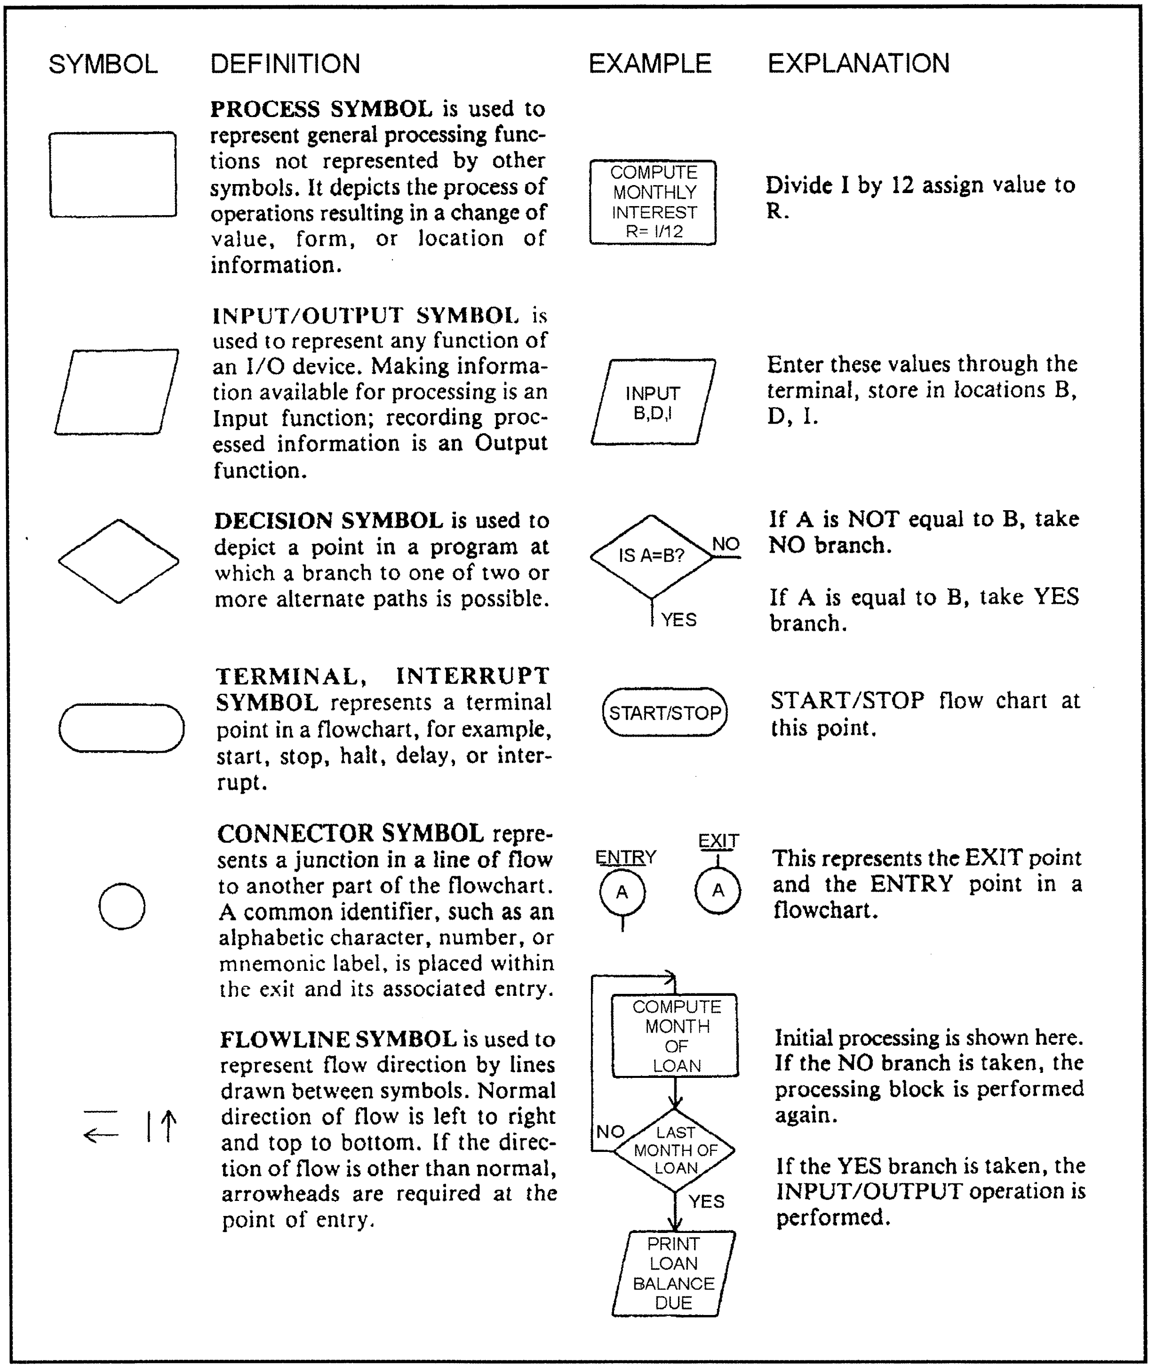


Figure 3-3.—Fundamental flowcharting symbols.

GRAPHIC SYMBOLS.—Within a flowchart, graphic symbols are used to specify arithmetic operations and relational conditions. The following are commonly-used arithmetic and relational symbols.

+	plus, add
-	minus, subtract
*	multiply
/	divide
±	plus or minus
=	equal to
>	greater than
<	less than
≥	greater than or equal to
≤	less than or equal to
≠	not equal
YES or Y	Yes
NO or N	No
TRUE or T	True
FALSE or F	False

FLOWCHARTING TEMPLATE.—To aid in drawing the flowcharting symbols, you may use a flowcharting template. Figure 3-4 shows a template containing the standard symbol cutouts. A template is usually made of plastic with the symbols cut out to allow tracing the outline.

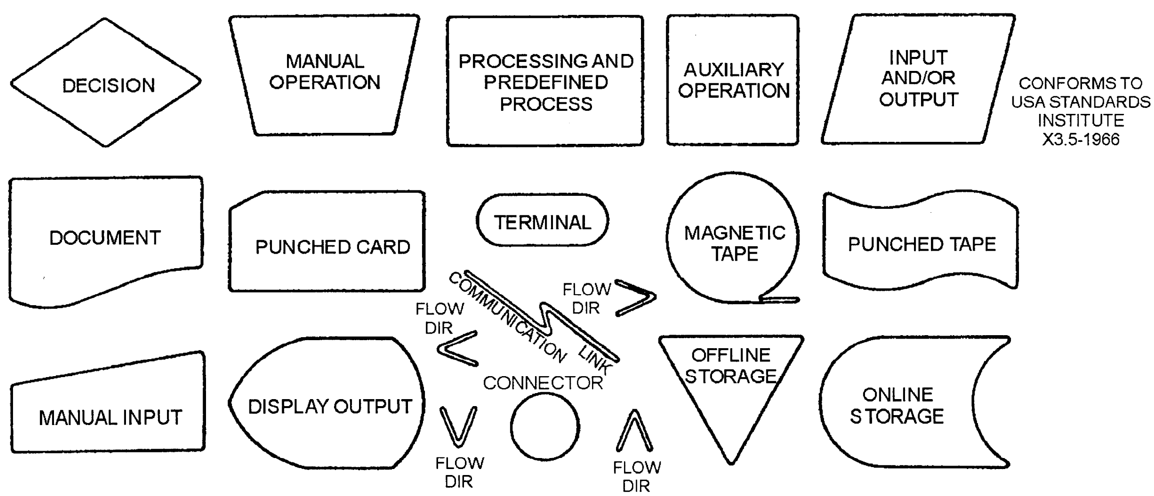

Figure 3-4.—Flowchart template.

FLOWCHART WORKSHEET.—The flowchart worksheet is a means of standardizing documentation. It provides space for drawing programming flowcharts and contains an area for identification of the job, including application, procedure, date, and page numbers (fig. 3-5). You may find it helpful when you develop flowcharts. If you don't have this form available, a plain piece of paper will do.

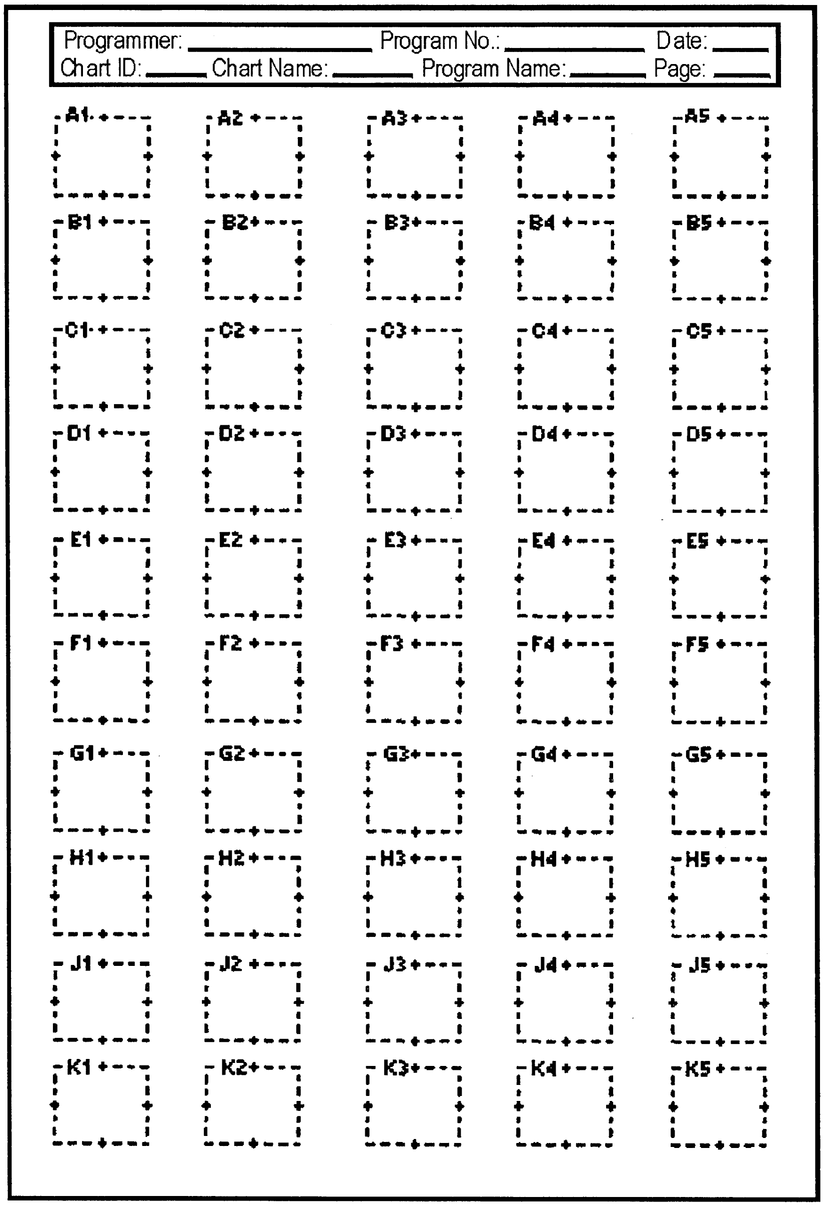

Figure 3-5.—Flowchart worksheet.

Constructing a Flowchart

There is no "best way" to construct a flowchart. There is no way to standardize problem solution. Flowcharting and programming techniques are often unique and conform to the individual's own methods or direction of problem solution.

This section will show an example of developing a programming flowchart. It is not the intent to say this is the best way; rather, it is one way to do it.

By following this text example you should grasp the idea of solving problems through flowchart construction. As you gain experience and familiarity with a computer system, these ideas will serve as a foundation.

To develop a flowchart, you must first know what problem you are to solve. It is then your job to study the problem definition and develop a flowchart to show the logic, steps, and sequence of steps the computer is to execute to solve the problem.

As an example, suppose you have taken a short-term second mortgage on a new home, and you want to determine what your real costs will be, the amount of interest, the amount to be applied to principal, and the final payment at the end of the 3-year loan period.

The first step is to be sure you understand the problem completely—What are the inputs and the outputs and what steps are needed to answer the questions? Even when you are specifying a problem of your own, you will find we don't usually think in small, detailed sequential steps. However, that is exactly how a computer operates, one step after another in a specified order. Therefore, it is necessary for you to think the problem solution through step by step. You might clarify the problem as shown by the Problem Definition in figure 3-6.

PROBLEM DEFINITION

MORTGAGE AMORTIZATION- This program is to determine the monthly amount of interest (A) and amount applied to the principal (P) of the mortgage giving the balance (B) at the end of a thirty-six month period.

INPUT: The monthly payment is to be entered as variable D, the beginning balance of the mortgage is to be entered as variable B, and the annual interest rate is to be entered as variable I. This input is to be entered into the system via the terminal.

OUTPUT: The end result is to be a listing displaying the amount applied to principal and interest and the current loan balance each month, with one final entry showing the final payment on the mortgage.

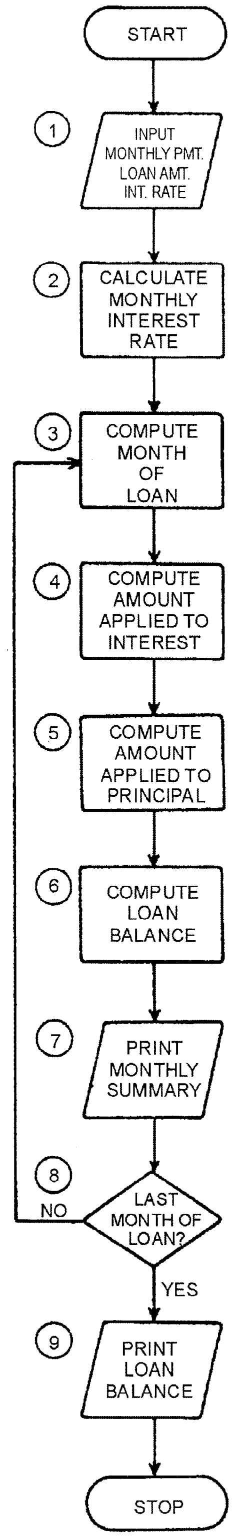

Figure 3-6.—Problem definition and programming flowchart.

After you have this level of narrative problem definition, you are ready to develop a flowchart showing the logic, steps, and sequence of steps you want the computer to execute to solve the problem. A programming flowchart of this problem is also shown in figure 3-6. Study both the problem definition and the flowchart to see their relationship and content.

You now have a plan of what you want the computer to do. The next step is to code a program that can be translated by a computer into a set of instructions it can execute. This step is called program coding.

PROGRAM CODING

It is important to remember program coding is not the first step of programming. Too often we have a tendency to start coding too soon. As we just discussed, a great deal of planning and preparation must be done before sitting down to code the computer instructions to solve a problem. For the example amortization problem (fig. 3-6), we have analyzed the specifications in terms of (1) the output desired; (2) the operations and procedures required to produce the output; and (3) the input data needed. In conjunction with this analysis, we have developed a programming flowchart that outlines the procedures for taking the input data and processing it into usable output. You are now ready to code the instructions that will control the computer during processing. This requires that you know a programming language.

All programming languages, FORTRAN, COBOL, BASIC and so on, are composed of instructions that enable the computer to process a particular application, or perform a particular function.

Instructions

The instruction is the fundamental element in program preparation. Like a sentence, an instruction consists of a subject and a predicate. However, the subject is usually not specifically mentioned; rather it is some implied part of the computer system directed to execute the command that is given. For example, the chief tells a sailor to "dump the trash." The sailor will interpret this instruction correctly even though the subject "you" is omitted. Similarly, if the computer is told to " ADD 1234," the control section may interpret this to mean that the arithmetic-logic section is to add the contents of address 1234 to the contents of the accumulator (a register in which the result of an operation is formed).

In addition to an implied subject, every computer instruction has an explicit predicate consisting of at least two parts. The first part is referred to as the command, or operation; it answers the question "what?" It tells the computer what operation it is to perform; i.e., read, print, input. Each machine has a limited number of built-in operations that it is capable of executing. An operation code is used to communicate the programmer's intent to the computer.

The second specific part of the predicate, known as the operand, names the object of the operation. In general, the operand answers the question "where?" Operands may indicate the following:

1. The location where data to be processed is found.

2. The location where the result of processing is to be stored.

3. The location where the next instruction to be executed is found. (When this type of operand is not specified, the instructions are executed in sequence.)

The number of operands and the structure or format of the instructions vary from one computer to another. However, the operation always comes first in the instruction and is followed by the operand(s). The programmer must prepare instructions according to the format required by the language and the computer to be used.

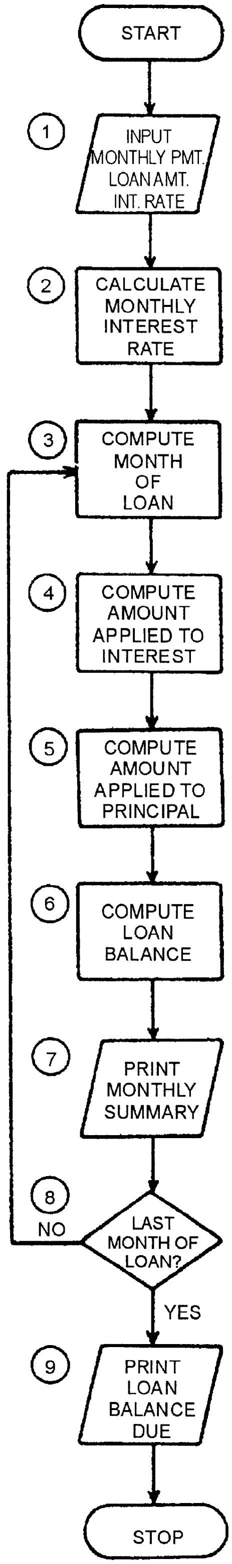
Instruction Set

The number of instructions in a computer's instruction set may range from less than 30 to more than 100. These instructions may be classified into categories by the action they perform such as input/output (I/O), data movement, arithmetic, logic, and transfer of control. Input/output instructions are used to communicate between I/O devices and the central processor. Data movement instructions are used for copying data from one storage location to another and for rearranging and changing of data elements in some prescribed manner.

Arithmetic instructions permit addition, subtraction, multiplication, and division. They are common in all digital computers. Logic instructions allow comparison between variables, or between variables and constants. Transfer of control instructions are of two types, conditional and unconditional. Conditional transfer of control instructions are used to branch or change the sequence of program control, depending on the outcome of the comparison. If the outcome of a comparison is true, control is transferred to a specific statement number. If it proves false, processing continues sequentially through the program. Unconditional transfer of control instructions are used to change the sequence of program control to a specified program statement regardless of any condition.

Coding a Program

Regardless of the language used, there are strict rules the programmer must adhere to with regard to punctuation and statement structure when coding any program. Using the programming flowchart introduced earlier, we have now added a program coded in BASIC to show the relationship of the flowchart to the actual coded instructions (fig. 3-7). Don't worry about complete understanding, just look at the instructions with the flowchart to get an idea of what coded instructions look like.



```
10 PRINT "ENTER MONTHLY PAYMENT, ";
20 PRINT "LOAN AMOUNT, INTEREST RATE"
30 INPUT D,B,I
40 LET R= I/12
50 FOR M = 1 TO 36
60 LET A = B*R
70 LET P = D-A
80 LET B = B-P
90 PRINT M;D;B,P,A
100 NEXT M
110 PRINT "WITH ONE FINAL PAYMENT OF" ,B
120 END
```

Figure 3-7.—Programming flowchart and coded program.

You will have to have specific information about the computer you are to use. It will tell you how the language is implemented on that particular computer, in order to code a program. The computer manufacturers or software designer will provide these specifics in their user's manual. Get a copy of the user's manual and study it before you begin to code. The differences may seem minor to you, but they may prevent your program from running.

Once coding is completed, the program must be debugged and tested before implementation.

Debugging

Errors caused by faulty logic and coding mistakes are referred to as "bugs." Finding and correcting these mistakes and errors that prevent the program from running and producing correct output is called "debugging."

Rarely do complex programs run to completion on the first attempt. Often, time spent debugging and testing equals or exceeds the time spent in program coding. This is particularly true if insufficient time was spent on program definition and logic development. Some common mistakes which cause program bugs are mistakes in coding punctuation, incorrect operation codes, transposed characters, keying errors, and failure to provide a sequence of instructions (a program path) needed to process certain conditions.

To reduce the number of errors, you will want to carefully check the coding sheets before they are keyed into the computer. This process is known as "desk-checking" and should include an examination for program completeness. Typical input data should be manually traced through the program processing paths to identify possible errors. In effect, you will be attempting to play the role of the computer. After you have desk checked the program for accuracy, the program is ready to be assembled or compiled. Assembly and compiler programs prepare your program (source program) to be executed by the computer, and they have error diagnostic features which detect certain types of mistakes in your program. These mistakes must be corrected. Even when an error-free pass of the program through the assembly or compiler program is accomplished, this does not mean your program is perfected. However, it usually means the program is ready for testing.

Testing

Once a program reaches the testing stage, generally, it has proved it will run and produce output. The purpose of testing is to determine that all data can be processed correctly and that the output is correct. The testing process involves processing input test data that will produce known results. The test data should include: (1) typical data, which will test the commonly used program paths; (2) unusual but valid data, which will test the program paths used to process exceptions; (3) incorrect, incomplete, or inappropriate data, which will test the program's error routines. If the program does not pass these tests, more testing is required. You will have to examine the errors and review the coding to make the coding corrections needed. When the program passes these tests, it is ready for computer implementation. Before computer implementation takes place, documentation must be completed.

Documentation

Documentation is a continuous process, beginning with the problem definition. Documentation involves collecting, organizing, storing, and otherwise maintaining a complete record of the programs and other documents associated with the data processing system.

The Navy has established documentation standards to ensure completeness and uniformity for computer system information between commands and between civilian and Navy organizations. SECNAVINST 5233.1 establishes minimum documentation requirements.

A documentation package should include:

1. A definition of the problem. Why was the program written? What were the objectives? Who requested the program, and who approved it? These are the types of questions that should be answered.

2. A description of the system. The system environment (hardware, software, and organization) in which the program functions should be described (including systems flowcharts). General systems specifications outlining the scope of the problem, the form and type of input data to be used, and the form and type of output required should be clearly defined.

3. A description of the program. Programming flowcharts, program listings, program controls, test data, test results, and storage dumps — these and other documents that describe the program and give a historical record of problems and/or changes should be included.

4. Operator instructions. Items that should be included are computer switch settings, loading and unloading procedures, and starting, running, and termination procedures.

Implementation

After the documentation is complete, and the test output is correct, the program is ready for use. If a program is to replace a program in an existing system, it is generally wise to have a period of parallel processing; that is, the job application is processed both by the old program and by the new program. The purpose of this period is to verify processing accuracy and completeness.

Q-16. What is programming?

Q-17. In programming, how many steps are involved in solving a problem on a computer?

Q-18. What is required before you can actually start to write or code a program?

Q-19. In flowcharting, what method is used to represent different operations, data flow, equipment, and so forth?

Q-20. What type of flowchart is constructed by the programmer to represent the sequence of operations the computer is to perform to solve a specific problem?

Q-21. How many tools are used in flowcharting?

Q-22. Is there a "best way" to construct a flowchart?

Q-23. What controls the computer during processing?

Q-24. What is the fundamental element in program preparation?

Q-25. What type of instructions permit addition, subtraction, multiplication, and division?

Q-26. Where is specific information about the computer you are to use contained?

Q-27. How do we refer to errors caused by faulty logic and coding mistakes?

Q-28. What is the purpose of testing a program?

PACKAGED SOFTWARE

Fortunately you don't have to write a program for every problem to be solved. Instead, you can use packaged or off-the-shelf programs that are designed for specific classes of applications. Everyday more and more packaged software (software written by the manufacturer, a software house, or central design agency [CDA]) becomes available for general use. It may be up to you to set up and process a job within the specifications of a packaged program. Let's look at four classes of packaged software you may work with: word processing, data management, spreadsheets, and graphics.

WORD PROCESSING

You can use word processing software for any function that involves text: letters, memos, forms, reports, and so on. At a minimum, it includes routines for creating, editing, storing, retrieving, and printing text. Under the word processing software control, you generally enter the text on the keyboard and it is printed on a display screen as shown in figure 3-8. At that point, you may store it on disk or tape, print it on a printer, or change (edit) it. Using the edit functions you can add or delete words, characters, lines, sentences, or paragraphs. You can rearrange text; for example, move a paragraph or block of information to another place in the same document or even move it to a different document. Word processing is particularly useful for text documents that are repetitive or that require a lot of revisions. It saves a lot of rekeying.

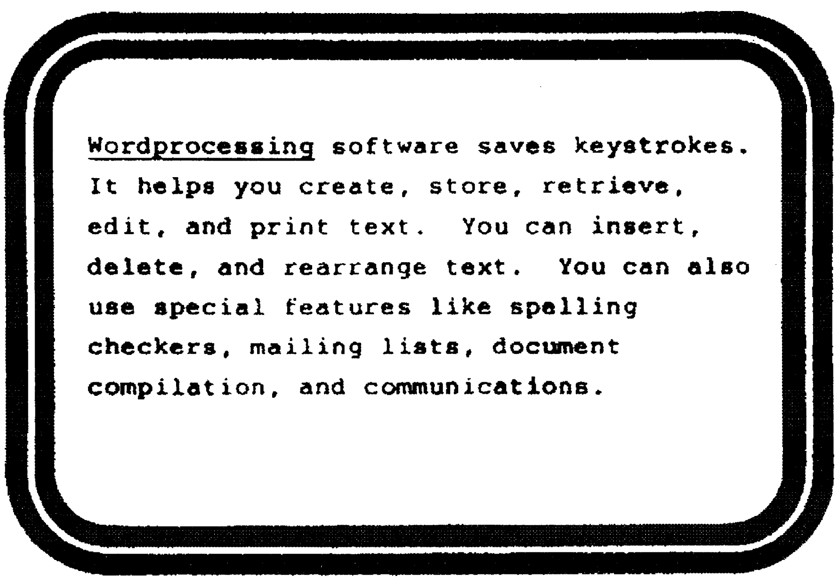


Figure 3-8.—Word processing example.

Other features and software often available with a word processing software package include: spelling checkers, mailing list programs, document compilation programs, and communications programs.

Spelling checker software helps find misspelled words but not misused words. It scans the text matching each word against a dictionary of words. If the word is not found in the dictionary, the system flags the word. You check it. If it is misspelled, you can correct it. You will still have to proofread the document to see that everything was keyed and that the words are used correctly.

Mailing list programs are for maintaining name and address files. They often include a capability to individualize letters and reports by inserting names, words, or phrases to personalize them.

Document compilation programs are useful when you have standard paragraphs of information that you need to combine in different ways for various purposes. For example, you may be answering inquiries or putting together contracts or proposals. Once you select the standard paragraphs you want, you add variable information. This saves both keying and proofreading time.

Communications software and hardware enable you to transmit and receive text on your microcomputer. Many organizations use this capability for electronic mail. In a matter of minutes you can enter and transmit a memo to other commands or to personnel in other locations. You can transmit monthly reports, notices, or any documents prepared on the microcomputer.

DATA MANAGEMENT

Data management software allows you to enter data and then retrieve it in a variety of ways. You define your data fields and set up a display screen with prompts. You enter the data records according to the prompts. Figure 3-9, view A, shows an example. The system writes the records on a disk or tape. Once you have a file keyed and stored, you can retrieve records by a field or several fields or by searching the records for specific data. For example, if you wanted a list of all personnel who reported aboard before January 1988, you could tell the system to search the file and print selected fields of all records that meet that condition. You tell the system what fields to print (that is name, rate, SSN, date reported) and where (what print positions) to print them. At the same time, you can specify in what order you want the records printed. For example, figure 3-9, view B, shows the records printed in alphabetical order by last name. The software also provides routines so you can easily add, delete, and change records.

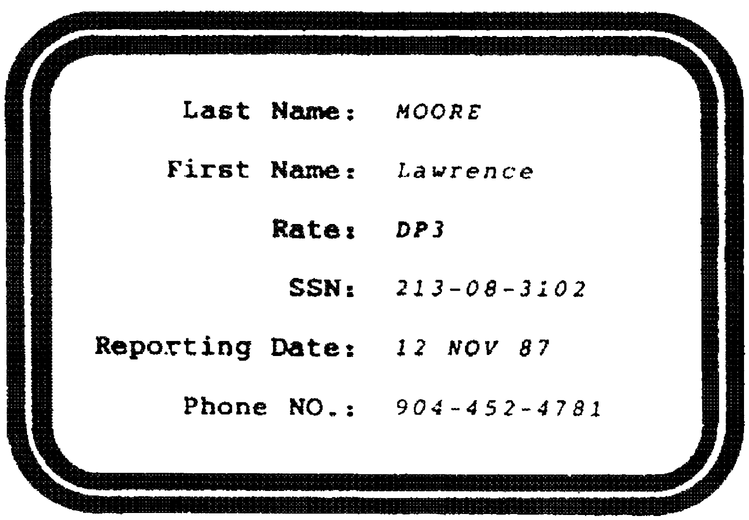

Figure 3-9A.—Data management example. PROMPTS (IN BOLD) AND DATA (IN ITALICS).

RATE	NAME LAST	FIRST	SSN	REPORTING DATE
DS2	FREDERICK	Jan	712-36-4279	5 SEP 87
DP2	HOWARD	Al	123-07-0736	15 DEC 87
DP3	MOORE	Lawrence	213-08-3102	12 NOV 87
:				
ET2	RAY	William	219-47-3261	5 NOV 87
:				

Figure 3-9B.—Data management example. SAMPLE PRINTED REPORT (SORTED BY LAST NAME).

You can also generate reports by specifying what records to use, what fields to print, where to print the fields, and which data fields, if any, need to be combined. For example, your supply officer wants to know the value of the inventory. You can specify that the extended price is to be calculated by multiplying the item quantity by the unit price, and that the extended prices are to be totaled.

INVENTORY VALUE			
ITEM	QUANTITY	UNIT PRICE	EXTENDED PRICE
Swabs	47	1.65	77.55
Brooms	62	2.25	139.50
Foxtails	36	1.85	66.60
TOTAL			283.65

You can also specify the information to be used in report and column headings.

While the data management programs on micros are not as sophisticated as the data base management systems on mainframes and minis, they do provide an extremely useful capability in offices or aboard ship.

SPREADSHEETS

Spreadsheets are tables of rows and columns of numbers. Figure 3-10 shows an example. Spreadsheet processors allow you to set up a table of rows and columns and specify what calculations to perform on the columns. You enter values for the basic information into the appropriate rows and columns. Then the processor performs the calculations. In our example (fig. 3-10), we used a spreadsheet to project magnetic media costs. You enter the item descriptions, column headings, report title, and data for columns 1, 2, and 4, and the software calculates column 3 by adding columns 1 and 2. Then it multiplies column 3 times column 4 and puts the result in column 5. It also subtotals and totals the columns you specify; in this case, columns 1 through 3 and column 5.

MAGNETIC MEDIA REQUIREMENTS
SPREAD SHEET

ITEM	NUMBER TO BE REPLACED (1)	NUMBER FOR EXPANSION (2)	TOTAL NEEDED (3)	COST PER ITEM (4)	TOTAL COST (5)
TAPES	*15*	*30*	**45**	*27.50*	**1237.50**

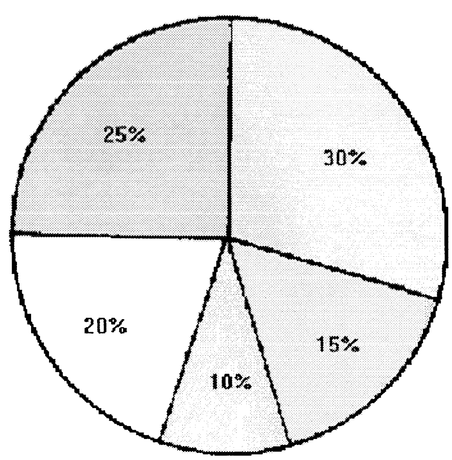
SUBTOTAL	**20**	**80**	**100**		**148.00**
TOTAL	**39**	**115**	**154**		**4535.50**

ITALICS -- DATA YOU ENTER
BOLD -- INFORMATION CALCULATED BY THE PROGRAM

Figure 3-10.—Spreadsheet example.

GRAPHICS

Graphics capability is available on many microcomputers. One use is to produce data displays, like bar charts, pie charts, and graphs. See figure 3-11, view A and view B. On some micros, you can do line drawings; on others you can create sophisticated engineering drawings. High resolution color graphics are also available for specialized applications.



A. PIE CHART

Figure 3-11A.—Graphics examples. PIE CHART.

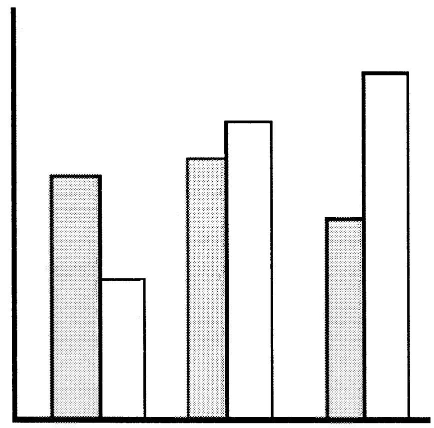


Figure 3-11B.—Graphics examples. BAR CHART.

You cannot use all printers for graphics output. They must be capable of producing graphics and also be compatible with the software. Some character printers can be used for limited graphics. Dot-matrix printers and plotters work well for graphics output. Laser and ink jet printers are also good for both text and graphics.

Q-29. What is packaged software?

Q-30. What are some of the other features and software available with a word processing software package?

Q-31. What software allows you to enter data and then retrieve it in a variety of ways?

Q-32. What are spreadsheets?

Q-33. Are all printers capable of handling graphics output?

SUMMARY

Congratulations you have just finished chapter 3. By now you should be convinced that anyone, with a little study, can understand digital computers. You probably thought when you first started this *NEETS* MODULE that it would get more difficult as your studies progressed. Our objective was to show you that the more you learn, the easier the material is to understand.

OPERATING SYSTEMS are a collection of many programs used by the computer to manage its own resources and operations and to perform commonly used functions like copy, print, and so on.

UTILITY PROGRAMS perform such tasks as sorting, merging, and transferring (copying) data from one input/output device to another: card to tape, tape to tape, tape to disk, and so on.

SORT-MERGE PROGRAMS arrange data records in a predefined sequence or order and are capable of combining two or more ordered files into one file.

REPORT PROGRAM GENERATORS are used to generate programs to print detail and summary reports of data files.

PROGRAMMING LANGUAGES are the means by which human-computer communication is achieved. They are used to write the instructions to tell the computer what to do to solve a given problem.

A **MACHINE LANGUAGE** uses a string of numbers that represent the instruction codes and operand addresses to tell the computer what to do.

SYMBOLIC LANGUAGES improved the program preparation process by substituting letter symbols (mnemonic codes) for basic machine language instruction codes.

A **PROCEDURE ORIENTED LANGUAGE** is a programming language oriented toward a specific class of processing problems. Examples are BASIC, COBOL, and FORTRAN.

PROGRAMMING is the process of planning and coding the computer instructions to solve a problem.

FLOWCHARTING is one method of pictorially representing a procedural (step-by-step) solution to a problem before you actually start to write the computer instructions required to produce the desired results.

PACKAGED SOFTWARE is designed for specific classes of applications. Examples are word processing, spreadsheets, data management, and graphics. These off-the-shelf programs are written by the manufacturer, a software house, or a central design agency.

ANSWERS TO QUESTIONS Q1. THROUGH Q33.

A-1. *The operating system.*

A-2. *Single user/single tasking.*

A-3. *Multiuser/multitasking.*

A-4. *Because, to use applications software, it must be compatible with the operating system.*

A-5. *Some software comes in several versions so it can run under several different operating systems.*

A-6. *Utility programs.*

A-7. *By providing information about files, data fields, and the process to be used.*

A-8. *Sorting.*

A-9. *What data field or fields to sort on.*

A-10. *To generate programs to print detail and summary reports of data files.*

A-11. *Machine.*

A-12. *In the early 1950's.*

A-13. *The development of mnemonic techniques and macroinstructions.*

A-14. *FORTRAN.*

A-15. They require more space in memory and they process data at a slower rate than symbolic languages.

A-16. The process of planning the solution to a problem.

A-17. Four.

A-18. Advance preparation.

A-19. Different shaped symbols.

A-20. A programming flowchart.

A-21. Four.

A-22. No, there isn't a way to standardize problem solution.

A-23. Coded instructions.

A-24. The instruction.

A-25. Arithmetic.

A-26. In the computer manufacturers or software designers user's manual.

A-27. Bugs.

A-28. To determine that all data can be processed correctly and that the output is correct.

A-29. Off-the-shelf programs designed for specific classes of applications.

A-30. Spelling checkers, mailing list programs, document compilation programs, and communications programs.

A-31. Data management.

A-32. They are tables of rows and columns of numbers.

A-33. No.

CHAPTER 4

DATA REPRESENTATION AND COMMUNICATIONS

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to do the following:

1. Explain data and how it is represented.
2. Explain computer coding systems.
3. Define a parity bit and what it is used for.
4. Explain data storage concepts.
5. Describe three storage access methods.
6. Describe networks and data communications.

INTRODUCTION

One of the major problems we face in using a digital computer is communicating with it. We must have one or more ways of getting data into the computer to be processed. You learned in chapter 2 that there are several types of input devices that read data into a computer. But how does one prepare the data to be used as input? How do we convert human-readable documents into a computer-readable form, and what type of input media do we use? If the data is to be used by another computer some distance away, how do we transmit it? Well, as you probably suspect, there are several ways to perform this conversion and transmission process, and that is the chapter of our discussion.

DATA

Data is a general term used to describe raw facts. To put it simply, data is nothing more than a collection of related elements or items, that when properly coded into some type of input medium, can be processed by a computer. Data items might include your service number, your name, your paygrade, or any other fact. Until some meaning has been given to the data, nothing can really be determined about it; therefore, it remains data. When this data has been processed together with other facts, it then has meaning and it becomes information we can understand and properly use.

DATA REPRESENTATION

Data is represented by symbols. Symbols convey meaning only when understood. The symbol itself is not the information, but merely a representation of it. Symbol meaning is one of convention (fig. 4-1). Symbols may convey one meaning to you and me, another meaning to others, and no meaning at all to those that do not know their significance. Data must be reduced to a set of symbols that the computer can read and interpret before there can be any communication with the computer. The first computers were designed to manipulate numbers to solve arithmetic problems. But as you can see in figure 4-1, we create, use, and manipulate many other symbols to represent facts in the world in which we live. We are fortunate that early computer experts soon realized the need to manipulate nonnumerical symbols as well. Manipulating these symbols is possible if an identifying code or coded number is assigned to the symbol to be stored and processed. Thus, the letters in a name such as ALBERT or CAROL can be represented by different codes, as can all special characters, such as #, (,), &, $, @, and yes, even the comma. The data to be represented is called source data.

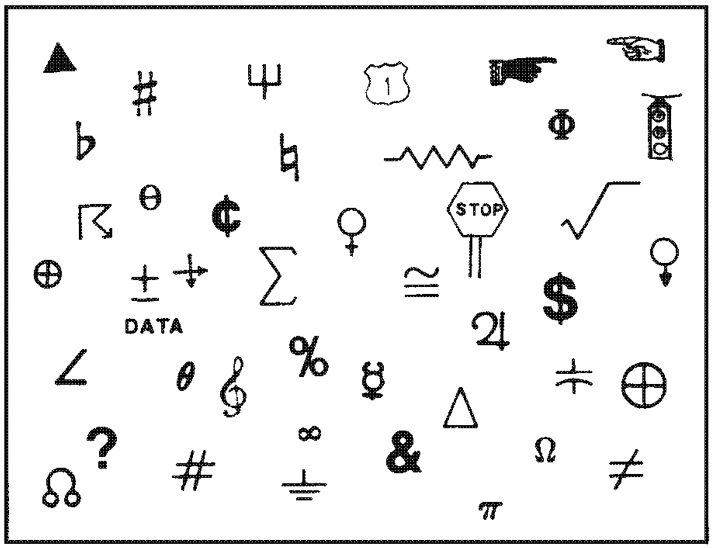

Figure 4-1.—Communications symbols.

SOURCE DATA

Source data or raw data is typically written on some type of paper document, which we refer to as a source document. The data contained on the source document must be converted into a machine-readable form for processing either by direct or indirect means. The data may be entered directly into the computer in its original form; namely right from the source document on which it is recorded by way of magnetic ink characters, optically recognizable characters, or bar code recognition. Or the data on the documents may be entered indirectly on input media, such as punched cards, paper tape, magnetic tape, or magnetic disk. It may also be keyed directly into a computer from a keyboard.

If you look at figure 4-2, you see a list of SERVMART items that have been typed on a preprinted form. To most people this is just another piece of paper; however, to the Storekeeper (SK) it is a source document to be used to provide input data to the computer. In this example, the SERVMART form deals with requisitioning supplies. The form could be sent to the data-entry department to be used as a source document. There the data-entry operator can key the data into or on whatever computer medium is to be used, according to a prescribed format. The data elements are numbered in the order they are to be keyed: (1) document identification, (2) stock number, (3) unit of issue, (4) quantity, and so on. You'll notice we need more than numbers, and that is where coding systems come into play.

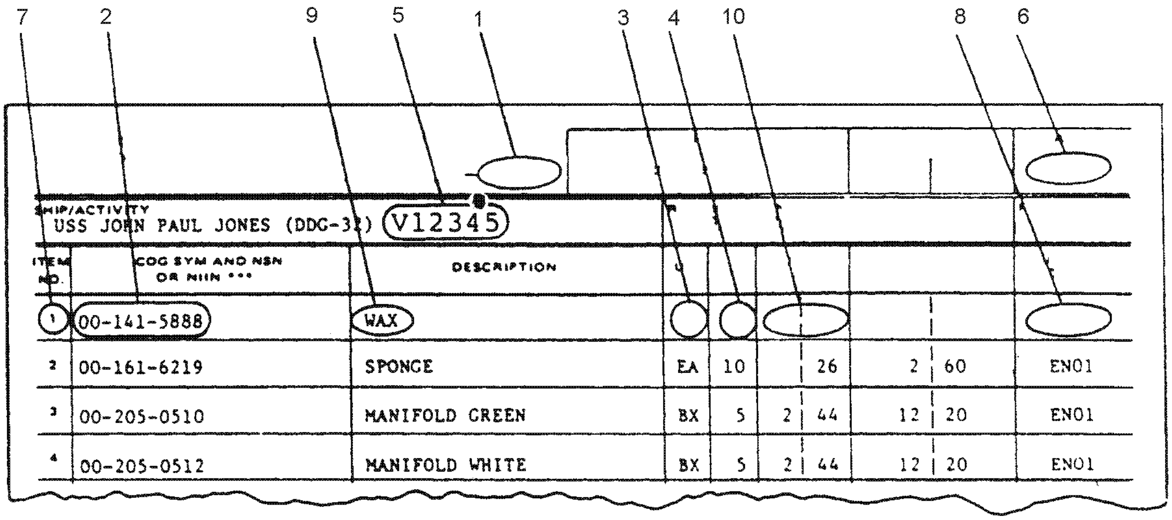

Figure 4-2.—SERVMART shopping list (source document).

Q-1. What is a general term used to describe raw facts?

Q-2. How is data represented?

Q-3. What were the first computers designed to manipulate in order to solve arithmetic problems?

Q-4. By what two means can the data contained on a source document be converted into a machine-readable form for processing?

Q-5. What are some of the types of input media on which data may be indirectly entered?

COMPUTER CODING SYSTEMS

To represent numeric, alphabetic, and special characters in a computer's internal storage and on magnetic media, we must use some sort of coding system. In computers, the code is made up of fixed size groups of binary positions. Each binary position in a group is assigned a specific value; for example 8, 4, 2, or 1. In this way, every character can be represented by a combination of bits that is different from any other combination.

In this section you will learn how the selected coding systems are used to represent data. The coding systems included are Extended Binary Coded Decimal Interchange Code (EBCDIC), and American Standard Code for Information Interchange (ASCII).

EXTENDED BINARY CODED DECIMAL INTERCHANGE CODE (EBCDIC)

Using an 8-bit code, it is possible to represent 256 different characters or bit combinations. This provides a unique code for each decimal value 0 through 9 (for a total of 10), each uppercase and lowercase letter (for a total of 52), and for a variety of special characters. In addition to four numeric bits, four zone bit positions are used in 8-bit code as illustrated in figure 4-3. Each group of the eight bits makes up one alphabetic, numeric, or special character and is called a byte.

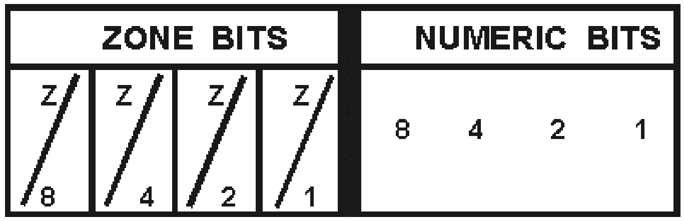

Figure 4-3.—Format for EBCDIC and ASCII codes.

When you look at figure 4-3, you will notice that the four rightmost bits in EBCDIC are assigned values of 8, 4, 2, and 1. The next four bits to the left are called the zone bits. The EBCDIC coding chart for uppercase and lowercase alphabetic characters and for the numeric digits 0 through 9 is shown in figure 4-4, with their hexadecimal equivalents. Hexadecimal is a number system used with some computer systems. It has a base of 16 (0-9 and A-F). A represents 10; B represents 11; C represents 12; D represents 13; E represents 14; and F represents 15. In EBCDIC, the bit pattern 1100 is the zone combination used for the alphabetic characters A through I, 1101 is used for the characters J through R, and 1110 is the zone combination used for characters S through Z. The bit pattern 1111 is the zone combination used when representing decimal digits. For example, the code 11000001 is equivalent to the letter A; the code 11110001 is equivalent to the decimal digit 1. Other zone combinations are used when forming special characters. Not all of the 256 combinations of 8-bit code have been assigned characters. Figure 4-5 illustrates how the characters DP-3 are represented using EBCDIC.

D	P	—	3
1100 0100	1101 0111	0110 0000	1111 0011

Figure 4-5.—DP-3 represented using 8-bit EBCDIC code.

Since one numeric character can be represented and stored using only four bits (8-4-2-1), using an 8-bit code allows the representation of two numeric characters (decimal digits) as illustrated in figure 4-6. Representing two numeric characters in one byte (eight bits) is referred to as packing or packed data. By packing data (numeric characters only) in this way, it allows us to conserve the amount of storage space required, and at the same time, increases processing speed.

DECIMAL VALUE	9	2	7	3
EBCDIC CODE	1001	0010	0111	0011
BIT PLACE VALUES	8421	8421	8421	8421
	BYTE 1		BYTE 1	

Figure 4-6.—Packed data.

AMERICAN STANDARD CODE FOR INFORMATION INTERCHANGE (ASCII)

Another 8-bit code, known as the American Standard Code for Information Interchange (ASCII) (pronounced ASS-KEY), was originally designed as a 7-bit code. Several computer manufacturers cooperated to develop this code for transmitting and processing data. The purpose was to standardize a binary code to give the computer user the capability of using several machines to process data regardless of the manufacturer: IBM, HONEYWELL, UNIVAC, BURROUGHS, and so on. However, since most computers are designed to handle (store and manipulate) 8-bit code, an 8-bit version of ASCII was developed. ASCII is commonly used in the transmission of data through data communications and is used almost exclusively to represent data internally in microcomputers.

The concepts and advantages of ASCII are identical to those of EBCDIC. The important difference between the two coding systems lies in the 8-bit combinations assigned to represent the various alphabetic, numeric, and special characters. When using ASCII 8-bit code, you will notice the selection of bit patterns used in the positions differs from those used in EBCDIC. For example, let's look at the characters DP3 in both EBCDIC and ASCII to see how they compare.

Character	D	P	3
EBCDIC	1100 0100	1101 0111	1111 0011
ASCII	0100 0100	0101 0000	0011 0011

In ASCII, rather than breaking letters into three groups, uppercase letters are assigned codes beginning with hexadecimal value 41 and continuing sequentially through hexadecimal value 5A. Similarly, lowercase letters are assigned hexadecimal values of 61 through 7A. The decimal values 1 through 9 are assigned the zone code 0011 in ASCII rather that 1111 as in EBCDIC. Figure 4-7 is the ASCII coding chart showing uppercase and lowercase alphabetic characters and numeric digits 0 through 9.

ALPHABETIC CHARACTERS

4	0011 0100	3 4	9	0011 1001	3 9

Figure 4-7.—Eight-bit ASCII coding chart (including hexadecimal equivalents).

At this point you should understand how coding systems are used to represent data in both EBCDIC and ASCII. Regardless of what coding system is used, each character will have an additional bit called a check bit or parity bit.

PARITY BIT

This additional check or parity bit in each storage location is used to detect errors in the circuitry. Therefore, a computer that uses an 8-bit code, such as EBCDIC or ASCII, will have a ninth bit for parity checking.

The parity bit (also called a check bit, the C position in a code) provides an internal means for checking the validity, the correctness, of code construction. That is, the total number of bits in a character, including the parity bit, must always be odd or always be even, depending upon whether the particular computer system or device you are using is odd or even parity. Therefore, the coding is said to be in either odd or even parity code, and the test for bit count is called a parity check.

Now, let's talk about bits and bytes, primary storage, and storage capacities; or, to put it another way, the capacity of a storage location. Sit back, keep your memory cycling, and we will explain the ways data may be stored and retrieved inside the computer.

Q-6. What does the acronym EBCDIC stand for?

Q-7. By using an 8-bit code, how many characters or bit combinations can be represented?

Q-8. What is the base of a hexadecimal number system?

Q-9. What term is used for the representation of two numeric characters stored in eight bits?

Q-10. What does the acronym ASCII mean?

Q-11. What was the purpose of several computer manufacturers cooperating to develop ASCII code for processing and transmitting data?

Q-12. Are there any differences in the concepts and advantages of ASCII and EBCDIC?

Q-13. How is the parity bit in each storage location used?

Q-14. A computer or device that uses 8-bit ASCII or EBCDIC will use how many bits to store each character?

DATA STORAGE CONCEPTS

You learned in chapter 2 that a computer's primary storage area is divided into four areas, each serving a specific purpose. The input storage area accepts and holds input data to be processed. The working storage area holds intermediate processing results. The output storage area holds the final processing results. The program storage area holds the processing instructions (the program). You also learned that these separate areas do not have built-in physical boundaries, rather the boundaries are determined by the individual programs being used.

You also may recall in chapter 2, we talked about the different types of primary storage used in computers and how they differ from one another. Some were magnetic in nature, such as magnetic core storage; others were electronic, such as semiconductor and bubble storage. For purposes of simplicity, we have selected magnetic core storage to show you how data is represented and stored in the computer's primary memory.

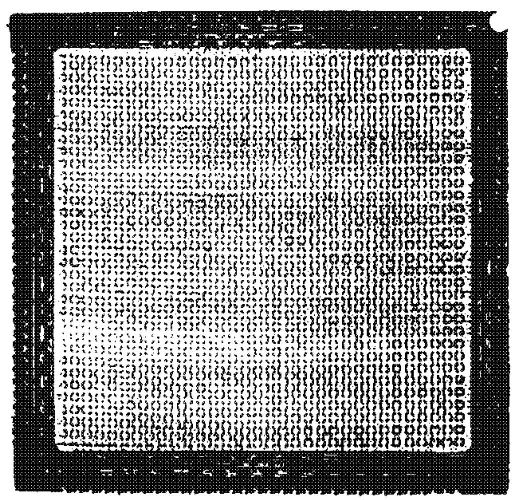
BITS AND BYTES

A bit is a single binary digit. It represents the smallest unit of data just like the good old American penny). However, computers usually do not operate on single bits, rather they store and manipulate a fixed number of bits. Most often, the smallest unit or number of bits a computer works with is eight bits. These eight bits make up a byte. You just learned that both EBCDIC and ASCII codes use eight bits (excluding the parity bit), and that eight bits represent a single character, such as the letter A or the number 7. Thus, the computer can store and manipulate an individual byte (a single character) or a group of bytes (several characters, a word) at a time. These individual bytes, or groups of bytes, form the basic unit of memory.

Primary storage capacities are usually specified in number of bytes. The symbol "K" is used whenever we refer to the size of memory, especially when the memory is quite large. The symbol K is equal to 1,024 units or positions of storage. Therefore, if a computer has 512K bytes (not bits) of primary storage, then it can hold 512 × 1,024 or 524,288 characters (bytes) of data in its memory.

MAGNETIC CORE STORAGE

In primary storage, many magnetic cores are strung together on a screen of wire to form what is called a core plane (fig. 4-8, view A). As you may know, each core can store one binary bit (0 or 1) of data. A core is magnetized by current flowing through the wires on which the core is strung. Hence, a core magnetized in one direction represents a binary 0, and when magnetized in the opposite direction, a binary 1. It is the direction that the core is magnetized that determines whether it contains a binary 0 or a binary 1 (refer to fig. 4-8, view B). These core planes look very much like small window screens and are arranged vertically to represent data as shown in figure 4-8, view C. In looking at this figure, you will notice that nine planes are needed to code in 8-bit EBCDIC. The ninth plane provides for a parity (check) bit. Figure 4-8, view C, shows DP-3 in EBCDIC code, even parity.



A. ONE OF MANY CORE PLANES THAT MAKE UP PRIMARY STORAGE.

Figure 4-8A.—Core storage with DP-3 represented using 8-bit EBCD1C code.

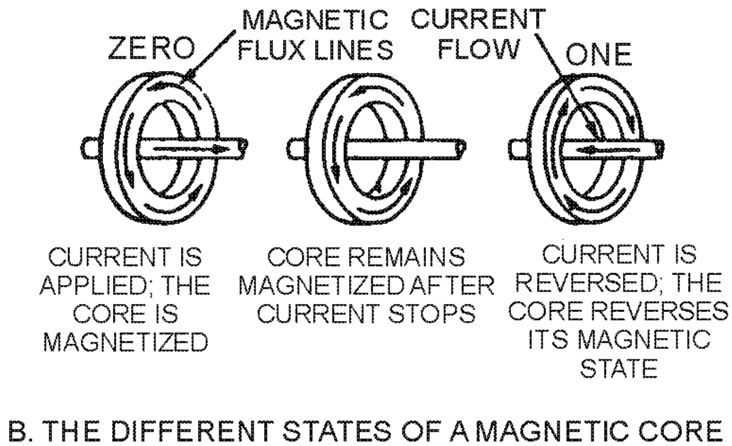


Figure 4-8B.—Core storage with DP-3 represented using 8-bit EBCD1C code.

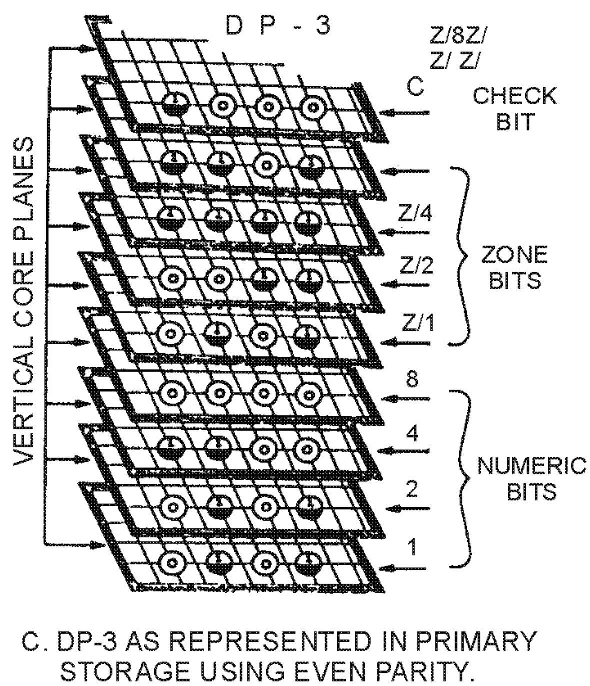

Figure 4-8C.—Core storage with DP-3 represented using 8-bit EBCD1C code.

STORAGE CAPACITY AND ADDRESSES

The storage capacity of an address is designed and built into the computer by the manufacturer. Over the years several different design approaches to partition primary storage have been used. With this in mind, let's take a look at some of the ways primary storage is partitioned into addresses.

One way to design or organize the primary storage section is to store a fixed number of characters (bytes) at each address location. We can then reference these characters as a single entity called a word, as illustrated in figure 4-9, view A. The name CHARLIE (address location 400) or the amount he is paid, in this case $69.00 (address location 401), are each treated as a single word. Computers that are built to retrieve, manipulate, and store a fixed number of characters in each address are said to be word-oriented, word-addressable machines, or fixed-word-length computers.

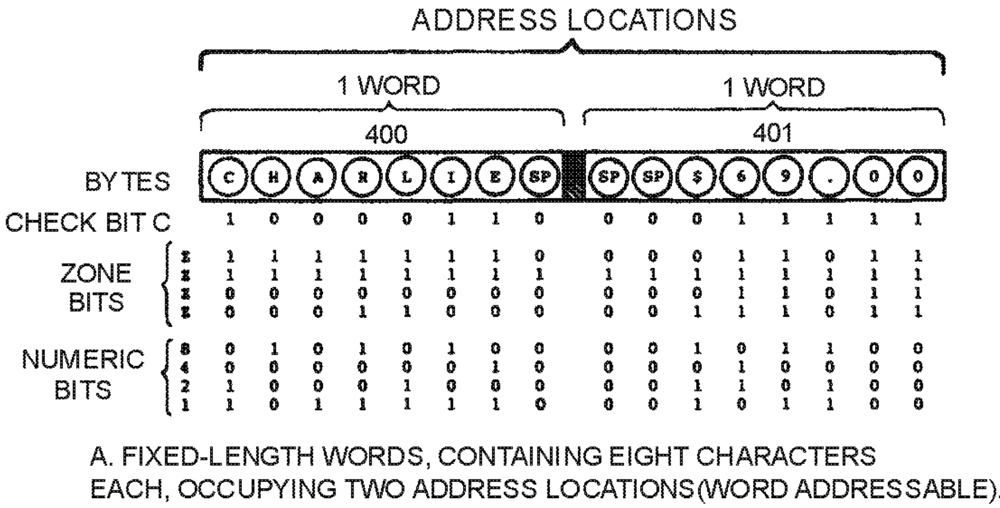

Figure 4-9A.—Fixed-word-length vs variable-word-length storage. FIXED-LENGTH WORDS, CONTAINING EIGHT CHARACTERS EACH, OCCUPYING TWO ADDRESS LOCATIONS (WORD ADDRESSABLE).

Another way to design the primary storage section is to store a single character, such as the letter L or the number 8, in each address location. An address is assigned to each location in storage. Computers designed in this way are said to be character-oriented or character addressable. We also call them variable-word-length computers. Therefore, the name CHARLIE (fig. 4-9, view B) now requires seven address locations (300 through 306), while amount paid ($69.00) occupies six address locations (307 through 312).

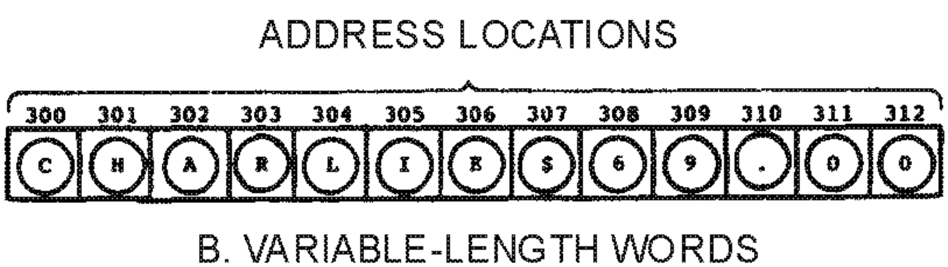

Figure 4-9B.—Fixed-word-length vs variable-word-length storage. VARIABLE-LENGTH WORDS (CHARACTER ADDRESSABLE).

Whether a computer addresses a group of bytes as a word or addresses each byte individually is a function of the circuitry. Both designs have advantages and disadvantages. Variable-word-length computers make the most efficient use of available storage space, since a character can be placed in every storage location. In a fixed-word-length computer, storage space may be wasted. For example, if the storage capacity in each address of a fixed-word-length computer is eight bytes, and some of the data elements to be stored contain only three or four characters, then many of the storage positions in each word are not being used.

Fixed-word-length computers have faster calculating speeds. They can add two data words in a single operation. This is not so with character-addressable computers. Here, only one digit (byte) in each number can be added during a single machine operation. Thus, eight steps are required to complete the calculation.

The larger mainframe computers (super-computers like the CRAY-1 and CYBER 205) use only fixed-word-length storage. Most microcomputers use the variable-word-length approach allowing them to operate on one character at a time. Somewhere in between these two extremes are the dozens of existing minicomputer and mainframe models that have what is called built-in flexibility.

These flexible computers are byte-oriented but can operate in either a fixed- or variable-word-length mode through the use of proper program instructions. Let's take a look at how these flexible computers operate in a variable- and fixed-word-length environment.

Working in a variable-word-length environment, each address holds one alphanumeric character as shown in figure 4-9, view B. Since a byte usually represents a single alphanumeric character, unless you are using packed decimal, a flexible computer is often said to be byte-addressable. Don't become confused; the terms character-addressable, character-oriented, and byte-addressable all have the same meaning. By using the appropriate program instructions, a programmer can retrieve a stored data element by identifying the address of the first character (say position 300 as in fig. 4-9, view B) and specifying the number of address locations to be included in the word. In this case there are seven, positions 300 through 306.

When a flexible computer is working in a fixed-word-length environment, each address identifies a group of bytes that can be operated on as a unit. This processing method helps to achieve faster calculating speeds. A programmer can use program instructions to cause the computer to automatically retrieve, manipulate, and store, as a unit, a fixed word of say, two, four, or eight bytes of data in one machine operation by identifying the address of the first character of data. At the same time all remaining bytes are acted upon as a unit moving from left to right. Figure 4-10 illustrates the different word lengths possible with many byte-addressable computers. They are half-word (2 bytes), full-word (4 bytes), and double-word (8 bytes).

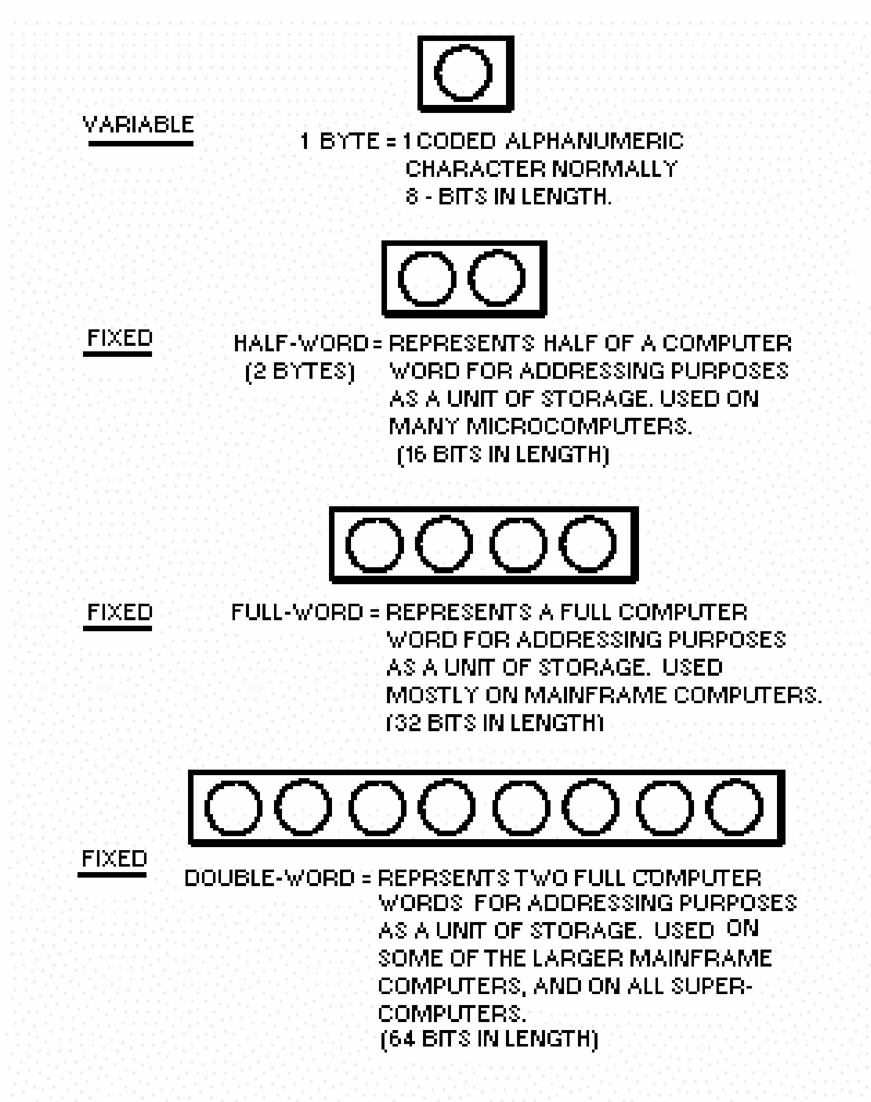

Figure 4-10.—Word lengths used on flexible byte-addressable computers.

By now, you should have a good idea of how primary storage locations are identified by their storage addresses, how these addressable storage locations are used, and how the storage capacity at an address can vary depending on the design of the computer.

Now, let's go one step further, to see how these bits and bytes are represented (coded) on some of the more common secondary storage media.

SECONDARY STORAGE DATA ORGANIZATION

Remember, secondary storage devices (also called auxiliary or mass storage devices) are those devices which are not part of the central processing unit (cpu). They include: external core; semiconductor, thin film, and bubble memories; punched cards; paper tape; and several different types of mass storage, such as magnetic tape, disk, and drum.

You already know it takes a certain number of bits to make one byte (normally eight), and when bytes are grouped together at a single address they make up a word in the computer's memory. When data is recorded on some type of magnetic storage medium, such as disk or tape, it is normally organized by bits, characters (bytes), fields, records, and files (fig. 4-11). The following definitions should help you understand the relationship between bits, characters, bytes, words, fields, records, and files.

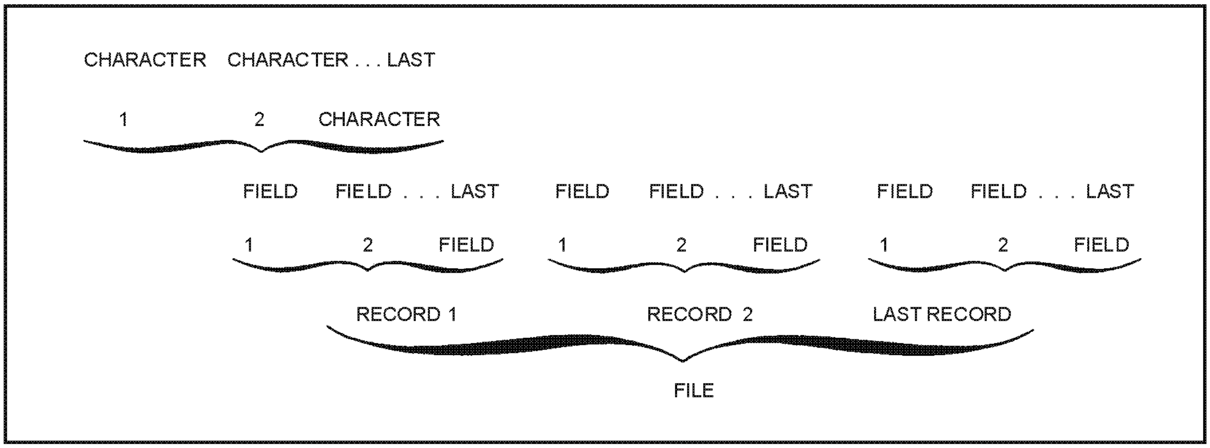

Figure 4-11.—Data organization.

BIT—The smallest unit of data; it represents one binary digit (0 or 1).

CHARACTER (BYTE)—A group of related bits (usually eight) that make up a single character-letter, number, or special character.

WORD—A group of related bytes that are treated as a single addressable unit or entity in memory.

FIELD—One or more related characters that are treated as a unit of information. A field (also referred to as a data item) may be alphabetic, numeric, or alphanumeric, and may be either fixed or variable in length. For example, your social security number (SSN) is of a fixed length; that is, it's always 9 positions in length. Whereas, names are variable length because they may be from 2 to 25 positions in length.

RECORD—A group of related fields, all pertaining to the same subject; a person, a thing, or an event. For example, your payroll record (LES statement) might include fields for your name, amount paid, taxes withheld, earned leave, and any allotments you might have. On the other hand, a supply inventory record might consist of fields containing stock number, the name of the item, its unit price, the quantity on hand, and its bin location.

FILE—A collection of related records, such as the payroll or supply inventory records. Normally, all records within the file are in the same format.

When processing data, we think in terms of data files. For example, to process a parts inventory, you would need the master parts inventory file and the file that contains up-to-date information on each part that has been issued. The master parts inventory file would have a record for every part in the inventory. The update file, parts issued file, would have a record for each part issued. You would use a program to read the records on the parts issued file and update the matching records on the master parts inventory file. Depending on whether the data is stored on magnetic tape or disk or in internal storage, the program would use different methods to access storage to obtain the data. In the next section you'll learn about storage access methods.

Q-15. What area in the computer's primary storage area holds the processing instructions (the program)?

Q-16. How are the boundaries determined for the separate areas of the computer's primary storage area?

Q-17. What is a bit?

Q-18. How many bits make up a byte?

Q-19. Primary storage capacities are usually specified in what unit of measure?

Q-20. How are core planes formed?

Q-21. Where are core planes used?

Q-22. Who designs and builds the storage capacity of an address into a computer?

Q-23. What is another name for computers designed to be character-oriented or character-addressable?

Q-24. Which computer has the faster calculating speeds, the variable-word-length or the fixed-word-length?

Q-25. What is the normal organization of data recorded on magnetic storage media?

Q-26. What is a file?

STORAGE ACCESS METHODS

How data files are stored in secondary storage varies with the types of media and devices you are using. Data files may be stored on or in sequential-access storage, direct-access storage, or random-access storage.

SEQUENTIAL-ACCESS STORAGE

Punched cards, paper tape, and magnetic tape are examples of sequential-access storage media. When operating in a sequential environment, a particular record can be read only by first reading all the records that come before it in the file. When you store a file on tape, the 125th record cannot be read until the 124 records in front of it are read. The records are read in sequence. You cannot read just any record at random. This is also true when reading punched cards or paper tape.

DIRECT-ACCESS STORAGE

Direct-access storage allows you to access the 125th record without first having to read the 124 records in front of it. Magnetic disks and drums are examples of direct-access storage media. Data can be obtained quickly from anywhere on the media. However, the amount of time it takes to access a record is dependent to some extent on the mechanical process involved. It is usually necessary to scan some (but not all) of the preceding data.

RANDOM-ACCESS STORAGE

Random-access storage media refers to magnetic core, semiconductor, thin film, and bubble storage. Here, a given item of data can be selected from anywhere in storage without having to scan any preceding items. And, the access time is independent of the storage location.

Q-27. Punched cards, paper tape, and magnetic tape use what storage access method?

Q-28. What kind of storage allows you to access the 125th record without having to read the 124 records in front of it?

Q-29. Random-access storage media refers to what types of storage?

NETWORKS

A network can be defined as any system composed of one or more computers and terminals; however, most are composed of multiple terminals and computers. In this section you will learn how this allows dissimilar computers to work together as a team.

LOCAL AREA NETWORKS (LANs)

In local area networks (LANs), various machines are linked together within a building or adjacent buildings. Figure 4-12 shows an example of a LAN. A LAN allows dissimilar machines to exchange information within one universal system. With the ability to communicate, the dissimilar machines act as a team. The information that exists in one system can be reused without being reentered via keyboard or disk into another separate system. A universal system for the integration and exchange of information is connected to all input devices. The entire system is usually housed within the same building or the same geographic area. A local area network is made up of a communications facility (for example, a coaxial cable, such as that used for cable television) and interface units creating a link for the computers and terminals to the communications facility. Two designs can be used: broadband or baseband.

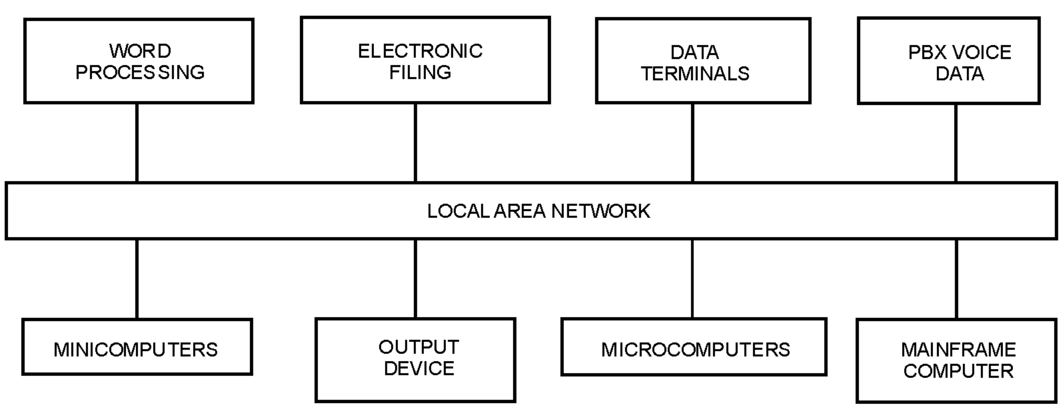

Figure 4-12.—Local area network system.

A baseband communications channel uses the basic frequency band of radio waves and a coaxial cable. This coaxial cable has one channel, which is like a party line. Only two machines can use this cable at one time, even though many have the channel available, but there is no central switching unit to route traffic over the network.

A more expensive channel, called a broadband communications channel, can handle more advanced applications. This includes transmission of voice as well as data and text. Because of the use of a controller to route traffic for a large number of simultaneous users, the users are able to share one of the many individual channels of the system.

WIDE AREA NETWORKS

Wide area networks provide for global connections and are sometimes referred to as global networks. Organizations are able to send information from city to city, across the nation, and to other countries throughout the world, through the expansion of local area networks into larger network configurations. Combinations of telephone lines, microwave radio links, and satellites are used by these larger telecommunications networks to send information. In 1965, the first successful communications satellite for business applications was launched. It was not the only try, it was preceded by many more primitive satellites. With the launching of larger and more complex satellites, the size and complexity of earth stations have been shrinking. Since satellite services' costs have been steadily decreasing, it is becoming more cost effective to employ them for business-type uses.

MODEMS

Since both signals and data can be transmitted and received through cables (communications lines), we refer to them as input/output channels. And when we transmit data directly to a computer over long distances, it becomes necessary to add two other devices, one at each end of the communications line. These devices are called modems (fig. 4-13). The word modem is an acronym for modulator/ demodulator (combines first syllable of each word). A modem converts the digital signal produced by your terminal or the computer to an audio signal suitable for transmission over the communications line. The modem at the other end of the line converts the audio signal back to a digital signal before it is supplied to the computers or your terminal. If this conversion were not carried out, the digital signal would degenerate during transmission and become garbled.

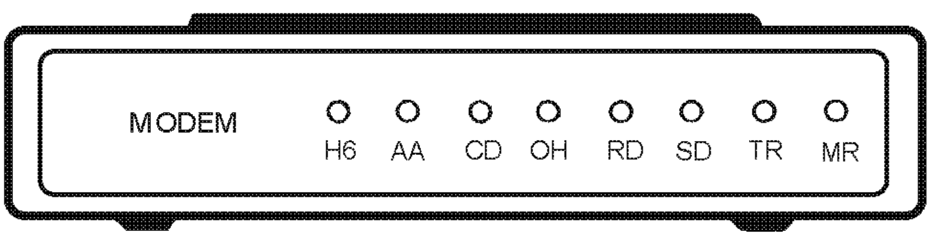

Figure 4-13.—Modem.

The physical link or medium that is used to carry (or transmit) data from one location to another is a communications channel. It allows remotely located input/output devices to communicate directly with the computer's central processing unit (cpu). Telephone lines (often referred to as land lines) are a frequently used type of communications channel.

In a simple data communications system, terminals and other remote I/O devices are linked directly to one or more cpu's to allow users to enter data and programs and receive output information. Interface elements (those devices that serve to interconnect), such as modems are used to bridge and control the different data communications environments. Modems are used to permit the system to switch back and forth from computer digital data to analog signals that can be transmitted over communications lines.

A modem never knows exactly when to expect data; therefore, it must be given some type of signal warning that data is about to be transmitted. This gives the modem time to get itself aligned and in synchronization with the incoming signal. Special characters, known as message characters, provide this warning and are placed in front of and behind the data to mark the beginning and ending of the message. Two methods are used: asynchronous and synchronous.

With asynchronous transmission, each character of data must be surrounded by message characters. As a result, more total bits must be transmitted (transferred) than would be necessary if the synchronous method were used.

With synchronous transmission, only a single set of start and stop message characters is needed per block of data, thus allowing more characters to be transmitted per second. As you can see, synchronous transmission is more efficient and faster. However, it has the disadvantage of requiring a more complex and expensive modem than does asynchronous transmission.

You should be aware that whenever data is transferred between devices, it also involves an exchange of prearranged signals. This is known as handshaking. These signals, in combination with a prearranged pattern of message characters, define the rules for exchanging data over a communications line. The exact rules depend upon each individual computer manufacturer, the telephone company, and the related devices (the modems) that make up the computer system. Protocol is the term used for the specific set of rules that govern handshaking and message characters.

In the system illustrated in figure 4-14, data to be sent to the main computer's cpu is entered through a remote online user terminal (far left). As the data is keyed, it is keyed in digital form and sent to a nearby modem to be converted into an analog signal suitable for transmission. This converted data is then transmitted over the telephone (or land) lines to another modem, that is located near the main computer system's cpu. The data, now in digital form, can be sent directly to the cpu for processing. The same route is followed when information is sent from the cpu back to the remote terminal.

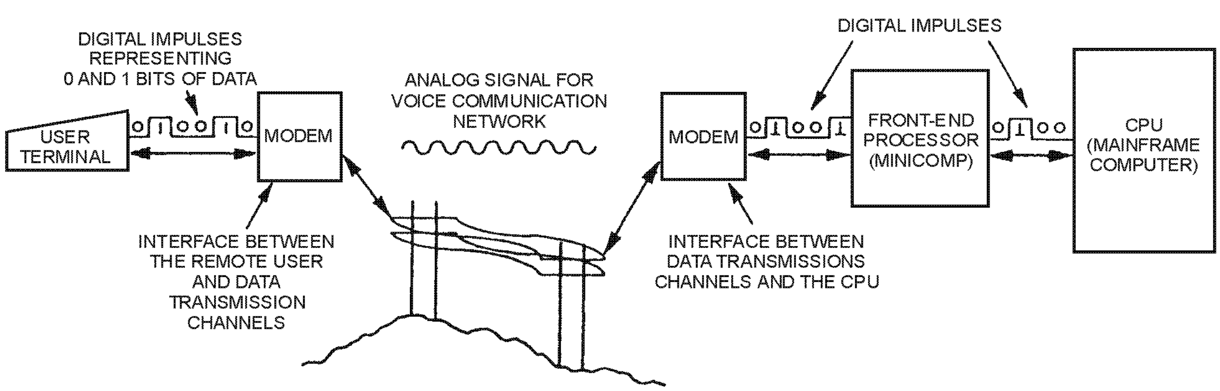

Figure 4-14.—Modems used in network system.

Data communications and networks expand our use of computer technology by providing a means for computers and other machines to talk to each other.

Q-30. Any system composed of one or more computers and terminals can be defined as what?

Q-31. A network system allows dissimilar machines to do what within one universal system?

Q-32. What does the make-up of a local area network consist of?

Q-33. How many designs of local area networks are there that can be used?

Q-34. What are the different designs of local area networks called?

Q-35. What is a baseband communication channel like?

Q-36. What do wide area networks provide for?

Q-37. Where does the word modem come from?

Q-38. What are interface elements?

Q-39. How does a modem know when to expect data?

Q-40. Whenever data is transferred between devices, it involves the exchange of prearranged signals; what is this process called?

SUMMARY

Congratulations! You have just finished the last chapter in *Introduction to Digital Computers*. In this chapter you learned about many things that were mentioned in other chapters, without a detailed explanation. This was done intentionally, as some of the subjects would have been too difficult and hard to understand without background knowledge. Through your study of chapters 1, 2, and 3, you gained enough knowledge to understand chapter 4. This chapter should have answered a lot of questions for you and made certain subjects more clear.

DATA is a general term used to describe raw facts like your service number, name, and paygrade.

SOURCE DATA is raw data typically written on some type of paper document.

DATA REPRESENTATION is accomplished by the use of symbols. The symbol itself is not the information, but merely a representation of it. Symbols convey meaning only when understood. In computers, symbols are represented by CODES.

COMPUTER CODING SYSTEMS are used to represent numeric, alphabetic, and special characters in computer storage and on magnetic media.

EXTENDED BINARY CODED DECIMAL INTERCHANGE CODE (EBCDIC) is an 8-bit code used in computers to represent numbers, letters, and special characters.

AMERICAN STANDARD CODE FOR INFORMATION INTERCHANGE (ASCII) is another 8-bit code developed to standardize a binary code to give the computer user the capability of using several machines to process data regardless of the manufacturer.

A **PARITY (CHECK) BIT** is used to detect errors in computer circuitry.

MAGNETIC CORE STORAGE is used as primary storage in some computers.

PRIMARY STORAGE CAPACITY AND ADDRESSES are designed and built into the computer by the manufacturer.

Computers may be **WORD-ADDRESSABLE, CHARACTER-ADDRESSABLE**, or **FLEXIBLE**.

Data in **SECONDARY STORAGE** like disk or tape is normally organized by bits, characters (bytes), fields, records, and files.

STORAGE ACCESS METHODS vary with the types of media and devices you are using.

SEQUENTIAL-ACCESS STORAGE is associated with punched cards, paper tape, and magnetic tape.

DIRECT-ACCESS STORAGE is obtained by using magnetic disks and drums.

RANDOM-ACCESS STORAGE refers to magnetic core, semiconductor, thin film, and bubble storage.

A **NETWORK** is any system composed of one or more computers and terminals; however, most are composed of multiple terminals and computers.

LOCAL AREA NETWORKS (LANs) allow dissimilar machines to exchange information within one universal system within a building or small geographic area.

WIDE AREA NETWORKS provide for global connections and are sometimes referred to as global networks.

A **MODEM** converts the digital signal produced by your terminal or the computer to an audio signal suitable for transmission over a communications line. It also converts the audio signal back to a digital signal before it is supplied to your terminal or computer.

ANSWERS TO QUESTIONS Q1. THROUGH Q40.

A-1. Data.

A-2. By symbols.

A-3. Numbers.

A-4. By either direct or indirect means.

A-5. Punched cards, paper tape, magnetic tape, or magnetic disk.

A-6. Extended Binary Coded Decimal Interchange Code.

A-7. 256.

A-8. 16.

A-9. Packing or packed data.

A-10. American Standard Code for Information Interchange.

A-11. To standardize a binary code to give the computer user the capability of using several machines to process data regardless of the manufacturer.

A-12. No, they are identical.

A-13. To detect errors in the circuitry.

A-14. Nine.

A-15. Program storage area.

A-16. By the individual programs being used.

A-17. A single binary digit.

A-18. Eight.

A-19. Number of bytes.

A-20. Magnetic cores are strung together on a screen of wire.

A-21. In primary storage.

A-22. The manufacturer.

A-23. Variable-word-length or byte-addressable.

A-24. Fixed-word-length.

A-25. By bits, characters (bytes), fields, records, and files.

A-26. A collection of related records.

A-27. Sequential-access.

A-28. Direct-access storage.

A-29. Magnetic core, semiconductor, thin film, and bubble.

A-30. A network.

A-31. Exchange information.

A-32. A communications facility and interface units.

A-33. Two.

A-34. Broadband and baseband.

A-35. A party line.

A-36. Global connections.

A-37. It is an acronym for modulator/demodulator.

A-38. Those devices that serve to interconnect.

A-39. It is given a signal warning that data is about to be transmitted.

A-40. Handshaking.

APPENDIX I

GLOSSARY

ACCESS TIME—The amount of time between the time a request for data from a storage device is made and the time the data is delivered.

ADA—A high-level programming language designed by the Department of Defense.

ALPHAMERIC (ALPHANUMERIC) CHARACTER SET—The set of characters that includes letters, numbers, and special characters.

ANALOG COMPUTER—A computer that solves problems using continuous data from physical quantities like voltage or temperature.

APPLICATION (PROGRAMS) SOFTWARE—Programs written to solve user problems.

ARITHMETIC-LOGIC UNIT—The part of the cpu that contains the logic capability and performs all the arithmetic functions (addition, subtraction, multiplication, and division).

ARTIFICIAL INTELLIGENCE—The capability of a machine to perform human-like intelligence functions, such as learning, adapting, reasoning, and self-correction.

ASCII (American Standard Code for Information Interchange)—A standardized 8-bit code (originally a 7-bit code) designed for transmitting and processing data.

ASSEMBLER—A computer program that translates source programs written in assembly language into machine language (object) programs.

ASSEMBLY LANGUAGE—A low-level, machine-oriented programming language in which each instruction (written as a mnemonic) translates into a single machine language (computer) instruction.

AUTOMATIC DATA PROCESSING (ADP)—A general term used to define a system for automatically performing a series of data processing functions by means of machines using mechanical, electromechanical, and electronic circuitry.

AUXILIARY EQUIPMENT—The peripheral equipment or devices that may or may not be in direct communication with the central processing unit of a computer.

AUXILIARY STORAGE—See storage, secondary.

BACKUP FILE—A copy of a program or data file to be used in the event something happens to the original.

BASIC (Beginners All Purpose Symbolic Instruction Code)—A high-level, general-purpose programming language primarily used on microcomputers. See NAVEDTRA 10079, *Introduction to Programming in BASIC*.

BAUD—A unit for measuring data transmission speed. For practical purposes, it is now used interchangeably with bits per second as the unit of measure of data flow.

BINARY—Two values (0 or 1) or states (ON or OFF); the number system used in computers.

BIT—An abbreviation for binary digit; the smallest unit of data, either a 0 or 1.

BLOCKED RECORDS—One or more logical records grouped and treated as a unit (physical record or block) for input/output processing.

BLOCKING FACTOR—The number of records stored in a record block.

BOOT OR BOOTSTRAP—(1) A set of instructions that causes additional instructions to be loaded until the complete computer program is in storage. (2) A technique or device designed to bring itself into a desired state by means of its own action; e.g., a machine routine whose first few instructions are sufficient to bring the rest of itself into the computer from an input device. (3) That part of a computer program used to establish another version of the computer program.

BUG—A mistake in a program.

BYTE—A group of bits next to each other that is considered a unit; for example an 8-bit byte.

CENTRAL PROCESSING UNIT (cpu)—The part of the computer hardware that directs the sequence of operations, interprets the coded instructions, performs arithmetic and logical operations, and initiates the proper commands to the computer circuits for execution. It controls the computer operation as directed by the program it is executing.

CHARACTER—One symbol; for example, A, Z, a, z, 0, 1, 9, !, ".

CHIP—A small piece of silicon impregnated with impurities in such a way as to form transistors, diodes, and resistors. Electrical paths are formed on the silicon by depositing thin layers of aluminum or gold.

COBOL (COmmon Business Oriented Language)—A high-level programming language designed for business-type applications.

COMPATIBLE SOFTWARE—Programs that can be run on more than one type of computer. These programs come in several different versions so they can be run under several different operating systems.

COMPILER—A program that translates source programs written in a high-level programming language (for example COBOL or FORTRAN) into machine language.

COMPUTER—A programmable electronic device that can store, retrieve, and process data.

COMPUTER OPERATOR—The person who sets up and operates the computer system.

COMPUTER PROGRAMMER—A person who designs, writes, tests, debugs, and documents programs.

COMPUTER SYSTEM—The cpu (mainframe) with its console, input, and output devices, and secondary (auxiliary) storage devices.

COMPUTER USERS—See users.

COMPUTER WORD—See word, computer.

CONSOLE—The unit of the computer used by the computer operator to communicate with and control the computer system.

CONTROL SECTION—The part of the cpu that directs the flow of operations and data, maintains order in the computer, and initiates execution of the instructions.

CRT (Cathode-Ray Tube) TERMINAL—A computer terminal that displays its output on a television-like screen that may be black and white or color.

CURSOR—A pointer (a dot of light) on a crt screen to let you know the next position in which data will be entered. By depressing cursor control keys, the operator can move the cursor from line to line and from character to character.

CUSTOM SOFTWARE—Programs designed and written to the specifications of a user or an organization.

DATA—Facts represented by numbers, letters, or symbols to which meaning is or can be assigned.

DATA BASE—A structured collection of data that can be extracted, organized, and manipulated by a program.

DATA COMMUNICATIONS—The means by which data is transmitted electronically from one location to another over a communications channel.

DATA ELEMENT—One item of information; the smallest unit of data that can be referenced.

DATA FLOWCHART—See flowchart.

DATA, REFERENCE—The source document identification.

DATA REPRESENTATION—The symbols and codes used by computers to represent letters, numbers, and special characters.

DEBUGGING—The process of finding errors (bugs) in a program or system and correcting them so that the program or system runs correctly.

DENSITY, RECORDING—The number of bits, bytes, characters, or frames per linear inch on a recording medium, like tape or disk.

DIGITAL COMPUTER—A computer that solves problems on discrete data using 0's and 1's (OFF and ON states) to represent data and operations.

DIRECT ACCESS—A storage method that allows the computer to locate and read a particular record without having to search through an entire file. The computer is able to access data independent of its location. Magnetic disks, diskettes, and drums are considered direct access devices.

DISK DRIVE—A direct-access storage device for recording and retrieving data on hard (rigid) disk or floppy disks (diskettes).

DISK PACK—A mass storage device in which information is stored on one or both sides of a rigid disk that can be magnetized. The disk is rotated by a disk drive and information is stored and retrieved by one or more magnetically sensitive read/write heads.

DISKETTE—A mass storage device in which information is stored on one or both sides of a flexible disk that can be magnetized. The diskette is rotated by a diskette drive and information is stored and retrieved by one or more magnetically sensitive read/write heads. Diskettes are also called floppy disks because the disk bends easily.

DOWNTIME—The length of time the computer is not operating, either because of preventive maintenance (scheduled downtime) or a malfunction (nonscheduled downtime).

EBCDIC (Extended Binary Coded Decimal Interchange Code)—An 8-bit coding system for representing uppercase and lowercase letters, numbers, and special characters.

EPROM—The acronym for erasable programmable read-only memory.

FIELD, DATA—An item of information in a data record. One or more related characters that are treated as a unit of information.

FILE—A collection of related records; for example, a payroll file. Any collection of records holding similar data or transactions that are stored together to permit systematic access and modification.

FILE, MASTER—The file that contains all the data records in up-to-date form. It is a main reference file of relatively more permanent information, which is usually updated periodically.

FIRMWARE—A set of program instructions, a microprogram, permanently stored in read-only memory.

FLAT PANEL DISPLAY—A display device that consists of a grid of electrodes in a flat, gas-filled panel. The image can persist for a long period of time without refresh.

FLOPPY DISK—See diskette.

FLOWCHART—A graphic representation of the processing steps (logic) of a program (a program flowchart) or the inputs, outputs, and processing steps of a system (a systems [data] flowchart). The graphic representation uses symbols to represent operations and directional lines to indicate sequence and direction of flow.

FORMAT—The arrangement or layout of data in or on a data medium.

FORTRAN (FORmula TRANslator)—A high-level programming language for scientific and mathematical applications.

FULL-DUPLEX CHANNEL—A channel that provides for simultaneous transmission in both directions, such as the telephone.

GENERAL-PURPOSE COMPUTER—A computer designed to operate on a program of instructions for the purpose of solving many different types of processing problems.

GENERATIONS OF COMPUTERS—Historically, the distinctive types of computers from the 1940s to the present; the first generation was based on vacuum tubes, the second on transistors, the third and current features integrated circuits. Recent developments involve the use of VLSI (very large scale integration) and semiconductor memories.

GRAPHICS—The use of pictorial means to present data in the form of plotted curves, graphs (bar, pie, line, and so on), or diagrams. These may be displayed on a crt or printed.

HANDSHAKING—The process through which the rules for exchanging data over a communications line are defined for the two devices involved.

HARD COPY—The term given to humanly readable printed output from a computer.

HARDWARE—The visible, physical equipment of a system, including the computer (cpu) and related peripheral equipment; as distinguished from software.

HEAD POSITIONING—Placing a read/write head over a specified track on a disk or drum.

HEXADECIMAL—The number system with base 16 (0-9 and A-F). A represents 10; B represents 11; C represents 12; D represents 13; E represents 14; and F represents 15. Used in some computer systems.

HIGH-LEVEL LANGUAGES—Programming languages that allow the programmer to write programs in English-like terms and symbols and mathematical notation, rather than the 0's and 1's used by the computer. These high-level programs must be translated into machine language before the computer can execute them. FORTRAN, Ada, COBOL, and BASIC are examples.

HOST COMPUTER—The main or controlling computer in a distributed data processing network (ddp).

HYBRID COMPUTER—A computer that combines the functions of both analog and digital computers.

I/O—Input/Output.

INPUT—The data entered into a computer system for processing.

INPUT DEVICES—Devices for reading data and programs into the computer system for processing.

INPUT/OUTPUT DEVICES—Secondary storage devices for writing and reading data. Magnetic tape drives, magnetic disk drives, and drums are examples.

INTEGRATED CIRCUIT—A miniaturized chip in which semiconductor components and other such technology combine the functions of a number of conventional components (such as transistors, resistors, capacitors, and diodes).

INTERNAL STORAGE (MEMORY)—See storage, primary.

INTERRECORD/INTERBLOCK GAP—A blank section of recording surface separating each record or block of records on a magnetic data medium.

K—An abbreviation for the value 1,024 which is 210. Often used to express the memory capacity of a computer. For example, a 512K computer has 524,288 bytes of memory.

KEY-TO-DISK—A process, similar to key-to-tape, in which data is transmitted from a keyboard to magnetic disk.

KEY-TO-TAPE—An operation in which data is transmitted from a keyboard to magnetic tape.

LANGUAGE TRANSLATOR—A program that reads a source program and converts it into an object (machine language) program. Assemblers and compilers are examples.

LOCAL-AREA NETWORK—A network that normally operates within a well-defined and generally self-enclosed area. The communication stations or terminals are usually linked by cable and are within 1,000 feet of each other.

LOGICAL RECORD—A record that includes all the data that belongs together as a unit regardless of the physical size or storage location of the data.

M—A unit of measurement approximately equal to one million and used to express the capacity of a computer memory. 1M is about 1,000,000 units. Memory size is usually measured in words or bytes.

MACHINE LANGUAGE—Machine instructions in binary bit patterns that the central processing unit can execute directly without additional interpretation or translation.

MACHINE (TAKE-UP) REEL—A reel that remains on the tape drive and on which magnetic tape is wound during the processing of a tape.

MAGNETIC MEDIA—Magnetic cards, tapes, disks, drums, cartridges, and cassettes used to record data or information.

MAGNETIC TAPE—A mass storage device in which information is stored on a plastic tape coated with a magnetic film. The tape is wound on reels that are rotated by tape drives. Information is stored and retrieved sequentially by magnetically sensitive read/write heads.

MAINFRAME COMPUTERS—This term is usually used to designate large-scale computer systems, although the precise definition of mainframe is the cpu and the control elements of any computer system.

MAIN STORAGE (MEMORY)—See storage, primary.

MASS STORAGE—Any external storage medium (magnetic tape, disk, drum, and so on) that supports and can be linked to the cpu's main memory in the computer. When the power is turned off, information in the mass storage is retained (not lost).

MEDIUM—The material on which data and instructions are recorded, such as punched cards, paper tape, and all forms of magnetic media (tape, disk, drum, and so on).

MEMORY—A device or section of the computer in which computer instructions and data can be stored for retrieval (synonymous with primary or internal storage).

MICROCOMPUTERS—The smallest category of computers, usually with the entire central processing unit on a single chip. Unlike large-scale and minicomputer systems, they are designed to be used by one person at a time (hence the term, personal computer [PC]).

MICROPROCESSOR—The semiconductor central processing unit (cpu) of a microcomputer that fits on a small silicon chip. The microprocessor is the central chip containing the control units of the computer.

MICROSECOND—One millionth of a second.

MILLISECOND—One thousandth of a second.

MINICOMPUTERS—Midsize computers that are smaller than large-scale systems but with the same components. They are less expensive and have less strict environmental requirements.

MODEM—Acronym for MOdulator-DEModulator. A device that converts data from digital-to-analog format for transmission on analog transmission lines and converts data in analog format to digital format for computer processing.

MULTIPROCESSING—A computer processing mode that provides for simultaneous processing of two or more programs or routines by use of multiple cpu's.

MULTIPROGRAMMING—A computer processing mode that provides for overlapping or interleaving the execution of two or more programs at the same time by a single processor.

NANOSECOND—A billionth of a second.

NETWORK—Computers and terminals linked together through a communications system to allow users at different locations to share data files, devices, and programs.

ONLINE PROCESSING—Processing from terminals under the direct control of a computer.

OPERATING SYSTEM—Software that controls the execution of programs. An operating system may provide services such as input/output control and data management. It may also provide job scheduling, memory allocation, and other general functions. It is usually loaded by a bootstrap program.

OUTPUT—The results of computer processing. It may be data transferred to tape, disk, paper, and so on.

PACKAGED SOFTWARE—Programs already written (and tested) to solve specific types of problems; usually designed by a central design agency (CDA) or purchased from a software firm or computer manufacturer.

PACKED DECIMAL—In ASCII and EBCDIC, the representation of two digits stored in one eight-bit byte.

PAPER TAPE—See punched tape.

PARALLEL TRANSMISSION—A method of data transmission in which all bits of a particular character are transmitted simultaneously.

PARITY BIT—A check bit; an extra bit added to a group of bits for use in detecting errors during data transfer.

PARITY CHECK—An internal error checking method in which the binary digits in a character or word are added and the sum is checked against a single previously computed parity digit. The check tests whether the number of one bits in a character or word are odd or even, depending on the parity of the computer.

PASSWORD—A protected word or string of characters that identifies or authenticates a user for access to a specific resource, such as a file or record.

PERIPHERAL EQUIPMENT—Equipment used for data entry, storage, or retrieval, but which is not a part of the central processing unit. Peripherals include crt displays, terminals, printers, and mass storage (tape, disk, and drum) devices.

PERSONAL COMPUTER (PC)—A computer, usually a microcomputer, that is more affordable than minicomputers or mainframes and is used by one person at a time.

PICTURE ELEMENT—Synonym for pixel. See pixel.

PIXEL—In computer graphics, the smallest element of a display surface that can be independently assigned color or intensity.

PRIMARY STORAGE—See storage, primary.

PRINTER—A device used with a computer to produce hard copy, printed output.

PROGRAM—(1) Verb—The act of writing instructions for computer execution. (2) Noun—The set of instructions that tells the computer the steps to execute to automatically solve a problem.

PROGRAM FLOWCHART—See flowchart.

PROM—Acronym for programmable read-only memory.

PUNCHED CARD—A card punched with hole patterns that represent data or program instructions. Punched cards can be read by an input device (card reader) to a computer.

PUNCHED TAPE—A tape punched with hole patterns that represent data or program instructions. Tape can be read by an input device to a computer.

RAM—Acronym for random-access memory.

RANDOM ACCESS—A method of accessing data (or instructions) without having to scan any preceding information. Magnetic core, semiconductor, and bubble memories are considered random access storage devices.

REAL-TIME PROCESSING—A computer processing method in which data about a particular event is entered directly into the computer as the event occurs and is immediately processed so it can influence future processing.

RECORD—A group of related fields, all pertaining to the same subject.

RECORD BLOCK—Several records blocked together.

RECORD LENGTH—The number of characters in a record.

REMOTE TERMINAL—A display terminal, such as a crt or other piece of equipment, which is not located with the computer but is connected by a communications line. In a typical online, real-time communications system, the remote device is usually a teletypewriter or a crt visual display unit.

ROM—Acronym for read-only memory.

ROTATIONAL DELAY—The time required for the read/write head to find a specified record on a disk, diskette, or drum once head positioning has occurred.

SECONDARY STORAGE—See storage, secondary.

SECTORS—The pie-shaped segments of a disk's recording surface.

SEQUENTIAL ACCESS—A storage technique in which the stored items of information become available only in a one after the other sequence, whether or not all the information or only some of it is desired. Magnetic tape is an example.

SOFT COPY—Output of a computer displayed on a display terminal or monitor (crt). It is nonpermanent.

SOFTWARE—Programs, routines, codes, and other written information used to direct the operation of a computer; as distinguished from hardware.

SORT—The process of arranging data records in a predefined sequence by use of sort keys; for example, to sequence personnel records by social security number (the sort key).

SOURCE DATA—The data in its initial state to be processed by a computer system.

SOURCE DOCUMENT—The document that contains the initial (raw) data for computer processing.

SOURCE PROGRAM—A computer program written in a language like COBOL, FORTRAN, or assembly language. It must be translated into an object program before it can be executed by a computer.

SPECIAL-PURPOSE COMPUTER—A computer designed to perform one specific function such as a weather computer.

STORAGE, PRIMARY (MAIN, INTERNAL)—The section of the cpu in which instructions and data are held. Also called main memory.

STORAGE, SECONDARY (AUXILIARY, EXTERNAL)—Storage outside the cpu where programs and data are stored for future computer processing; for example tapes, disks, and punched cards.

STORED PROGRAM—The set of instructions stored in computer memory for execution.

SUBROUTINE LIBRARY—A set of standard and proven computer routines that are kept on file for use at any time.

TELECOMMUNICATIONS—The transmission of data between computer systems and/or terminals in different locations.

TELEPROCESSING—A method of data processing in which communication devices are used.

TERMINAL—A device linked to the central processor for entering or receiving data and programs.

TIME SHARING—A processing mode in which many users share the computer systems' resources through online terminals. Each user gets a slice of computer time.

TRACK—(1) One of seven or nine, horizontal rows stretching the entire length of a magnetic tape and on which data can be recorded. (2) One of a series of concentric circles on the surface of a disk. (3) One of a series of circular bands on a drum.

UNBLOCKED—Having a blocking factor of one logical record per block.

USER PROGRAMS—Programs written to solve specific user problems, called applications software.

USERS—(1) The people who use the output from computer processing. (2) The people who operate a computer for their own purposes.

UTILITY PROGRAMS (UTILITIES)—Programs designed to perform often needed general functions.

WIDE AREA NETWORK—A network that usually covers large geographical areas. Communications between stations or terminals usually occur using standard telephone lines or microwave relays.

WORD, COMPUTER—A group of related bytes treated as a single addressable unit or entity in computer memory.

Assignment Questions

<u>Information</u>: The text pages that you are to study are provided at the beginning of the assignment questions.

ASSIGNMENT 1

Textbook assignment: Chapter 1, “Operational Concepts,” pages 1-1 through 1-25.

1-1. When was the first mechanical adding machine invented?

1. 1264
2. 1426
3. 1462
4. 1642

1-2. What year did electronics enter the computer scene?

1. 1918
2. 1919
3. 1920
4. 1921

1-3. In modern digital computers, circuits that store information, perform arithmetic operations, and control the timing sequences are known as what?

1. Flip-flops
2. Amplifiers
3. Oscillators
4. Multipliers

1-4. When was the UNIVAC I developed?

1. 1944
2. 1946
3. 1950
4. 1951

1-5. The field of research that is developing computer systems which mimic human thought in a specific area and improve performance with experience and operation is what field of research?

1. Human intelligence
2. Artificial intelligence
3. Animal intelligence
4. Computer intelligence

1-6. Mechanical computers are what type of devices?

1. Digital
2. Electrical
3. Analog
4. Electromechanical

1-7. What determines the size of an analog computer?

1. Where it will be installed
2. Number of operators using it
3. Cost
4. Number of functions it has to perform

1-8. What is the primary use of analog computers in the Navy?

1. Gun fire control
2. Data processing
3. Ships steering
4. Missile fire control

1-9. Compared to mechanical computers, electromechanical computers are different in which of the following ways?

1. They cost more
2. They are bigger
3. They are less accurate
4. They use electrical components to perform some of the calculations and to increase the accuracy

1-10. In early electronic computers, what was the weak link in electrical computations?

1. Transistors
2. Resistors
3. Vacuum tubes
4. Capacitors

1-11. A computer that is designed to perform a specific operation is what kind of computer?

1. All-purpose
2. General-purpose
3. Special-purpose
4. Single-purpose

1-12. How are the instructions that control a computer applied to a special-purpose computer?

1. From a stored program
2. From a keyboard
3. From an input device
4. From built-in instructions

1-13. What is a drawback to the specialization of a special-purpose computer?

1. Low speed
2. Lack of versatility
3. Large size
4. High cost

1-14. What gives a general-purpose computer the ability to perform a wide variety of operations?

1. It can store and execute different programs in its internal storage
2. It is a much larger computer
3. It has a huge built-in program
4. It can operate faster than other computers

1-15. All analog computers are what type?

1. Mechanical
2. Electromechanical
3. Special-purpose
4. General-purpose

1-16. What are computers called that combine the functions of both analog and digital?

1. Analog-digital computers
2. Mixed computers
3. Duplexed computers
4. Hybrid computers

1-17. A digital computer knows how to do its work by what means?

1. By a list of instructions called a program
2. By a list of instructions called a job sequence
3. By its hardware
4. By its peripheral equipment

1-18. What is the most popular generic term for computer programs?

1. Hardware
2. Software
3. Wordprocessing
4. Graphics

1-19. First generation computers were characterized by what technology?

1. Transistors
2. Resistors
3. Vacuum tubes
4. Printed circuits

1-20. What type of computer language was used with first generation computers?

1. Machine
2. COBOL
3. BASIC
4. Fortran

1-21. Computers of the second generation were characterized by what technology?

1. Vacuum tubes
2. Capacitors
3. Transistors
4. Resistors

1-22. The small, long lasting transistors used in second generation computers had which of the following effects?

1. They increased processing speeds and reliability
2. They decreased processing speeds and increased reliability
3. They increased processing speeds and decreased reliability
4. They decreased processing speeds and reliability

1-23. Internal processing speeds of second generation computers were measured at what speed?

1. Hundredths of a second
2. Thousandths of a second
3. Millionths of a second
4. Billionths of a second

1-24. Third generation computers are characterized by what technology?

1. Capacitors
2. Transistors
3. Resistors
4. Miniaturized circuits

1-25. A circuit and its components can be etched onto which of the following materials?

1. Plastic
2. Silicon
3. Gold
4. Pressed fiber

1-26. The internal processing speeds of third generation computers are measured at what speed?

1. Hundredths of a second
2. Thousandths of a second
3. Millionths of a second
4. Billionths of a second

1-27. Fourth generation technology has which of the following results for the computer industry?

1. Computers that are significantly smaller and lower in cost
2. Computers that are significantly larger and lower in cost
3. Computers that are significantly smaller and higher in cost
4. Computers that are significantly larger and higher in cost

1-28. What does the acronym ROM stand for?

1. Run-on manual
2. Read-only minutes
3. Read-only memory
4. Read-only manual

1-29. Which of the following will be one of the future challenges involving computer power?

1. How to properly and effectively use the computing power available
2. How to increase computer storage capacity
3. How to increase computer power
4. How to properly install the computers available

1-30. What term is used for programs such as assemblers, compilers, operating systems, and applications programs?

1. Hardware
2. Peripheral devices
3. Software
4. Sub-systems

1-31. Which of the following is one of the more widespread uses of the computer in the Navy?

1. Research
2. Word processing
3. Manufacturing
4. Games

1-32. Computers have an advantage over typewriters in what area?

1. Cost
2. Speed
3. Reliability
4. Correcting errors

1-33. What does the acronym S-N-A-P stand for?

1. Shipboard navigational aid package
2. Shipboard Navy applied program
3. Shipboard non-tactical ADP program
4. Shipboard nuclear active program

1-34. Which computer is used with the SNAP II system?

1. UYK-4
2. UYK-7
3. UYK-20
4. AN/UYK-62 (V)

1-35. Where are the user terminals for SNAP II placed on board ship?

1. Engineering spaces
2. Work centers
3. Supply spaces
4. Electronics spaces

1-36. The work center supervisor can update which of the following items from a user terminal?

1. COSAL, APL, EIC, and CSMP only
2. APL, EIC, SHIP'S FORCE WORK LIST, and CSMP only
3. COSAL, APL, SHIP'S FORCE WORK LIST, and CSMP only
4. COSAL, APL, EIC, SHIP'S FORCE WORK LIST, and CSMP

1-37. What type of classified use does SNAP II allow?

1. Unclassified
2. Confidential
3. Secret
4. Top Secret

1-38. What is a central set of programs called that manages execution of other programs and performs common functions like read, write, and print?

1. Managing system
2. Execution system
3. Operating system
4. Word processing system

1-39. What is the function of a built-in program called a bootstrap loader?

1. To load a word processor into the computer's internal memory
2. To load an external operating system into the computer's internal memory
3. To load a graphics program into the computer's internal memory
4. To load a bootstrap program into the computer's internal memory

1-40. When an error message such as device error is shown on the display screen, which of the following problems could be the cause?

1. No floppy disk in drive A
2. Floppy disk inserted incorrectly in drive
3. Lock handle on drive A not lowered
4. Each of the above

1-41. A display similar to this A> means what in computer terminology?

1. A device error
2. No system
3. A prompt
4. Run again

1-42. What does it mean when the computer displays a prompt on the screen?

1. The computer has made an error
2. There is no system in the computer
3. You need to stop putting information into the computer
4. You can tell the computer what to do next

1-43. To tell the operating system what program to run, you should take which of the following actions following the operating system prompt A>?

1. Type help
2. Reboot the computer
3. Press the execute key
4. Type the program name

1-44. Online HELP screens serve what purpose?

1. Display the contents of memory
2. Display the operating system directory
3. Tell the operator how to perform a given function
4. Stop computer processing so the operator can read the instruction manual

1-45. Floppy disks provide which of the following functions?

1. Store data
2. Perform arithmetic operations
3. Provide alternate power to the computer
4. Check the accuracy of computer operations

1-46. Touching the exposed area seen through the timing hole and the read/write slots on a floppy disk can do what, if anything, to the data in that area?

1. Ruin it
2. Add to it
3. Move it
4. Nothing

1-47. What maximum number of disks should be stacked horizontally?

1. 5
2. 10
3. 15
4. 20

1-48. What is perhaps the most common source of a magnetic field that can affect a floppy disk?

1. Crt's
2. Printer
3. Telephone
4. Disk drives

1-49. In which of the following ways does smoke affect a computer?

1. It damages the electronics
2. It causes the monitor to fail
3. It coats the keyboard
4. It causes buildup on disks and disk drives

1-50. What, if anything, can happen to a floppy disk when it is exposed to direct sunlight or excessive heat?

1. It can become warped or distorted so it cannot be used
2. It can become sticky, which stops the drive
3. It can lose part of the data recorded on it
4. Nothing, it is not affected

1-51. Typically, floppy disks will operate only in what temperature range?

1. 40 to 120 degrees Fahrenheit
2. 50 to 120 degrees Fahrenheit
3. 60 to 120 degrees Fahrenheit
4. 70 to 120 degrees Fahrenheit

1-52. A floppy disk will accept what relative humidity range?

1. 5% to 60%
2. 10% to 70%
3. 10% to 80%
4. 10% to 90%

1-53. When a pencil or ballpoint pen is used to write on the label after it is attached to the disk, what, if anything, can happen to a disk?

1. Some of the data written on the label can be added to the disk
2. All of the data can be lost, but the disk can be used again
3. The disk can be destroyed
4. Nothing; there can be no effect

1-54. In the computer world, what method provides a means to ensure that any data lost can be recovered?

1. Records
2. Backup files
3. Tracks
4. Blocks

1-55. What two media are commonly used for backup?

1. Paper tape and punched cards
2. Magnetic tape and punched cards
3. Disk and magnetic tape
4. Disk and drum

1-56. What is the most common method of creating a backup for a microcomputer?

1. Copying the disk onto a magnetic tape
2. Copying the disk onto a paper tape
3. Copying the disk onto a punched card
4. Copying the disk onto another disk

ASSIGNMENT 2

Textbook assignment: Chapter 2, "Hardware," pages 2-1 through 2-35.

2-1. The components or tools of a computer system can be grouped into what two categories?

1. Hardware and software
2. Hardware and firmware
3. Firmware and software
4. Software and programs

2-2. What section/unit is the brain of a computer system?

1. Control section
2. Arithmetic-logic section
3. Central processing unit
4. Input unit

2-3. What section/unit is the computing center of a computer system?

1. Arithmetic-logic section
2. Central processing unit
3. Control section
4. Output unit

2-4. The central processing unit is made up of which of the following sections?

1. Control and internal storage only
2. Central and arithmetic-logic only
3. Arithmetic-logic and internal storage only
4. Control, internal storage, and arithmetic-logic

2-5. When a program is so large and complex that it exceeds the memory capacity of a stored-program computer, where is the overflow stored?

1. Input storage area
2. Output storage area
3. Primary memory
4. Auxiliary memory

2-6. What part of the computer dictates how and when each specific operation is to be performed?

1. Control section
2. Arithmetic-logic section
3. Input storage area
4. Output storage area

2-7. Of the four major types of instructions, which one has the basic function of moving data from one location to another?

1. Control
2. Logic
3. Arithmetic
4. Transfer

2-8. To send commands to devices not under direct command of the control section, what type of instructions are used?

1. Control
2. Logic
3. Arithmetic
4. Transfer

2-9. Operations like adding and multiplying are performed by what section?

1. Control-logic
2. Storage-logic
3. Arithmetic-logic
4. Transfer-logic

2-10. When processing is taking place, data is transferred back and forth between what two sections?

1. Control and internal storage
2. Internal storage and arithmetic-logic
3. Control and arithmetic
4. Arithmetic and output

2-11. The process by which instructions and data are read into a computer is called what?

1. Moving
2. Storing
3. Inputting
4. Loading

2-12. An auxiliary (wired) memory is used in some computers to permanently store a small program that makes manual loading unnecessary. What is this program called?

1. Operating system
2. Bootstrap
3. Word processing
4. Graphics

2-13. The tiny doughnut-shaped rings used to make up magnetic core storage are made of what material?

1. Aluminum
2. Steel
3. Tin
4. Ferrite

2-14. Data is stored in computers in what form?

1. Binary
2. Decimal
3. Octal
4. Hexadecimal

2-15. The state of each core in magnetic core storage is changed by what?

1. The amount of magnetism
2. The amount of current
3. The direction of magnetism
4. The direction of current

2-16. Electronic circuits are placed on a silicon chip by what method?

1. Wired
2. Drawn
3. Etched
4. Printed

2-17. Each of the individual electronic circuits on a silicon chip is called what?

1. A memory cell
2. A bit cell
3. A byte cell
4. A holding cell

2-18. Semiconductor storage has which of the following drawbacks?

1. It is too slow
2. It is expensive
3. It is volatile
4. It is unreliable

2-19. Using a very thin crystal made of semiconductor material, what type of memory can be created?

1. Bubble
2. Magnetic core
3. Semiconductor
4. Capacitive

2-20. In bubble memory, where is the control circuit imprinted on the crystal of semiconductor material?

1. The side
2. The bottom
3. The middle
4. The top

2-21. Who installs the programs in read-only memory?

1. The programmer
2. The manufacturer
3. The operator
4. The dealer

2-22. Programs that are tailored to certain needs and permanently installed in ROM by the manufacturer are called what?

1. Firmware
2. Software
3. Hardware
4. Diskware

2-23. What kind of memory used inside computers has a read/write capability without any additional special equipment?

1. ROM
2. RAM
3. EPROM
4. PROM

2-24. A special device is needed to burn the program into what type of memory?

1. ROM
2. PROM
3. ERAM
4. RAM

2-25. EPROM can be erased by what method?

1. With a current charge
2. With a voltage change
3. With a burst of ultra-violet light
4. With a special program

2-26. To coat magnetic disks, what magnetizable recording material is used?

1. Plastic
2. Mylar®
3. Aluminum oxide
4. Iron oxide

2-27. What is the size range of the diameters of magnetic disks?

1. 3 inches to 4 feet
2. 4 inches to 3 feet
3. 5 inches to 6 feet
4. 6 inches to 5 feet

2-28. Data is stored on all disks in a number of invisible concentric circles called what?

1. Cracks
2. Grooves
3. Paths
4. Tracks

2-29. A floppy disk surface has what maximum number of tracks?

1. 66
2. 77
3. 88
4. 99

2-30. When data is written on a disk in the same area where data is already stored, the old data is affected in which of the following ways, if at all?

1. It is moved to a new area
2. It is mixed with the new data
3. It is replaced
4. It is not affected

2-31. How are records on a track separated?

1. By a gap in which no data is recorded
2. By a gap in which the name of the record is recorded
3. By a gap in which the record is numbered
4. By a gap in which the operator's name is placed

2-32. To increase the amount of data we can store on one track, what technique can be used?

1. Records
2. Files
3. Disk address
4. Blocking

2-33. Designers were able to increase the data density of a disk by increasing the number of tracks. What code name was given to this technology?

1. Computer
2. Winchester
3. Solid state
4. Colt

2-34. During reading and writing, which of the following changes are achieved by reducing the distance of the read/write heads over the disk surface?

1. Data density can be improved and storage capacity decreased
2. Data density is lessened and storage capacity increased
3. Data density can be improved and storage capacity increased
4. Data density is lessened and storage capacity decreased

2-35. To physically organize data on diskettes, what method is used?

1. Records
2. Cylinder
3. Files
4. Sector

2-36. The lengths of magnetic tapes used with computers have what range?

1. From 400 to 1,000 feet
2. From 500 to 2,000 feet
3. From 600 to 3,000 feet
4. From 700 to 4,000 feet

2-37. Magnetic tapes can be packaged in which of the following ways?

1. Open reel only
2. Cartridge and cassette only
3. Open reel and cartridge only
4. Open reel, cartridge, and cassette

2-38. By which of the following methods are magnetic tape units categorized?

1. Type of packaging used for tape
2. Size of tape
3. Speed of tape
4. Cost of tape

2-39. What determines if a standard 1/2-inch tape will have either seven or nine tracks of data?

1. The brand of tape
2. The read/write heads installed in the tape unit
3. The type of computer used
4. The speed at which the tape unit is run

2-40. For multitrack tapes, what is the range of common recording densities in bits/bytes per inch (bpi)?

1. From 200 to 6,250 bpi
2. From 300 to 6,275 bpi
3. From 400 to 6,300 bpi
4. From 500 to 6,350 bpi

2-41. On magnetic tape, the size of a record that holds the data is restricted in what two ways?

1. By the thickness of the tape and the capacity of internal storage
2. By the length of the tape and the speed of internal storage
3. By the width of the tape and the speed of internal storage
4. By the length of the tape and the capacity of internal storage

2-42. In computer terminology, what is called a file?

1. A collection of tapes
2. A collection of disks
3. A collection of records
4. A collection of characters

2-43. In order for data to be read from or written on a magnetic tape, the tape must do what?

1. Speed up
2. Move at a predetermined speed
3. Slow down
4. Stop

2-44. Storing single records on a magnetic tape has which of the following disadvantages?

1. It takes too long to record the data
2. It takes too long to recover the data
3. Too much of the recording surface is wasted
4. Too much of the recording surface is used

2-45. The magnetic drum is another example of what type of access storage device?

1. Random
2. Direct
3. Multiple
4. Single

2-46. What is the speed range of a magnetic drum?

1. 300 to 3,000 rpm
2. 400 to 4,000 rpm
3. 500 to 5,000 rpm
4. 600 to 6,000 rpm

2-47. When using a magnetic drum, what is rotational delay?

1. Time that occurs in coming up to speed
2. Time that occurs in slowing down
3. Time that occurs in reaching a desired record location
4. Time that occurs in changing a drum

2-48. What is the storage capacity range of magnetic drums in characters or bytes of data?

1. From 20 million to more than 150,000 million
2. From 30 million to more than 150,000 million
3. From 40 million to more than 200,000 million
4. From 50 million to more than 200,000 million

2-49. Input data may be in any one of how many forms?

1. Five
2. Two
3. Three
4. Four

2-50. When data is input from a keyboard, a high average speed is how many characters per second?

1. One to two
2. Two to three
3. Three to four
4. Four to five

2-51. Output information is made available in how many forms?

1. One
2. Two
3. Three
4. Four

2-52. Magnetic tape stores data in what manner?

1. Sequential
2. Non-sequential
3. Direct
4. Random

2-53. The magnetic tape unit reads and writes data in channels or tracks along the length of the tape. How are these tracks referenced to each other?

1. Perpendicular
2. Parallel
3. Vertical
4. Random

2-54. How does a two gap head allow for increased speed?

1. By checking before writing
2. By using two gaps to write
3. By checking while writing
4. By using two gaps to check

2-55. What are the most common tape densities in bits/bytes per inch?

1. 500 and 1,000 bpi
2. 600 and 1,200 bpi
3. 700 and 1,500 bpi
4. 800 and 1,600 bpi

2-56. The drive motor of a disk drive unit rotates the disk at a constant speed, normally how many revolutions per minute?

1. 2,000 rpm
2. 2,500 rpm
3. 3,000 rpm
4. 3,600 rpm

2-57. The usual range of rotational speed for floppy disks is what?

1. 100 to 200 rpm
2. 200 to 300 rpm
3. 300 to 400 rpm
4. 400 to 500 rpm

2-58. The distance between the read/write head and the surface of a hard disk is called what?

1. The flying height
2. The disk height
3. The head height
4. The recording height

2-59. Floppy disks come in several sizes with diameters of what size range?

1. 2 to 6 inches
2. 3 to 8 inches
3. 4 to 9 inches
4. 5 to 10 inches

2-60. In the character-at-a-time impact printer class, which printer has the most professional-looking, pleasing-to-the-eye print?

1. Dot-matrix
2. Ink jet
3. Daisy-wheel
4. Laser

2-61. What is another name for the dot-matrix printer?

1. Hammer-matrix
2. Pin-matrix
3. Ink-matrix
4. Wire-matrix

2-62. Dot-matrix printers have which of the following ranges of speeds in characters per second?

1. 50 to 200 cps
2. 60 to 350 cps
3. 70 to 400 cps
4. 80 to 450 cps

2-63. Ink jet printers have what maximum speed in characters per seconds?

1. 300 cps
2. 400 cps
3. 500 cps
4. 600 cps

2-64. Laser printers can print up to approximately what total number of characters per second?

1. 20,666 cps
2. 22,666 cps
3. 24,666 cps
4. 26,666 cps

2-65. What are the two styles of typewriter keyboard arrangements used with a computer?

1. QWERYT or DVORAK
2. QWERTY or DVORAK
3. ABCDEF or DVORAK
4. ABCDEF or DVOARK

2-66. When working with display devices, what does the term soft-copy mean?

1. The information displayed is not permanent
2. The information displayed is permanent
3. The information displayed has a soft glow
4. The information displayed has no glow

2-67. On a raster scan crt, a raster is a series of what type of lines across the face of a crt?

1. Diagonal
2. Vertical
3. Horizontal
4. Wavy

2-68. Each field of a raster scan crt is made up of approximately how many lines?

1. 525
2. 550
3. 575
4. 600

2-69. In a video monitor, what do the frequency bandwidth, the number of characters to be displayed on a line, and the physical size of the screen determine?

1. Actual level of brightness
2. Actual number of picture elements
3. Actual speed of scan rate
4. Actual number of vertical lines that can be displayed

2-70. A monitor that uses 1,000 picture elements per line with a horizontal resolution of 1,000 can display what total number of vertical lines?

1. 10
2. 100
3. 1,000
4. 10,000

2-71. A raster frame is displayed approximately how many times a second?

1. 5
2. 10
3. 20
4. 30

2-72. To reduce the depth of the crt caused by the length of the tube, what type of displays were designed?

1. Wide panel
2. Flat panel
3. Narrow panel
4. Short panel

2-73. Compared to the gas plasma and electroluminescent displays, a liquid crystal display differs in which of the following ways?

1. It does not use as many picture elements
2. It does not use a light for the picture elements
3. It does not generate its own light for the picture elements
4. It does not have a backlight

2-74. The operation of an electroluminescent display requires what total number of volts?

1. 5
2. 10
3. 15
4. 20

ASSIGNMENT 3

Textbook assignment: Chapter 3, “Software,” pages 3-1 through 3-29.

3-1. What must you load into a computer to manage its resources and operations?

1. Bootstrap program
2. Word processor
3. Graphics program
4. Operating system

3-2. What program controls the execution of other programs according to job information?

1. An operating system
2. A bootstrap program
3. A word processor
4. A utility program

3-3. The simplest and most commonly used operating systems on microcomputers are which of the following types?

1. Multiuser/single tasking
2. Single user/single tasking
3. Single user/multitasking
4. Multiuser/multitasking

3-4. Which of the following programs must be compatible with the operating system in use?

1. CP/M-86
2. UNIX
3. Applications
4. MS-DOS

THIS SPACE LEFT BLANK INTENTIONALLY.

3-5. To overcome the applications software compatibility problem, which of the following is done so the application can be run under several different operating systems?

1. Some software comes in several versions
2. Computers are designed to accept all applications software
3. Software comes in a universal version
4. Operating systems are changed to be compatible

3-6. What is another term for "initial program load" the system?

1. Start
2. Boot
3. Kick
4. Run

3-7. When the symbol A> is on the screen of a computer crt, it tells the operator/user which of the following information?

1. The system is not ready, and drive A is busy
2. The system is ready, and drive A is assigned as your secondary drive
3. The system is ready, and drive A is assigned as your primary drive
4. The system is activating, and no drive is available

3-8. The three characters following each directory entry are called what?

1. Files
2. Records
3. Locators
4. Extensions

3-9. Commands built into the operating system that control actions, like diskcopy and rename, are what type of commands?

1. Independent
2. Copy
3. Spread
4. Utility

3-10. To eliminate the need for programmers to write new programs when all they want to do is copy, print, or sort a data file, which of the following types of programs can be used?

1. Word processor
2. Graphics
3. Utility
4. Spreadsheet

3-11. What is the term given to arranging records in a predefined sequence or order?

1. Sorting
2. Merging
3. Writing
4. Shifting

3-12. On a computer, what is the sequence of characters called?

1. Numerical sequence
2. Collating sequence
3. Random sequence
4. Alphabetic sequence

3-13. To sort a data file, what must you tell the sort program?

1. How many characters are in the file
2. How many records are in the file
3. The length of the data file
4. The data field or fields to sort on

3-14. Sort-merge programs usually have which of the following characteristics?

1. Specific file length
2. Specific run time
3. Phases
4. Names

3-15. What personnel or methods are used to generate programs to print detail and summary reports of data files?

1. Programmers
2. Operating systems
3. Sort-merge programs
4. Report program generators

3-16. What are report program generators designed to save?

1. Run time
2. Programming time
3. Operator time
4. Printer time

3-17. Each time there is a control break, what does the program developed by the report program generator print?

1. Input information
2. Output information
3. Summary information
4. Programming information

3-18. A computer language that is a string of numbers which represents the instruction code and operand addresses is what type?

1. Machine
2. Printed
3. Symbolic
4. Procedure-oriented

3-19. Mnemonic instruction codes and symbolic addresses were developed early in what decade?

1. 1940s
2. 1950s
3. 1960s
4. 1970s

3-20. Compared to machine language coding, symbolic languages have which of the following advantages?

1. Detail is reduced
2. Fewer errors are made
3. Less time is required to write a program
4. All of the above

3-21. An instruction that allows the programmer to write a single instruction which is equivalent to a specified sequence of machine instructions is what type of instruction?

1. Machine language instruction
2. Graphic language instruction
3. Macroinstruction
4. Scientific instruction

3-22. What does the acronym COBOL stand for?

1. Computer ordered byte oriented language
2. Computer ordered business oriented language
3. Common business oriented language
4. Common business ordered language

3-23. PASCAL is being used by many colleges and universities to teach programming for which of the following reasons?

1. It is fairly easy to learn and more powerful than BASIC
2. It is hard to learn and weaker than BASIC
3. It is easy to learn and cheaper than BASIC
4. It is a shorter course and produces better programmers

3-24. The development of Ada was initiated by what organization?

1. U. S. Navy
2. U. S. Army
3. U. S. Department of Defense
4. U. S. Department of Transportation

3-25. What are the two most familiar of the procedure-oriented languages used for scientific or mathematical problems?

1. PASCAL and FORTRAN
2. PASCAL and COBOL
3. COBOL and FORTRAN
4. BASIC and FORTRAN

3-26. Compared with programs written in symbolic languages, programs written in procedure-oriented languages differ in which of the following ways?

1. They can only be used with small computers
2. They can only be used with large computers
3. They can only be used with the computer for which the program was written
4. They can be used with a number of different computer makes and models

3-27. Compared with symbolic languages, procedure-oriented languages have which of the following disadvantages?

1. They require more space in memory, and they process data at a slower rate
2. They require more space in memory, and they process data too fast for some printers
3. They require a special memory, and they process data at a slower rate
4. They require a special memory, and they process data too fast for some printers

3-28. Which of the following is a simple definition of programming?

1. The process of planning which computer system to use
2. The process of planning the computer solution to a problem
3. The process of planning the mathematical solution to a problem
4. The process of planning which computer program to use

3-29. Which of the following is NOT a basic characteristic of a computer?

1. It needs commands
2. It needs specifically defined operations
3. It can think
4. It can understand instructions only in an acceptable form

3-30. How many fundamental and discrete steps are involved in solving a problem on a computer?

1. Five
2. Two
3. Three
4. Four

3-31. In the advance planning phase of programming, what are the first two steps?

1. Program coding and machine readable coding preparation
2. Problem understanding/ definition and flowcharting
3. Test data preparation and test run performance
4. Documentation completion and operator procedures preparation

3-32. Which of the following is NOT part of defining every aspect of a problem?

1. What information (or data) is needed
2. Where and how will the information be obtained
3. What is the desired output
4. What is the computation time

3-33. Once you have a thorough understanding of the problem, what is the next step in programming?

1. Gathering information
2. Coding the program
3. Flowcharting
4. Debugging

3-34. The method of pictorially representing a step-by-step solution to a problem before computer instructions are written to produce the desired results is called what?

1. Flowcharting
2. Constructing
3. Documenting
4. Debugging

3-35. What two types of flowcharts are there?

1. System and programming
2. System and data
3. Processing and programming
4. Processing and data

3-36. What are the four basic tools used in flowcharting?

1. Advanced symbols, graphic symbols, flowcharting template, and flowcharting worksheet
2. Fundamental symbols, graphic symbols, flowcharting template, and flowcharting worksheet
3. Fundamental symbols, mathematical symbols, flowcharting symbols, and flowcharting worksheet
4. Fundamental symbols, advanced symbols, flowcharting template, and flowcharting worksheet

QUESTION 3-37 IS TO BE JUDGED TRUE OR FALSE.

3-37. Fundamental symbols are standard for the military, as directed by Department of the Navy Automated Data Systems Documentation Standards, SECNAVINST 5233.1.

1. True
2. False

3-38. Within a flowchart, what type of symbols are used to specify arithmetic operations and relational conditions?

1. Fundamental symbols
2. Graphic symbols
3. Arithmetic symbols
4. Arabic symbols

3-39. What is the graphic symbol for less than or equal to?

1. >
2. <
3. ≤
4. ≥

QUESTION 3-40 IS TO BE JUDGED TRUE OR FALSE.

3-40. The flowchart worksheet is a means of standardizing documentation.

1. True
2. False

3-41. To develop a flowchart, which of the following must you know first?

1. What type of computer is to be used
2. What problem you are to solve
3. What code you are going to use
4. What logic the computer will use to solve a problem

3-42. In solving a problem, which of the following ways does a computer operate?

1. Two steps at a time in random order
2. It processes the problem as a whole
3. One step after another in specified order
4. One step after another in random order

3-43. What is the step called in which you code a program that can be translated by a computer into a set of instructions it can execute?

1. Program booting
2. Program execution
3. Program logic
4. Program coding

QUESTION 3-44 IS TO BE JUDGED TRUE OR FALSE.

3-44. It is important to remember program coding is the first step of programming.

1. True
2. False

3-45. Before sitting down to code the computer instructions to solve a problem, you should complete which of the following activities?

1. A course in computer operation
2. A course in mathematics
3. Planning and coding
4. Planning and preparation

3-46. What is the fundamental element in program preparation?

1. Subject
2. Predicate
3. Computer
4. Instruction

3-47. The first part of a computer instruction, which answers the question what, is known by which of the following terms?

1. Operation only
2. Command only
3. Command or operation
4. Operand

3-48. The second specific part of the predicate in a computer instruction, known as the operand, in general answers what question?

1. Who
2. What
3. When
4. Where

3-49. What part of the program must the programmer prepare according to the format required by the language and the computer to be used?

1. Documentation
2. Implementation
3. Instructions
4. Length

3-50. To copy data from one storage location to another and to rearrange and change data elements in some prescribed manner, what type of instructions are used?

1. Input/output
2. Data movement
3. Transfer of control
4. Conditional logic

3-51. Transfer of control instructions are classified as which of the following types?

1. Conditional only
2. Unconditional only
3. Conditional and unconditional
4. Conditional and distributed

3-52. Errors caused by faulty logic and coding mistakes are referred to as what?

1. Mistakes
2. Errors
3. Faults
4. Bugs

3-53. The process of carefully checking the coding sheets before they are keyed into the computer is known as what?

1. Desk-checking
2. Code-checking
3. Program-checking
4. Computer-checking

3-54. A definition of the problem, a description of the system, a description of the program, and operator instructions make up what package?

1. Training
2. Security
3. Orientation
4. Documentation

3-55. Which of the following is another name for packaged software?

1. Rented programs
2. Manufactured programs
3. Off-the-shelf programs
4. On-the-shelf programs

3-56. Under the word processing software control, you generally enter the text using what method?

1. Tape
2. Disk
3. Drum
4. Keyboard

QUESTION 3-57 IS TO BE JUDGED TRUE OR FALSE.

3-57. Spelling checker software helps find misspelled words not misused words.

1. True
2. False

3-58. What type of software allows you to enter data and then retrieve it in a variety of ways?

1. Communications
2. Data retrieval
3. Data management
4. Document compilation

QUESTIONS 3-59 AND 3-60 ARE TO BE JUDGED TRUE OR FALSE.

3-59. Spreadsheets are tables of rows and columns of text.

1. True
2. False

3-60. You can use all printers for graphics output.

1. True
2. False

Assignment 4

Assignment: Topic 4, "Data Representation and Communications"
Pages: 4-1 through 4-17

4-1. In using a digital computer, which of the following is one of the major problems we face?

1. Finding disks to fit the drives
2. Locating a stable power source
3. Communicating with the computer
4. Arranging the proper environment

4-2. In computer terminology, what is a general term to describe raw facts?

1. Characters
2. Bits
3. Bytes
4. Data

4-3. In computer terminology, when data has been processed with other facts and has meaning, it is described as which of the following?

1. Information only the computer can understand and properly use
2. Information we can understand and properly use
3. Information the input device can understand and properly use
4. Information the output device can understand and properly use

4-4. Data is represented by which of the following means?

1. By symbols
2. By electricity
3. By magnetics
4. By mechanics

QUESTION 4-5 IS TO BE JUDGED TRUE OR FALSE.

4-5. The first computers were designed to manipulate numbers to solve arithmetic problems.

1. True
2. False

4-6. What is data to be represented called?

1. Numeric data
2. Alphanumeric data
3. Information data
4. Source data

4-7. Raw data is typically written on some type of paper document referred to as what type of document?

1. End document
2. Source document
3. Classified document
4. Unclassified document

4-8. Numeric, alphabetic, and special characters are represented in a computer's internal storage and on magnetic media through the use of what kind of system?

1. Coding
2. Reading
3. Writing
4. Labeling

4-9. It is possible to represent a maximum of 256 different characters or bit combinations by using which of the following codes?

1. 8-bit
2. 16-bit
3. 32-bit
4. 64-bit

4-10. In addition to four numeric bits, there are four other bit positions used in an a-bit code, what are they called?

1. Area bits
2. Zone bits
3. Region bits
4. District bits

4-11. Which of the following numbering systems has a base of 16?

1. Octal
2. Binary
3. Decimal
4. Hexadecimal

4-12. Representing two numeric characters in one byte (eight bits) is referred to as what?

1. Packing
2. Stacking
3. Doubling
4. Crowding

4-13. By packing data within an 8-bit code, which of the following results are achieved?

1. Storage space required increases and processing speed increases
2. Storage space required increases and processing speed decreases
3. Storage space required decreases and processing speed increases
4. Storage space required decreases and processing speed decreases

4-14. Through the cooperation of several manufacturers, what a-bit code was developed for transmitting and processing data?

1. EBCDIC
2. EBCDTC
3. ASCIT
4. ASCII

QUESTION 4-15 IS TO BE JUDGED TRUE OR FALSE.

4-15. The concepts and advantages of ASCII are identical to those of EBCDIC.

1. True
2. False

4-16. The letter D is represented by what coding in (a) EBCDIC and (b) ASCII?

1. (a) 1111 0011
   (b) 0011 0011
2. (a) 0011 0011
   (b) 1111 0011
3. (a) 0100 0100
   (b) 1100 0100
4. (a) 1100 0100
   (b) 0100 0100

4-17. An additional bit in each storage location called a parity bit is used for what purpose?

1. To stop errors
2. To erase errors
3. To detect errors
4. To reroute errors

4-18. The parity bit is also called what?

1. Odd bit
2. Even bit
3. Code bit
4. Check bit

4-19. The test for bit count is called what?

1. Odd check
2. Even check
3. Stop check
4. Parity check

4-20. What storage area accepts and holds input data to be processed?

1. Input
2. Output
3. Working
4. Program

4-21. A single binary digit is called what?

1. Bit
2. Byte
3. Word
4. Record

4-22. What symbol is used when we refer to the size of computer memory?

1. M
2. m
3. K
4. k

4-23. When many magnetic cores are strung together on a screen of wire, what type of plane is formed?

1. A wire plane
2. A core plane
3. A screen plane
4. A magnetic plane

4-24. When a core is magnetized, what characteristic of magnetism determines whether it contains a binary 0 or a binary 1?

1. Amount
2. Duration
3. Direction
4. Saturation

4-25. The storage capacity of an address is designed and built into the computer by which of the following people or organizations?

1. Operator
2. Installer
3. Programmer
4. Manufacturer

4-26. Computers that are built to retrieve, manipulate, and store a fixed number of characters in each address are said to be which of the following types of computers?

1. Fixed-bit-length
2. Fixed-word-length
3. Fixed-file-length
4. Fixed-number-length

4-27. Computers that store a single character in each address location are said to be which of the following types of computers?

1. Variable-addressable
2. Data-addressable
3. Fixed-addressable
4. Character-addressable

QUESTION 4-28 IS TO BE JUDGED TRUE OR FALSE.

4-28. Fixed-word-length computers have slower calculating speeds than character-addressable computers.

1. True
2. False

4-29. Flexible computers that are byte oriented can operate in either a fixed- or variable-word-length mode by which of the following techniques?

1. Proper program length
2. Proper program density
3. Proper program instructions
4. Proper program flexibility

4-30. Different word lengths, such as half-word, full-word, and double-word, are possible with what type of computer?

1. Bit-addressable
2. Byte-addressable
3. File-addressable
4. Record-addressable

4-31. When a flexible computer is working in a fixed-word-length environment, each address identifies what group of elements that can be operated on as a unit?

1. Bits
2. Bytes
3. Files
4. Records

4-32. To automatically retrieve, manipulate, and store a fixed word of data as a unit on a flexible computer, what means can a programmer use?

1. Parity bit
2. Program length
3. Storage capacity
4. Program instructions

4-33. In computer terminology, a group of related bits is known by which of the following terms?

1. Word
2. File
3. Record
4. Character

4-34. What group of related items form a record?

1. Bits
2. Bytes
3. Fields
4. Characters

4-35. The variations in how data files are stored in secondary storage is determined by what?

1. Types of media and devices used
2. Cost of the installation
3. Size of the installation
4. Type of power available

4-36. When you store a file on tape, the 125th record cannot be read until the 124 records in front of it are read. This is called what type of storage?

1. Input-access
2. Direct-access
3. Random-access
4. Sequential-access

4-37. When data can be obtained quickly from anywhere on the media without having to read the records in front of it, which of the following types of storage is being used?

1. Reading-access
2. Direct-access
3. Sequential-access
4. Processing-access

4-38. Which of the following is an example of random-access storage?

1. Disk
2. Thin film
3. Paper tape
4. Magnetic tape

4-39. Any system composed of one or more computers and terminals is the definition for what?

1. Network
2. ADP system
3. Computer system
4. Supply system

4-40. A network that consists of various machines linked together within a building or adjacent buildings is what type?

1. Wide area
2. Linked area
3. Local area
4. Narrow area

4-41. When dissimilar machines have the ability to communicate, they act in which of the following ways?

1. Human
2. As a team
3. Individually
4. Against each other

4-42. For local area networks, what two designs are used?

1. Broadband and bandpass
2. Broadpass and bandpass
3. Broadbase and baseband
4. Broadband and baseband

4-43. The communications channel that uses the basic frequency band of radio waves and a coaxial cable is what type?

1. Broadband
2. Broadpass
3. Baseband
4. Bandpass

4-44. The transmission of voice as well as data and text can be handled by what type of communications channels?

1. Broadband
2. Broadpass
3. Baseband
4. Bandpass

4-45. Wide area networks are sometimes referred to as which of the following networks?

1. Local
2. Global
3. Satellite
4. Telephone

4-46. The first successful communications satellite for business applications was launched in what year?

1. 1955
2. 1959
3. 1962
4. 1965

4-47. When we transmit data directly to a computer over long distances, it becomes necessary to add two other devices, one at each end of the communications line. These devices are called what?

1. Modems
2. Printers
3. Converters
4. Input/output buffers

4-48. A modem converts the digital signal produced by your terminal or the computer to what type of signal suitable for transmission over the communications line?

1. Video
2. Audio
3. Carrier
4. Hybrid

4-49. If conversion of the digital signal to be transmitted were not carried out, it would degenerate and become what?

1. Lost
2. Strong
3. Doubled
4. Garbled

4-50. Telephone lines are a frequently used type of communications channel. They are often referred to by which of the following terms?

1. Land lines
2. Microwave link
3. High frequency link
4. Communications lines

4-51. In communications, what name is given to those devices that serve to interconnect?

1. Connectors
2. System controllers
3. Interface elements
4. Impedance matchers

4-52. When using a modem, what are the two methods of data transmission?

1. Digital and analog
2. Mechanical and light
3. Continuous and non-continuous
4. Asynchronous and synchronous

4-53. The transmission method that uses a single set of start and stop message characters per block of data is which of the following types?

1. Synchronous
2. Asynchronous
3. Microwave link
4. Frequency modulated

4-54. Whenever data is transferred between devices, it also involves an exchange of prearranged signals known as what?

1. Nodding
2. Spacing
3. Handshaking
4. Coordinating

4-55. The specific set of rules used to govern handshaking and message characters is called what?

1. Sending
2. Protocol
3. Modulator
4. Transmitting

Navy Electricity and Electronics Training Series

Module 23—Magnetic Recording

NAVEDTRA 14195

Notice: NETPDTC is no longer responsible for the content accuracy of the NRTCs.

For content issues, contact the servicing Center of Excellence: Center for Surface Combat System (CSCS); (540) 284-1061 or DSN: 249-1061.

Although the words "he," "him," and "his" are used sparingly in this course to enhance communication, they are not intended to be gender driven or to affront or discriminate against anyone.

PREFACE

By enrolling in this self-study course, you have demonstrated a desire to improve yourself and the Navy. Remember, however, this self-study course is only one part of the total Navy training program. Practical experience, schools, selected reading, and your desire to succeed are also necessary to successfully round out a fully meaningful training program.

COURSE OVERVIEW: To introduce the student to the subject of Magnetic Recording who needs such a background in accomplishing daily work and/or in preparing for further study.

THE COURSE: This self-study course is organized into subject matter areas, each containing learning objectives to help you determine what you should learn along with text and illustrations to help you understand the information. The subject matter reflects day-to-day requirements and experiences of personnel in the rating or skill area. It also reflects guidance provided by Enlisted Community Managers (ECMs) and other senior personnel, technical references, instructions, etc., and either the occupational or naval standards, which are listed in the *Manual of Navy Enlisted Manpower Personnel Classifications and Occupational Standards,* NAVPERS 18068.

THE QUESTIONS: The questions that appear in this course are designed to help you understand the material in the text.

VALUE: In completing this course, you will improve your military and professional knowledge. Importantly, it can also help you study for the Navy-wide advancement in rate examination. If you are studying and discover a reference in the text to another publication for further information, look it up.

Sailor’s Creed

“I am a United States Sailor.

I will support and defend the Constitution of the United States of America and I will obey the orders of those appointed over me.

I represent the fighting spirit of the Navy and those who have gone before me to defend freedom and democracy around the world.

I proudly serve my country’s Navy combat team with honor, courage and commitment.

I am committed to excellence and the fair treatment of all.”

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

INSTRUCTIONS FOR TAKING THE COURSE

ASSIGNMENTS

The text pages that you are to study are listed at the beginning of each assignment. Study these pages carefully before attempting to answer the questions. Pay close attention to tables and illustrations and read the learning objectives. The learning objectives state what you should be able to do after studying the material. Answering the questions correctly helps you accomplish the objectives.

SELECTING YOUR ANSWERS

Read each question carefully, then select the BEST answer. You may refer freely to the text. The answers must be the result of your own work and decisions. You are prohibited from referring to or copying the answers of others and from giving answers to anyone else taking the course.

SUBMITTING YOUR ASSIGNMENTS

To have your assignments graded, you must be enrolled in the course with the Nonresident Training Course Administration Branch at the Naval Education and Training Professional Development and Technology Center (NETPDTC). Following enrollment, there are two ways of having your assignments graded: (1) use the Internet to submit your assignments as you complete them, or (2) send all the assignments at one time by mail to NETPDTC.

Grading on the Internet: Advantages to Internet grading are:

- you may submit your answers as soon as you complete an assignment, and
- you get your results faster; usually by the next working day (approximately 24 hours).

In addition to receiving grade results for each assignment, you will receive course completion confirmation once you have completed all the assignments. To submit your assignment answers via the Internet, go to:

https://courses.cnet.navy.mil

COMPLETION TIME

Courses must be completed within 12 months from the date of enrollment. This includes time required to resubmit failed assignments.

PASS/FAIL ASSIGNMENT PROCEDURES

If your overall course score is 3.2 or higher, you will pass the course and will not be required to resubmit assignments. Once your assignments have been graded you will receive course completion confirmation.

If you receive less than a 3.2 on any assignment and your overall course score is below 3.2, you will be given the opportunity to resubmit failed assignments. **You may resubmit failed assignments only once.** Internet students will receive notification when they have failed an assignment—they may then resubmit failed assignments on the web site. Internet students may view and print results for failed assignments from the web site. Students who submit by mail will receive a failing result letter and a new answer sheet for resubmission of each failed assignment.

COMPLETION CONFIRMATION

After successfully completing this course, you will receive a letter of completion.

STUDENT FEEDBACK QUESTIONS

We value your suggestions, questions, and criticisms on our courses. If you would like to communicate with us regarding this course, we encourage you, if possible, to use e-mail.

NAVAL RESERVE RETIREMENT CREDIT

If you are a member of the Naval Reserve, you may earn retirement points for successfully completing this course, if authorized under current directives governing retirement of Naval Reserve personnel. For Naval Reserve retirement, this course is evaluated at 2 points. (Refer to *Administrative Procedures for Naval Reservists on Inactive Duty,* BUPERSINST 1001.39, for more information about retirement points.)

THIS PAGE LEFT BLANK INTENTIONALLY.

NETPDTC 1550/41 (Rev 4-00)

CHAPTER 1

INTRODUCTION TO MAGNETIC RECORDING

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. They serve as a preview of the information you are expected to learn in the chapter. The comprehension check questions placed within the text are based on the objectives. By successfully completing those questions and the associated NRTC, you show that you have met the objectives and have learned the information. The learning objectives for this chapter are listed below.

After completing this chapter, you will be able to do the following:

1. Describe the history and purpose of magnetic recording.

2. State the prerequisites for magnetic recording.

3. Describe a magnetic recording head, how it's constructed, and how it operates.

INTRODUCTION

Have you ever wondered how a whole album of your favorite music got onto one of those little cassette tapes? Or, what about computer floppy disks; have you ever wondered how they can hold 180 or more pages of typed text? The answer to both of these questions is *magnetic recording*.

Magnetic recording devices seldom get much attention until they fail to work. But without magnetic recording, recording your favorite television show on a video cassette recorder would be impossible, portable tape players wouldn't exist, and you wouldn't be able to get money from an automated bank teller machine at two o'clock in the morning.

Now what about the Navy? Could it operate without magnetic recording? The answer is definitely no. Without it:

- Computer programs and data would have to be stored on either paper cards or on rolls of paper tape. Both of these methods need a lot of storage space, and they take much longer to load into and out of the computer.

- There wouldn't be any movies to show or music to play on the ship's entertainment system when the ship is at sea and is out of range for television and radio reception.

- Intelligence-collection missions would be impossible since you couldn't store the collected signals for later analysis.

As you can see, magnetic recording plays a very important part both in our Navy life and in our civilian life.

HISTORY OF MAGNETIC RECORDERS

In 1888, Oberlin Smith originated the idea of using permanent magnetic impressions to record sounds. Then in 1900, Vladeniar Poulsen brought Mr. Smith's dream to reality. At the Paris Exposition, he demonstrated a Telegraphone. It was a device that recorded sounds onto a steel wire. Although everyone thought it was a great idea, they didn't think it would succeed since you had to use an earphone to hear what was recorded. It wasn't until 1925, when electronic amplifiers were developed, that magnetic recording started to receive the attention it deserved.

The best magnetic recording is the one that produces an output signal identical to the input signal. It didn't take long to realize that the magnetism generated during the recording process didn't vary directly to the current which caused it. This is because there's a *step* in the magnetism curve where it crosses the zero point and changes polarity. This step causes the output signal to be distorted when compared with the input signal. Figure 1-1 shows this step.

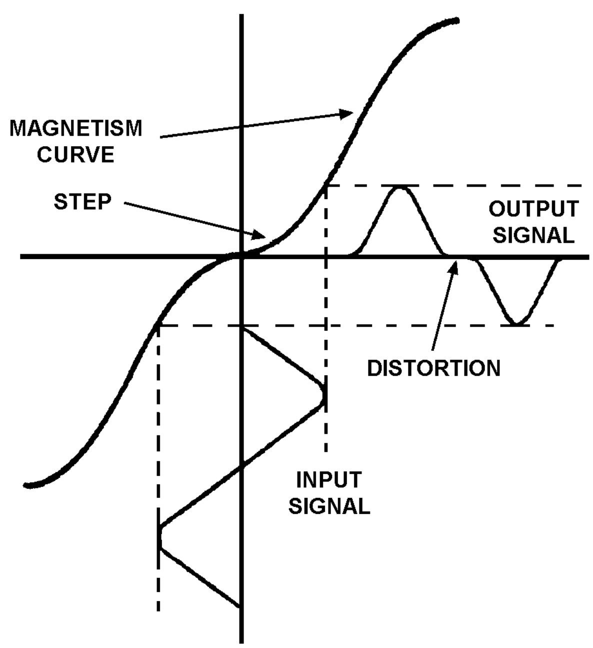

Figure 1-1.—Magnetic recording without bias voltage.

In 1907, Mr. Poulsen discovered a solution to this problem. He discovered *dc* bias. He found that if a fixed dc voltage were added to the input signal, it moved the input signal away from the *step* in the magnetism curve. This prevented the input signal from crossing the zero-point of the magnetism curve. The result is an output signal exactly like the input signal. Figure 1-2 shows this process.

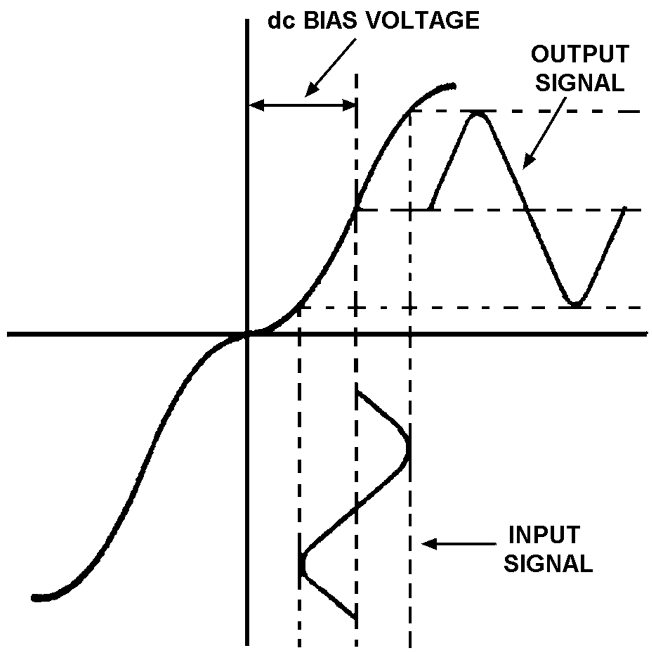

Figure 1-2.—Magnetic recording with dc bias voltage.

Unfortunately, dc bias had its problems. Since only a small portion of the magnetism curve was straight enough to use, the output signal was weak compared with the natural hiss of the unmagnetized tape passing the playback head. This is commonly called poor signal-to-noise ratio (SNR). We'll explain SNR in more detail later.

From the beginning, the U.S. Naval Research Laboratories (NRL) saw great potential in magnetic recording. They were especially interested in using it to transmit telegraph signals at high speed. After electronic amplifiers were invented around 1925, W.L. Carlson and G.W. Carpenter at the NRL made the next important magnetic recording discovery. They found that adding an ac bias voltage to the input signal instead of a fixed dc bias voltage would

- reproduce a stronger output signal
- greatly improve the signal-to-noise ratio
- greatly reduce the natural tape hiss that was so common with dc bias

To make ac bias work, they used an ac frequency for the bias voltage that was well above what could be heard, and a level that placed the original input signal away from both *steps* in the magnetism curve. This resulted in two undistorted output signals that could be combined into one strong output. See figure 1-3.

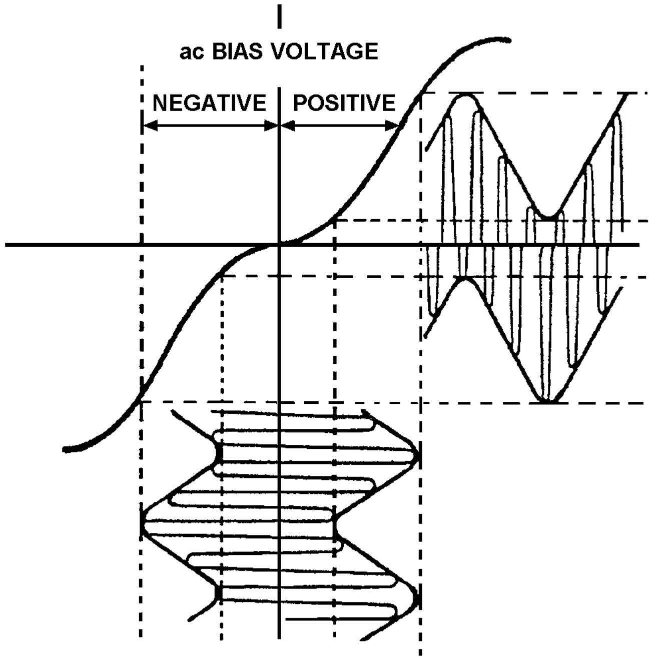

Figure 1-3.—Magnetic recording with ac bias voltage.

Until 1935, all magnetic recording was on steel wire. Then, at the 1935 German Annual Radio Exposition in Berlin, Fritz Pfleumer demonstrated his Magnetophone. It used a cellulose acetate tape coated with soft iron powder. The Magnetophone and its "paper" tapes were used until 1947 when the 3M Company introduced the first plastic-based magnetic tape.

In 1956, IBM introduced the next major contribution to magnetic recording—the hard disk drive. The disk was a 24-inch solid metal platter and stored 4.4 megabytes of information. Later, in 1963, IBM reduced the platter size and introduced a 14-inch hard disk drive.

Until 1966, all hard disk drives were "fixed" drives. Their platters couldn't be removed. Then in 1966, IBM introduced the first removable-pack hard disk drive. It also used a 14-inch solid metal platter.

In 1971, magnetic tape became popular again when the 3M Company introduced the first 1/4-inch magnetic tape cartridge and tape drive. In that same year, IBM invented the 8-inch floppy disk and disk drive. It used a flexible 8-inch platter of the same material as magnetic tape. Its main goal was to replace punched cards as a program-loading device.

The next contribution to magnetic recording literally started the personal computer (PC) revolution. In 1980, a little-known company named Seagate Technology invented the 5-1/4-inch floppy disk drive. Without it, PCs as we know them today would not exist.

From then on, it was all downhill. Magnetic tape became more sophisticated. Floppy disks and disk drives became smaller, while their capacities grew bigger. And hard disk capacities just went through the roof. All of the major hurdles affecting magnetic recording had been successfully cleared, and it was just a matter of refining both its methods and materials.

Q-1. Why did the early inventors of magnetic recording find it necessary to add a fixed dc bias to the input signal?

Q-2. How does dc bias added to the input signal correct the distortion in the output signal?

Q-3. Why does adding dc vice ac bias voltage to the input signal result in a poor signal-to-noise ratio (SNR)?

Q-4. What are three advantages of adding an ac bias voltage to the input signal instead of adding a fixed dc bias voltage?

Q-5. Why does using ac vice dc bias voltage result in a stronger output signal?

PREREQUISITES FOR MAGNETIC RECORDING

To perform magnetic recording, you need three things:

1. An input signal you wish to record.
2. A recording medium. (This is a recording surface that will hold the signal you wish to record.)
3. A magnetic head to convert the input signal into a magnetic field so it can be recorded.

If any one of these are missing, magnetic recording cannot take place.

Input Signal

An input signal can come from a microphone, a radio receiver, or any other source that's capable of producing a recordable signal. Some input signals can be recorded immediately, but some must be *processed* first. This processing is needed when an input signal is weak, or is out of the frequency response range of the recorder.

Recording Medium

A recording medium is any material that has the ability to become magnetized, in varying amounts, in small sections along its entire length. Some examples of this are magnetic tape and magnetic disks. These are thoroughly discussed in chapter 2 of this module.

Magnetic Heads

Magnetic heads are the heart of the magnetic recording process. They are the transducers that convert the electrical variations of your input signal into the magnetic variations that are stored on a recording medium. Without them, magnetic recording isn't possible.

Magnetic heads actually do three different things. They transfer, or *record*, the signal information onto the recording medium. They recover, or *reproduce*, the signal information from the recording medium. And they remove, or erase, the signal information from the recording medium.

MAGNETIC HEAD CONSTRUCTION.—A magnetic head is a magnetic core wrapped with a coil of very thin wire (see figure 1-4). The core material is usually shaped like the letter C, and is made from either iron or ceramic-ferrite material. The number of turns of wire placed on the core depends on the purpose of that specific head. The gap in the core is called a *head gap*. It's here that magnetic recording actually takes place. We'll go into more detail of magnetic head construction in chapter 3.

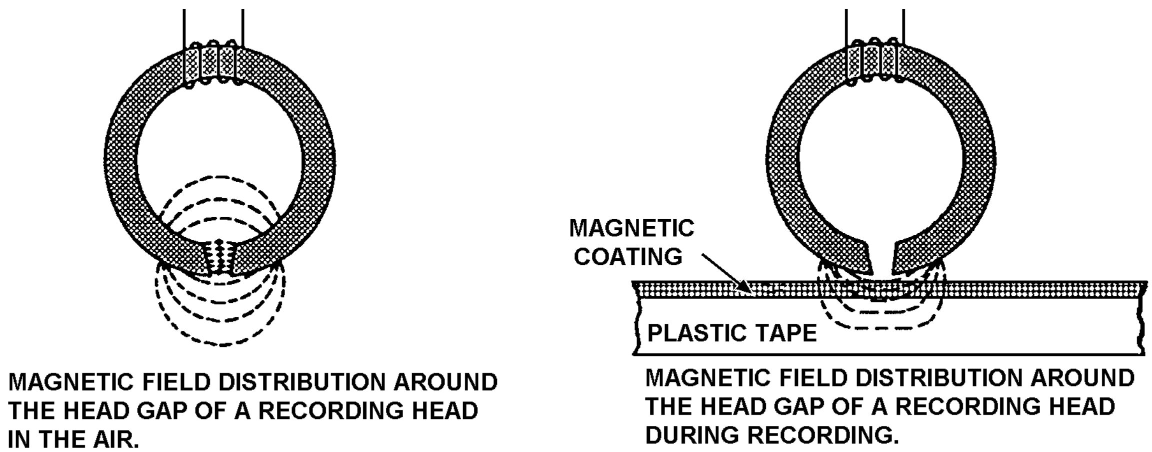

Figure 1-4.—Magnetic field distribution around the head gap.

MAGNETIC HEAD OPERATION.—Whether you're recording on magnetic tapes or disks, all magnetic heads operate the same way. When an electric current passes through the coil of a magnetic head, magnetic field lines associated with the electric current follow paths through the core material. When the magnetic fields get to the head gap, some of them spread outside the core to form a *fringing field*. When a recording medium is passed through this fringing field, it is magnetized in relation to the electric current. This is called magnetic recording. Figure 1-4 illustrates this process.

Q-6. What three things are required to perform magnetic recording?

Q-7. What is the meaning of the term recording medium as it pertains to magnetic recording?

Q-8. What are the three functions of the magnetic heads on a magnetic recording device?

SUMMARY

This chapter briefly covered the historical development of magnetic recording principles and devices. The following is a summary of important points in the chapter.

The **BEST MAGNETIC RECORDING** is one that produces an output signal that is identical to the input signal. However, a *step* in the magnetic curve causes the output signal to be distorted.

In 1907, **DC BIAS** was added to the input signal to remove the distortion in the output signal. But the dc bias caused a weak output signal with a poor SNR. Around 1925, the NRL used AC BIAS to reproduce a stronger output signal and greatly improve the SNR.

To perform magnetic recording, you need (1) an **INPUT SIGNAL**, (2) a **RECORDING MEDIUM**, and (3) a **MAGNETIC HEAD**.

A **RECORDING MEDIUM** is any material that can become magnetized in varying amounts (such as magnetic tape and disks).

MAGNETIC HEADS are used to (1) *record* the signal onto the recording medium, (2) *reproduce* the signal from the recording medium, and (3) *erase* the signal from the recording medium.

ANSWERS TO QUESTIONS Q1. THROUGH Q8.

A-1. Because a step in the magnetism curve where it crosses the zero point and changes polarity causes the output signal to be distorted. See figure 1-1.

A-2. The dc bias moves the input signal away from the step in the magnetism curve. This prevents the input signal from crossing the zero-point of the magnetism curve. See figure 1-2.

A-3. With dc bias, the SNR is poor because only a small portion of the magnetism curve is straight enough to use, thus the output signal is weak compared with the natural tape hiss.

A-4.

- *a. Reproduces a stronger output signal.*
- *b. Greatly improves the SNR.*
- *c. Greatly reduces the natural tape hiss.*

A-5. Because an ac bias voltage of the proper frequency and level places the input signal away from both steps in the magnetism curve. The result is two undistorted output signals that are combined into one strong output.

A-6.

- *a. An input signal.*
- *b. A recording medium.*
- *c. A magnetic head.*

A-7. A recording medium is any material that has the ability to become magnetized, in varying amounts, in small sections along its entire length.

A-8.

- *a. Record the signal onto the recording medium.*
- *b. Reproduce the signal from the recording medium.*
- c. *Erase the signal from the recording medium.*

CHAPTER 2

MAGNETIC TAPE

LEARNING OBJECTIVES

After completing this chapter, you'll be able to do the following:

1. Describe the physical properties of magnetic tape in terms of:

   a. The Three Basic Materials Used To Make Magnetic Tape.

2. The function of the magnetic tape's *base material*, *oxide coating*, and *binder glue*.

3. Describe the two types of magnetic recording tape.

4. Describe the following types of tape errors and their effects on magnetic tape recording: *signal dropout*, *noise*, *skew*, and *level*.

5. Describe the following causes of magnetic tape failure: *normal wear*, *accidental damage*, *environmental damage*, and *winding errors*.

6. Describe the purpose and makeup of tape reels and tape cartridges.

7. Describe the two methods for erasing magnetic tape, the characteristics of automatic and manual tape degaussers, and the procedures for degaussing magnetic tape.

8. Describe the proper procedures for handling, storing, and packaging magnetic tape, tape reels, and tape cartridges.

PHYSICAL PROPERTIES OF MAGNETIC TAPE

The three basic materials used to make magnetic tape are (1) the base material, (2) the coating of magnetic oxide particles, and (3) the glue to bind the oxide particles onto the base material. See figure 2-1.

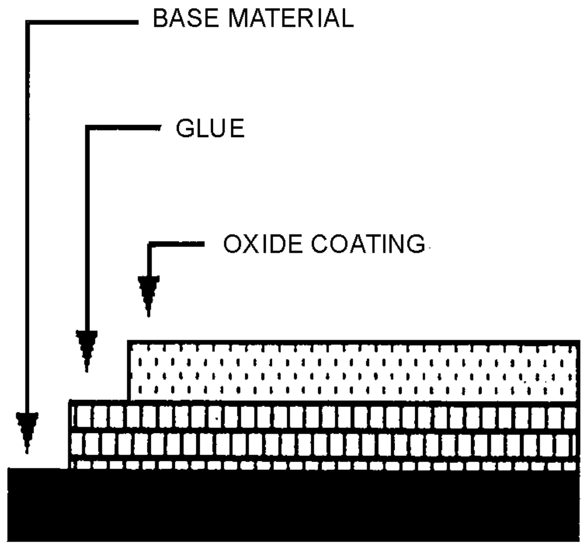

Figure 2-1.—Magnetic tape construction.

BASE MATERIAL

The base material for magnetic tape is made of either plastic or metal. Plastic tape is used more than metal tape because it's very flexible, it resists mildew and fungus, and it's very stable at high temperatures and humidity.

OXIDE COATING

Oxide particles that can be magnetized are coated onto the base material. The most common magnetic particles used are either gamma ferric oxide or chromium dioxide. It's very important that these magnetic particles are uniform in size. If they're not, the tape's surface will be abrasive and will reduce the life of the recorder's magnetic heads.

An ideal magnetic particle is needle-shaped. It's actual size depends on the frequency of the signal to be recorded. Generally, long particles are used to record long wavelength signals (low-frequency signals), and short particles are used to record short wavelength signals (high-frequency signals).

GLUE

The glue used to bond the oxide particles to the base material is usually an organic resin. It must be strong enough to hold the oxide particles to the base material, yet be flexible enough not to peel or crack.

TYPES OF MAGNETIC RECORDING TAPE

There are two basic types of magnetic recording tape in common use: *analog* and *digital*. Analog magnetic tape is used to record, store, and reproduce audio and instrumentation type signals. These signals are usually in a frequency band from very-low frequency (VLF) to 2.5 MHz. Digital magnetic tape is used to record, store, and reproduce computer programs and data. It's base material thickness is about 50 percent thicker than analog magnetic tape. This allows the digital tape to withstand the more strenuous starts and stops associated with digital magnetic recorder search, read, and write functions.

Digital magnetic tape is also held to much stricter quality control standards. It's important not to have any blemishes or coating flaws on the tape's surface. Because, if you lost one digital data bit, your computer program or data would be bad. In contrast, losing one microsecond of an analog signal is not nearly as critical.

Q-1. Magnetic tape is made of what three basic materials?

Q-2. Why is plastic magnetic tape used more than metal tape?

Q-3. Which of the two types of magnetic tape is used to record audio and instrumentation type signals in the VLF to 2.5MHz frequency range?

Q-4. What type of magnetic tape is used to record computer programs and data, and what are the additional thickness and quality standards for this type of tape?

TAPE ERRORS AND THEIR EFFECTS

Four types of tape errors that will degrade the performance of a magnetic recording system are signal dropout, noise, skew, and level (signal amplitude changes).

DROPOUT ERRORS

Signal dropout is the most common and the most serious type of tape error. It's a temporary, sharp drop (50% or more) in signal strength caused by either contaminates on the magnetic tape or by missing oxide coating on part of the tape.

During recording and playback, the oxide particles on the tape can flake off and stick to the recorder's guides, rollers, and heads. After collecting for awhile, the oxide deposits (now oxide lumps) break loose and stick to the magnetic tape. As the tape with the lumps passes over the head, the lumps get between the tape and the head and lift the tape away from the head. This causes the signal dropouts. Although oxide lumps cause most signal dropouts, remember that any contaminate (such as dust, lint or oil) that gets between the tape and the head can cause signal dropouts.

NOISE ERRORS

Noise errors are unwanted signals that appear when no signal should appear. They're usually caused by a cut or a scratch on the magnetic tape. It's the lack of oxide particles at the cut or the scratch that causes the noise error.

SKEW ERRORS

Skew errors only occur on multi-track magnetic tape recorders. The term skew describes the time differences that occur between individual tracks of a single magnetic head when the multi-track tape isn't properly aligned with the magnetic head.

There are two types of skew errors: *fixed* and *dynamic*. Fixed skew happens when properly aligned magnetic tape passes an improperly aligned magnetic head. Dynamic skew happens when misaligned tape passes a properly aligned head. This type of skew is usually caused by one or more of the following:

- A misaligned or worn-out tape transport system.
- A stretched or warped magnetic tape.

- A magnetic tape that is improperly wound on a reel.

LEVEL ERRORS

Magnetic tape is manufactured to have a specified output signal level (plus or minus some degree of error). Level errors happen when the actual output signal level either drops or rises to a level outside the expected range. For example, if a magnetic tape is rated for 10 volts (+/–10%), any output signal level below 9 volts or above 11 volts is a level error. Level errors are caused by an uneven oxide coating on the magnetic tape. This can come from either the original manufacturing process or from normal wear and tear.

Some causes of level errors are permanent and cannot be removed by any means. For example, a crease in the tape, a hole in the oxide, or a damaged edge. Other causes of level errors are removable and may be cleaned off the tape. For example, oxide flakes or clumps, metallic particles, or dirt are removable.

Q-5. What are four types of tape errors that can degrade a magnetic recording system's performance?

Q-6. What are signal dropouts, and what are two tape defects that can cause signal dropouts?

Q-7. What is the most common and most serious type of signal dropout?

Q-8. You see a build-up of dust and lint on the take-up reel of a tape recorder. This can cause which of the four types of tape errors?

Q-9. What type of tape error causes noise to appear on the tape when no signal should appear? What causes this type of tape error?

Q-10. The multi-track tape recorder in your computer system has a fixed skew error. What does this mean and what is the probable cause?

Q-11. Some tapes you are using may have level errors. What does this mean and what is the cause?

CAUSES OF MAGNETIC TAPE FAILURE

Tape failure happens when a magnetic tape's performance degrades to a point where it's no longer usable. The *exact* point where failure occurs will vary, depending on the type of tape and how it is used.

There are four main causes for tape failure:

1. Normal wear (natural causes)

2. Accidental damage

3. Environmental damage

4. Winding errors

NORMAL WEAR

Normal wear occurs because the tape must come in contact with fixed surfaces, such as a recorder's magnetic heads, rollers, and guides. Over time, this repeated contact with the fixed surfaces causes excessive dropout errors and makes the tape unusable.

ACCIDENTAL DAMAGE

Accidental tape damage that causes tape failure is any damage that wouldn't normally occur under ideal operating and handling conditions. It can be caused by either a human operator or the tape recorder itself. Accidental tape damage caused by human operators can range from accidentally dropping a reel of magnetic tape to improperly threading a magnetic tape recorder. Accidental tape damage caused by recording equipment can occur if the recorder is poorly designed or if the tape transport mechanism is adjusted improperly.

ENVIRONMENTAL DAMAGE

The negative effect of environmental extremes on tape can also cause tape failure. Magnetic tape is very flexible and can be used in a wide range of environmental conditions. It's designed for use in a temperature range of about 2 to 130 degrees Fahrenheit (−20 to 55 degrees Celsius), and in a relative humidity range of about 10 to 95%. Of course, these numbers are the *extreme*. Ideally, magnetic tape should be used and stored at a temperature of about 60 to 80º F (room temperature), and in a relative humidity of about 40 to 60%.

Large changes from the ideal relative humidity cause tape to expand or contract and thus affect the uniformity of a tape's oxide coating. High relative humidity causes the tape to stretch and increases the tape's friction. The increased friction causes increased head wear, head clog by oxide particles, and head-to-tape sticking. Low relative humidity encourages oxide shedding and increases static build-up on tape surfaces, causing the tape to collect airborne contaminants.

The effects of exceeding the ideal temperature and humidity ranges described above can cause the following environmental damage to magnetic tape: *tape deformation, oxide shedding, head-to-tape sticking, layer-to-layer sticking, dirt build-up, and excessive tape and head wear.*

Tape Deformation

Magnetic tapes are wound onto tape reels with tension applied. This tension causes great layer-to-layer pressure within the reel pack. Changes in temperature and humidity can cause the backing material to expand or contract, creating even more pressure. All of this pressure causes the tape to become deformed or warped.

Oxide Shedding

At temperatures above 130º F, a tape's oxide coating tends to become soft. At temperatures below 2º F, the oxide coating tends to be brittle. In both cases, the oxide coating will shed, flake off, or otherwise become separated from the base material. These free pieces of oxide will then stick to parts of the tape transport, to the magnetic heads, or back onto the tape and cause dropout or level errors.

Head-to-Tape Sticking

At higher temperatures, the tape binder glue can soften to the point where it will stick to the recorder's magnetic head. This head-to-tape sticking causes jerky tape motion.

Layer-to-Layer Adhesion

When reels of magnetic tape are stored at higher temperatures, the tape's binder glue may melt and cause the layers of tape to stick to one another. In very severe cases, layer-to-layer adhesion can separate the oxide coating from the base material and completely destroy a tape.

Dirt Build-up

Dirt build-up happens when the relative humidity level is less than 10%. The low humidity causes static electricity that attracts dirt and dust which builds up on the magnetic tape and other parts of the magnetic tape recorder.

Excessive Tape and Head Wear

When the relative humidity is more than 95%, the high humidity causes increased friction as the tape passes over the heads. This, in turn, causes excessive tape and head wear.

Q-12. What is tape failure?

Q-13. What are four main causes of tape failure?

Q-14. How does normal wear cause tape failure?

Q-15. Accidental damage to magnetic tape is normally caused by the tape recorder itself or by human operators of the recorder. What are three frequent causes of such accidental damage?

Q-16. Environmental damage to magnetic tape can occur when the tape is stored in an area that exceeds what <u>ideal</u> temperature and humidity ranges?

Q-17. What six types of environmental damage can occur to tapes in storage when the ideal temperature and humidity ranges are exceeded?

Q-18. After using a tape that was stored in an area where temperatures exceeded 130º F you notice pieces of oxide sticking to the recorder's tape-transport mechanism, to its magnetic heads, and onto the tape. What is the probable cause of these symptoms?

Q-19. Your activity stores its magnetic tape in an area where the temperature is 100º F. What two types of environmental damage could occur that would make these tapes unusable?

Q-20. When the relative humidity is below 10%, what happens to magnetic tape and parts of a tape recorder that could cause environmental damage?

Q-21. How does relative humidity over 95% cause excessive tape and head wear?

WINDING ERRORS

Winding errors are another cause of tape failure. They happen when improper winding practices create an excessive or uneven force as the tape is being wound onto a tape reel. The form taken by the tape after it is wound onto the reel is called the *tape pack*. Winding errors can cause a deformed tape pack that will prevent good head-to-tape contact.

In most cases, a deformed tape pack can be fixed simply by rewinding it onto another reel at the proper tension and at the right temperature and humidity. The four most common types of tape pack deformation are:

1. Cinching
2. Pack-slip
3. Spoking

4. Windowing

Cinching

Cinching happens when a tape reel is stopped too quickly. The sudden stop causes the outer layers of magnetic tape to continue to spin after the inner layers have stopped. This causes any loosely wound tape within the pack to unwind and pile up. Figure 2-2 shows an example of a cinched tape pack (note the complete foldover of one tape strand).

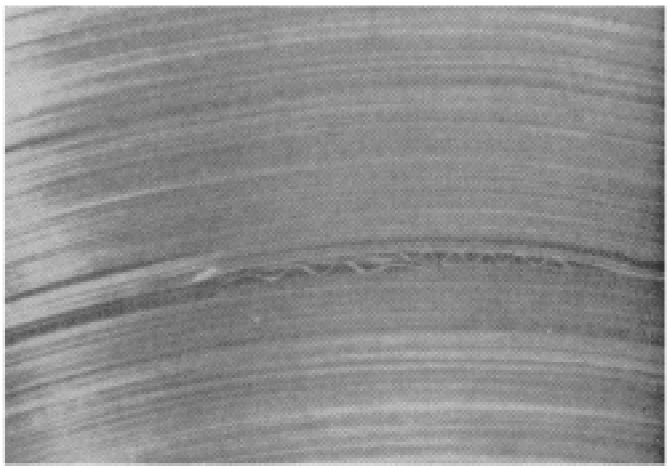

Figure 2-2.—Example of cinched tape pack.

Pack Slip

Pack slip happens when the tape is loosely wound on the reel and is exposed to excessive vibration or too much heat. This causes the tape to shift (side-to-side), causing *steps* in the tape pack. When a tape reel with pack slip is used, the magnetic tape will unwind unevenly and rub against the sides of the tape reel or the recorder's tape guides. This can damage the magnetic tape and cause oxide shedding. Figure 2-3 shows an example of pack slip.

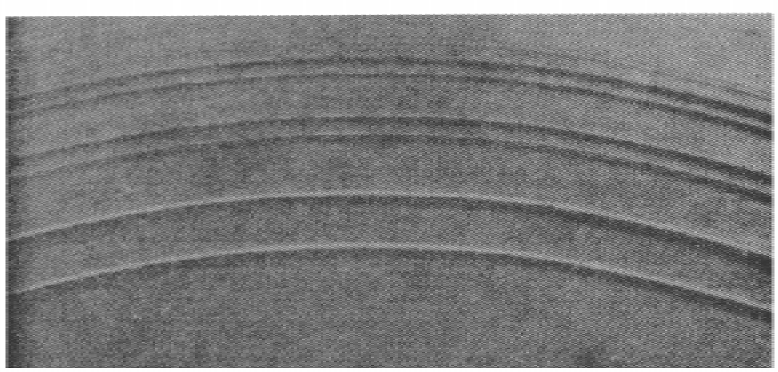

Figure 2-3.—Example of pack slip.

Spoking

Spoking happens when magnetic tape is wound onto the tape reel with the tension increasing toward the end of the winding. The higher tension on the outside of the tape pack causes the inner pack to buckle and deform. Spoking is also caused by the uneven pressures created when a tape is wound on a reel that has a distorted hub, or when the tape is wound over a small particle that is deposited on the hub. Figure 2-4 shows a spoked tape pack.

Figure 2-4.—Example of spoked tape pack.

Windowing

Windows are voids or see-through air gaps in the tape winding. They happen when magnetic tape is loosely wound onto a tape reel, and especially when the loosely wound reel is later exposed to extreme heat or humidity. Figure 2-5 shows a windowed tape pack.

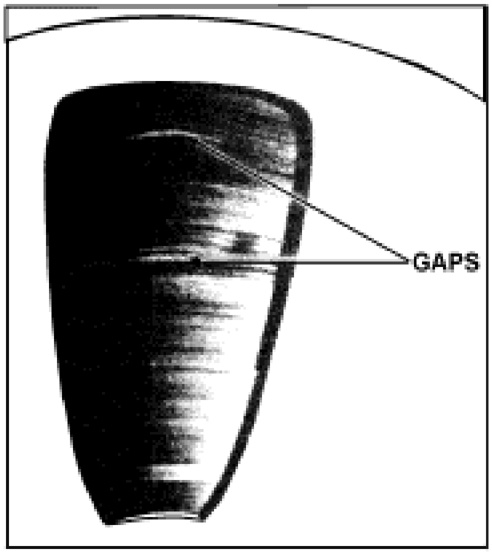

Figure 2-5.—Example of windowed tape pack.

Q-22. Tape winding errors can cause a deformed tape pack. What are four common types of tape pack deformation?

Q-23. After rewinding a tape onto its supply reel, you examine the tape pack and notice pile-ups of tape resembling the example in figure 2-2. What causes this condition?

Q-24. You notice steps in the tape pack such as those in figure 2-3. What causes this and how does it damage the magnetic tape?

Q-25. A tape pack is buckled and deformed as shown in figure 2-4. What are three possible causes for this condition?

Q-26. A tape pack has gaps in the tape winding as shown in figure 2-5. What causes this condition?

TAPE REELS AND TAPE CARTRIDGES

There are two types of magnetic tape carriers: tape *reels* and *tape* cartridges. Both types can be used for either analog or digital recording. Tape cartridges are normally used only for digital recording.

TAPE REELS

Tape reels are used on magnetic recorders that use a manually loaded tape supply reel and a separate take-up reel. A reel's purpose is to protect the magnetic tape from damage and contamination. It can be made of plastic, metal, or glass. A reel has two parts, the hub and the flanges.

A tape reel is designed to hold magnetic tape on its hub without letting the magnetic tape touch the sides of the flanges. Contrary to popular belief, the flanges <u>are not</u> designed to *guide* the magnetic tape onto the tape reel.

TAPE CARTRIDGES

Tape cartridges hold a spool of magnetic tape in the same way as tape reels, except that the inside of the cartridge contains both the supply reel and the take-up reel. Unlike tape reels which must be manually loaded into a recorder, when you insert a tape cartridge into a recorder, it's automatically loaded and ready to use. Figure 2-6 shows two typical tape cartridges.

Figure 2-6.—Typical tape cartridges.

Q-27. When winding a tape onto a plastic or metal reel, should the tape ever touch the reel's flanges?

TAPE ERASING AND DEGAUSSING

One advantage of magnetic tape is that you can erase what you've previously recorded, and record on the same tape again and again. The erasing is done by demagnetizing the magnetic tape. You demagnetize a magnetic tape by exposing it to a gradually decreasing ac (alternating current) magnetic field. There are two ways to do this: (1) with an *erase head* that's mounted on the magnetic recorder, or (2) with a separate *tape degausser*.

ERASE HEADS

A magnetic recorder's erase head erases magnetic tape by saturating it with an ac signal that's higher in frequency than the frequency range of the recorder itself. This method of erasing a tape works well in some cases, but it's not the best way because:

- It's slow; the tape must be run through the recorder to be erased.

- If the erase head is not completely demagnetized, it may not do a complete erasure.
- Some recorders do not have erase heads installed.

MAGNETIC TAPE DEGAUSSERS

By far, the best way to erase a magnetic tape is to use a separate magnetic tape degausser. There are two types of degaussers: *automatic* and *manual*.

Automatic Tape Degausser

Automatic degaussers erase magnetic tape by automatically moving the whole tape reel or cartridge slowly and steadily in and out of an intense ac magnetic field. This type of degausser erases a tape very well. Some automatic degaussers are made specifically for tape reels, and some are made for both tape reels and tape cartridges. Figure 2-7 shows a typical automatic degausser.

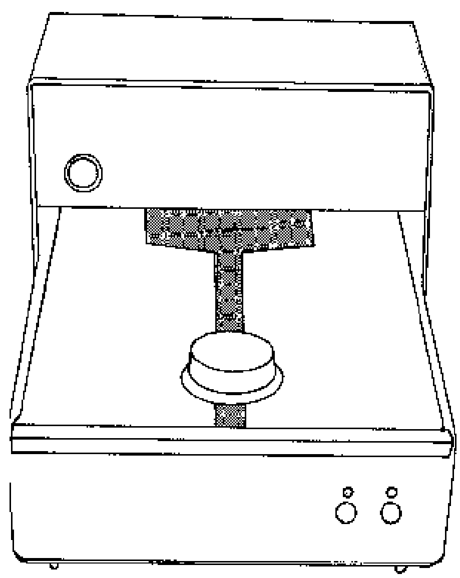

Figure 2-7.—Automatic tape degausser.

Manual Tape Degausser

Both manual and automatic tape degaussers use the same electronic principles for erasing magnetic tape. However, the manual version is much more portable. It's small, hand-held, and much less expensive. Figure 2-8 shows a typical manual degausser.

Figure 2-8.—Manual tape degausser.

To erase tapes with a manual degausser:

1. Place the tape reel or cartridge to be erased on a flat surface.

2. Hold the degausser very close to the magnetic tape and turn it on.

3. Slowly rotate the degausser in circles around the tape reel or cartridge for a few seconds.

4. Then slowly move it away until you're about 12 to 14 inches away from the tape reel or tape cartridge.

5. Turn off the degausser.

Q-28. *What are two disadvantages of using a recorder's erase head to erase data recorded on a magnetic tape?*

Q-29. *What method for erasing magnetic tape is much more effective and reliable than using a recorder's erase head?*

HANDLING, STORING, AND PACKAGING MAGNETIC TAPE

Today's magnetic tape coatings can store recorded signals for years. The data recorded is a permanent record that won't fade or weaken with age. And, it'll remain unchanged until it's altered by another magnetic field or until the tape coating deteriorates.

When magnetic tape recordings are ruined, the cause is usually poor handling, improper storage, or shipping damage. If you want your tape recordings to last a long time, you need to know how to properly handle, store, and ship magnetic tape.

HANDLING MAGNETIC TAPE

A magnetic tape reel or cartridge should always be in one of two places, either mounted on a tape recorder or in its storage container. When you handle magnetic tape, follow these rules:

- DO use extreme care when handling magnetic tape. Careless handling can damage magnetic tape, tape reels, and tape cartridges. Always hold a tape reel by the hub, NEVER by the flanges, and NEVER handle or touch the working tape surface.

- DO NOT let the magnetic tape trail on the floor. Even though the end of the tape may not have data stored on it, it can pick up dirt and dust that ends up on the recorder.

- DO clean your hands before handling magnetic tape. You can contaminate magnetic tape with dirt and oils from dirty hands.

- DO mount tape reels and cartridges properly. Improperly seated tape reels can cause unnecessary wear and tear on the magnetic tape.

- DO replace any warped take-up reels, as they can damage magnetic tape.

- DO keep the magnetic recorder and its take-up reel clean. Magnetic tape can pick up dirt and dust from the recorder itself.

- DO NOT use the top of a magnetic recorder as a work area. This can expose the magnetic tape to dirt, excessive heat, and stray magnetic fields.

- DO NOT allow eating, drinking, or smoking in areas where magnetic tape or devices are exposed.

STORING MAGNETIC TAPE

Most magnetic tape reels and cartridges spend a lot of time in storage. It's very important that you protect the stored tape from physical damage and the damaging effects of contamination and temperature and humidity extremes. If you don't, damage to the tape pack such as oxide shedding, layer-to-layer sticking, and tape deformation can happen. To protect magnetic tape from damage during storage, follow these rules:

- DO make sure that magnetic tape is wound properly on the reel hub and at the proper tension.

- DO always store tape reels vertically. DO NOT lay them on their side.

- DO maintain a proper environment. Keep the storage area clean, and at a 60 to 80F degree temperature and a 40 to 60% relative humidity.

- DO NOT store magnetic tapes near any equipment that generates stray magnetic fields.

- DO handle <u>all</u> tape reels and cartridges as gently as possible.

- DO NOT eat, drink, or smoke in a magnetic tape storage area.

PACKAGING MAGNETIC TAPE FOR SHIPPING

There may be times when you are asked to package magnetic tape reels or tape cartridges for shipment. If you want the tape to arrive in good condition, you must pack it properly to protect it from damage. The packaging you use must protect the tape reels or cartridges from impact, vibration, and temperature and humidity changes. Here are some simple rules to follow:

- DO always package tape reels so that they're supported by their hub. This prevents any pressure on the reel's flanges that might flex the flanges against the tape pack. Figure 2-9 shows a shipping box that supports the tape reel by the hub.

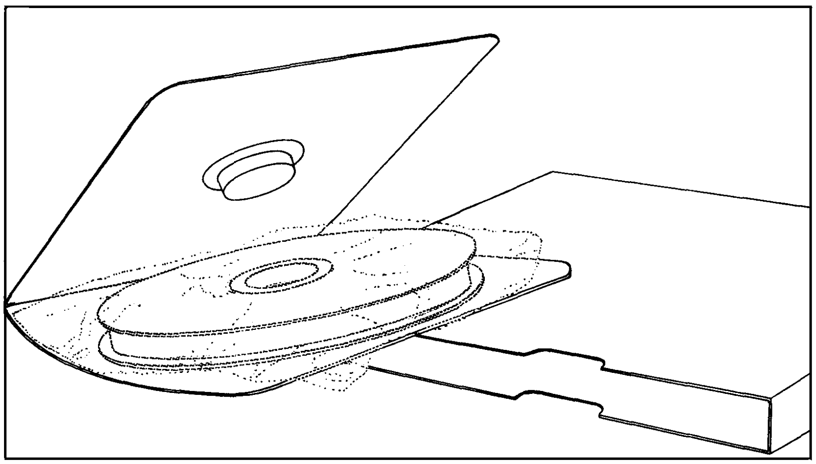

Figure 2-9.—Reel box that supports reel by the hub.

- DO always use reel bands where available. Reel bands are for placement around the outside edges of the reel flanges to help prevent the flanges from flexing and damaging the tape.

- DO always ship magnetic reels in a container designed so its normal positioning is with the reels in a vertical position. This will prevent the tape pack from shifting and damaging the edges of the magnetic tape.

- DO always package tape cartridges in their shipping cases. Tape cartridges are more durable than tape reels, but they still need to be protected during shipment.

Q-30. When magnetic tapes are ruined, what three factors are normally the cause?

Q-31. What is the correct way to hold a magnetic tape reel?

Q-32. The take-up reel on your recorder is warped. What should you do to/with the reel?

Q-33. If magnetic tape is stored in areas with temperature and humidity extremes, what are three types of tape damage that may occur?

Q-34. List four rules you should follow when storing magnetic tape to protect it from damage.

Q-35. When packaging tape reels or cartridges for shipping, what are four rules you should follow to protect the tape reels from impact and vibration?

SUMMARY

Now that you've finished chapter 2, you should be able to (1) describe the physical properties of magnetic tape, (2) recognize the four most common magnetic tape errors, (3) recognize the four causes of tape failure, (4) describe the two methods for erasing magnetic tape, and (5) use the proper procedures for handling, storing, and packaging magnetic tape, tape reels, and tape cartridges. The following is a summary of the important points in this chapter.

The three **BASIC MATERIALS** used to make magnetic tape are the (1) base material, (2) the oxide particles, and (3) the binder glue.

ANALOG and **DIGITAL** are the two basic types of magnetic tape in common use.

BLEMISHES OR **COATING FLAWS ON DIGITAL TAPE** can easily ruin the data or the computer program stored on the tape.

SIGNAL DROPOUT, NOISE, SKEW, AND **LEVEL** are four types of tape errors. Dropout errors are the most common.

OXIDE LUMPS accumulated on the tape cause most dropout errors. Other causes are dust or lint on the tape, or missing oxide coating on part of the tape.

MAGNETIC TAPE FAILURE has four main causes: (1) normal wear, (2) accidental damage, (3) environmental damage, and (4) winding errors.

IDEAL TEMPERATURE AND HUMIDITY RANGES for using and storing magnetic tape are 60 to 80º F and 40 to 60% relative humidity.

ENVIRONMENTAL TAPE DAMAGE caused by excessive temperature or humidity includes the following: (1) tape deformation, (2) oxide shedding, (3) head-to-tape sticking, (4) layer-to-layer sticking, (5) dirt buildup, and (6) excessive tape and head wear.

WINDING ERRORS can cause tape pack deformation. The four most common types are: (1) cinching, (2) pack slip, (3) spoking, and (4) windowing.

The **TWO PARTS OF A TAPE REEL** are the hub and the flanges. The tape should be wound on the hub. No part of the tape should be touching the flange sides.

ERASE HEADS AND **TAPE DEGAUSSERS** are two methods for erasing tape. Degaussers are the fastest and the most reliable.

Rules for **HANDLING MAGNETIC TAPE** are (1) always hold the reel by the hub, not the flanges, (2) never touch the working tape surface, (3) replace warped or damaged reels, and (4) mount reels and cartridges properly.

Rules for **STORING MAGNETIC TAPE** are (1) wind tape properly on the reel hub, (2) store tapes vertically, (3) keep storage area clean and at proper temperature and humidity levels, and (4) store tapes away from equipment that generates stray magnetic fields.

Rules for **PACKAGING TAPE FOR SHIPPING** are (1) support reels by their hubs, (2) use reel bands, (3) pack reels in containers vertically, and (4) keep tape cartridges in their shipping cases.

ANSWERS TO QUESTIONS Q1. THROUGH Q35.

A-1.

a. Base material.

b. Coating of magnetic oxide particles.

c. Glue that bonds the particles to the base.

A-2. Plastic tape is used more than metal because it's more flexible, resists mildew and fungus, and is very stable at high temperatures and humidity.

A-3. Analog magnetic tape.

A-4. Digital magnetic tape is for computer programs and data. Its base material is about 50% thicker. The tape's surface must not have blemishes or coating flaws because losing even one digital data bit could ruin the recorded computer program or data.

A-5. Signal dropout, noise, skew, and level. Dropout is the most common.

A-6. Dropouts are temporary, sharp drops (50% or more) in signal strength. They're caused by contaminates that lift the tape away from the magnetic head, or when magnetic oxide coating is missing on part of the tape.

A-7. Oxide particles that get onto the magnetic tape.

A-8. Signal dropout errors and level errors. The dust and lint on the reel will eventually get onto the tape where it can get between the tape and the recorder's heads.

A-9. Noise error is usually caused by a cut or a scratch on the magnetic tape.

A-10. Skew means there are time differences between the individual tracks of a multi-track recorder's magnetic head. It happens when the tape isn't properly aligned with the head. Fixed skew happens when the tape passes over an improperly aligned magnetic head.

A-11. The actual output signal level of the tape exceeds the manufacturer's specified range for the output signal level (+ / – 10%). It's caused by an uneven oxide coating on the tape due to worn tape or defective manufacture.

A-12. Tape's performance degrades to a point where it's no longer usable.

A-13. Normal wear, accidental damage, environmental damage, and winding errors.

A-14. Repeated contact with a recorder's fixed surfaces such as magnetic heads, tape rollers, and tape guides.

A-15.

a. Improperly adjusted tape transport mechanism.

b. Dropping a reel of tape.

c. Improperly threading tape.

A-16. Ideally, use and store tape at 60 to 80º F and at 40 to 60% relative humidity.

A-17. Tape deformation, oxide shedding, head-to-tape sticking, layer-to-layer sticking, dirt build-up, and excessive tape and head wear.

A-18. Oxide shedding. At temperatures above 130º F, oxide coating becomes soft and sheds.

A-19. Head-to-tape sticking and layer-to-layer adhesion.

A-20. Dirt build-up caused by static electricity.

A-21. High humidity causes increased friction as the tape passes over the heads.

A-22. Cinching, pack slip, spoking, and windowing.

A-23. The tape is stopped too quickly when winding or rewinding.

A-24. Pack slip. It's caused by loosely wound tape on a reel that is exposed to excessive vibration or heat. The vibration or heat causes the tape to shift, causing steps in the tape pack. The uneven tape will then rub against the reel's sides and the recorder's tape guides.

A-25.

- *a. Reel has a distorted hub,*
- *b. tape wound over small particle deposited on hub, and*
- *c. tape wound on reel with tension increasing toward end of winding.*

A-26. Tape is loosely wound on reel.

A-27. No. The reel is designed to hold the tape on its hub without letting the tape touch the sides of the flanges.

A-28. Using an erase head is slow, and it may not completely erase the tape.

A-29. Using a magnetic tape degausser.

A-30. Poor handling, improper storage, or shipping damage.

A-31. Always hold reel by the hub, never by the flanges. Never touch the working tape surface.

A-32. Always replace a warped reel.

A-33. Oxide shedding, layer-to-layer sticking, and tape deformation.

A-34.

- *a. Make sure the tape is wound properly on the reel hub,*
- *b. store tapes vertically,*
- *c. keep storage area at right temperature and humidity,*
- *d. store away from equipment that generates stray magnetic fields.*

A-35.

a. *Package reels so they're supported by their hub,*

b. *use reel bands,*

c. *package reels in vertical position,*

d. *package tape cartridges in their shipping cases.*

CHAPTER 3

MAGNETIC TAPE RECORDER HEADS

LEARNING OBJECTIVES

After completing this chapter, you'll be able to do the following:

1. Describe the construction, function, and placement of magnetic tape recorder record, reproduce, and erase heads.
2. Describe the preventive maintenance requirements for magnetic tape recorder heads.

MAGNETIC TAPE RECORDER HEADS

Magnetic tape recorder heads are the *heart* of magnetic tape recording, because it's the magnetic heads (as we'll call them in this chapter) that actually:

1. Record signal or data information onto magnetic tape
2. Reproduce (play back) signal or data information from magnetic tape
3. Erase any signal or data off of magnetic tape

To do these things, a magnetic tape recorder can have up to three different heads installed: one head for recording, one for reproducing, and one for erasing. Some magnetic tape recorders will use the same head for both recording and reproducing. Figure 3-1 shows a typical multitrack magnetic head.

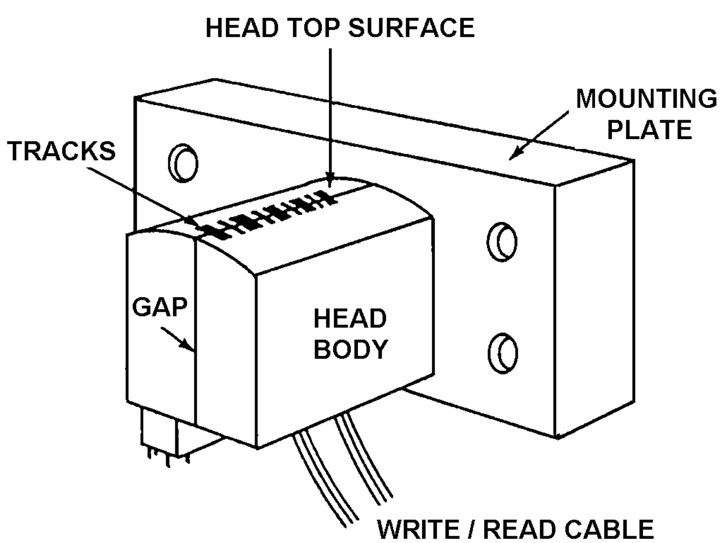

Figure 3-1.—Typical multitrack magnetic tape recorder head.

MAGNETIC HEAD CONSTRUCTION

Magnetic head construction is *basically* the same for all magnetic heads. They're all made up of a magnetic core wrapped with a coil of very thin wire. But, there's where the similarity ends. From here on, each magnetic head is built to perform a specific job. Will the head be used on a single track recorder? Will it be used on a multitrack recorder? Will it be a record head or a reproduce head? Or, will it be an erase head? What frequency will it be recording and/or reproducing? The answers to these questions will determine the final construction of a magnetic head.

Figure 3-2 shows the construction of a typical multitrack magnetic head. Magnetic cores are wound with very thin wire, cemented together, and placed inside a half-bracket. A tip piece is then placed on top of the ferrite core, and the two half-brackets are assembled together. It's during this final assembly process that the headgap and the resulting frequency response of the magnetic head are determined. After some final contouring to give the magnetic head its curved face, it's ready for use.

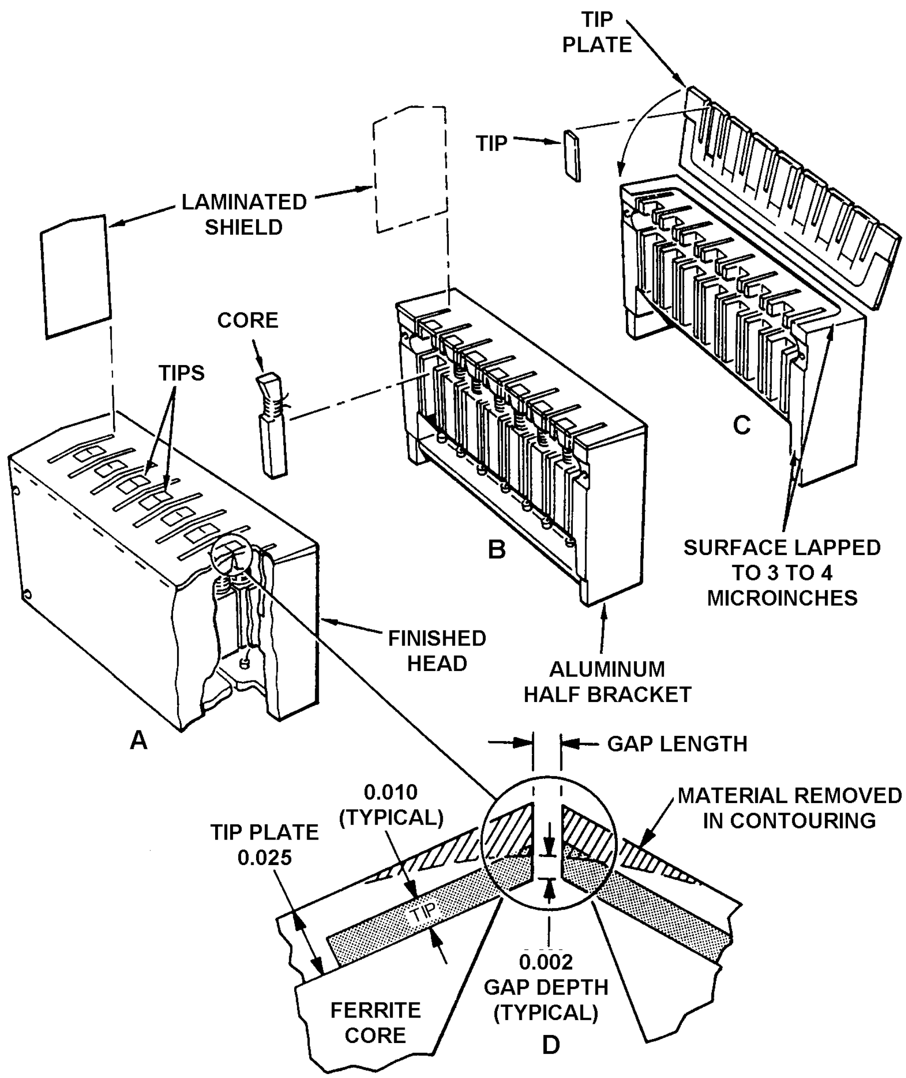

Figure 3-2.—Multitrack tape recorder head construction.

Record and Reproduce Heads

Record and reproduce heads convert and transfer electrical signals onto and off of magnetic tape. The maximum frequency these heads can transfer depends on the size of the headgap and the speed of the magnetic tape (we'll discuss speed in the next chapter). Most record and reproduce heads are in one of these three general bandwidth categories:

1. Narrowband—100 Hz to 100 kHz
2. Intermediate band—100 Hz to 500 kHz
3. Wideband—400 Hz to 2 mHz

The only physical difference between a record head and a reproduce head is in the number of turns of wire on the core. A reproduce head will have more turns than a record head. This is because reproduce heads must be able to recover low-level signals from magnetic tape. The extra turns of wire allow the reproduce head to output the highest level possible and at a good signal-to-noise level.

Record heads are always placed before reproduce heads on magnetic tape recorders. This allows you to monitor signals that you're recording. Figure 3-3 shows the placement of record and reproduce heads. Figure 3-4 shows some of the typical track arrangements used.

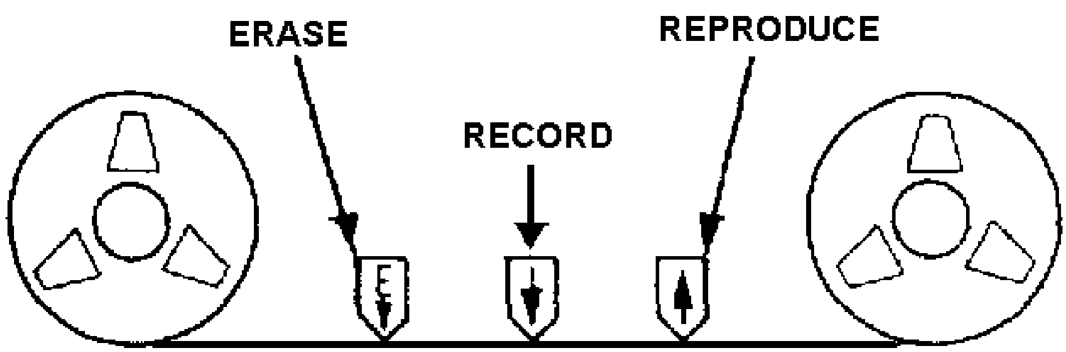

Figure 3-3.—Placement of magnetic tape recorder heads.

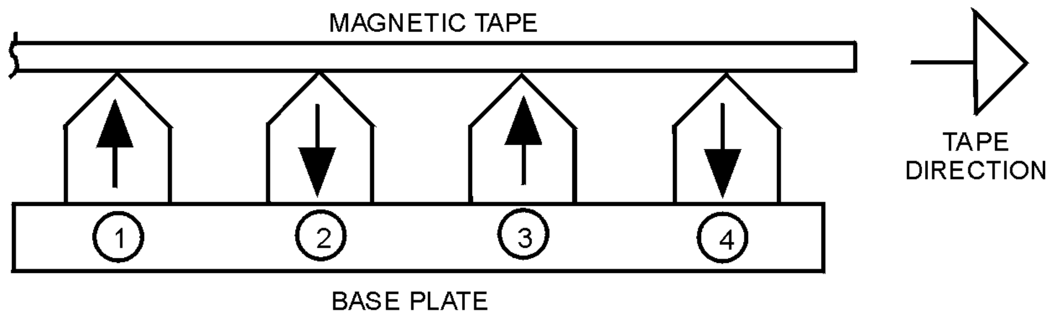

1 - ODD RECORD STACK
2 - ODD REPRODUCE STACK
3 - EVEN RECORD STACK
4 - EVEN REPRODUCE STACK

TRACK NUMBERING

HEAD STACK	14 TRACK	28 TRACK	42 TRACK
1	1-13 RECORD	1-27 RECORD	1-41 RECORD
2	1-13 REPRODUCE	1-27 REPRODUCE	1-41 REPRODUCE
3	2-14 RECORD	2-28 RECORD	2-42 RECORD
4	2-14 REPRODUCE	2-28 REPRODUCE	2-42 REPRODUCE

Figure 3-4.—Magnetic head track placement.

Erase Heads

Erase heads transfer a signal to the magnetic tape that causes the magnetic particles to assume a *neutralized* or *erased* state. To do this, a high current signal that is 3 to 5 times higher in frequency than the maximum frequency response of the record and reproduce heads is used. In some audio recorders, a simple direct current (dc) voltage is used.

Erase heads are always placed before the record and the reproduce heads on tape recorders. This allows you to erase the magnetic tape before it's recorded on. Figure 3-3 shows the placement of erase heads.

Q-1. Magnetic tape recorders can have up to three different heads installed. What are the three functions performed by a recorder's heads?

Q-2. The way a magnetic head will be used determines how it is constructed. Name three factors that determine the final construction of a magnetic head.

Q-3. What two specifications determine the maximum frequency that a recorder's record and reproduce heads will be able to transfer?

Q-4. Most record and reproduce heads are in one of what three bandwidth categories?

Q-5. Why are record heads always placed before reproduce heads on recorders?

Q-6. A recorder's erase head is always placed in what sequence on the record/reproduce track?

MAGNETIC HEAD MAINTENANCE

It's very important to *regularly* maintain magnetic heads. If you do, you'll greatly reduce the chance of getting a poor recording or playback. Regular preventive maintenance will also increase the life of the magnetic heads. There are two things you must do to properly maintain magnetic heads: (1) keep them clean, and (2) keep them demagnetized.

Cleaning Magnetic Heads

Through use, magnetic heads pick up dirt, dust, lint, and oxide particles from the magnetic tape. These particles collect on the magnetic head and, if left unchecked, could cause signal dropout errors that degrade the quality of recording and playback. To keep magnetic heads clean, regularly clean them with a cotton-tipped applicator soaked in either isopropyl alcohol or in a magnetic head cleaner recommended by the recorder's manufacturer. A good rule of thumb is to clean the heads each time you change a tape reel or cartridge.

Demagnetizing Magnetic Heads

Magnetic heads can become magnetized from many sources. It could happen

- during ac power losses,
- during testing or alignment,
- because of stray magnetic fields,
- from normal use.

No matter the cause, magnetized magnetic heads degrade the quality of the magnetic recording or playback.

To demagnetize magnetic heads, you'll use a hand-held degausser. It could be like the one shown in figure 3-5, or like the manual degausser shown in the previous chapter. No matter how they look, they all generate an ac magnetic field that demagnetizes the metal parts of a magnetic head.

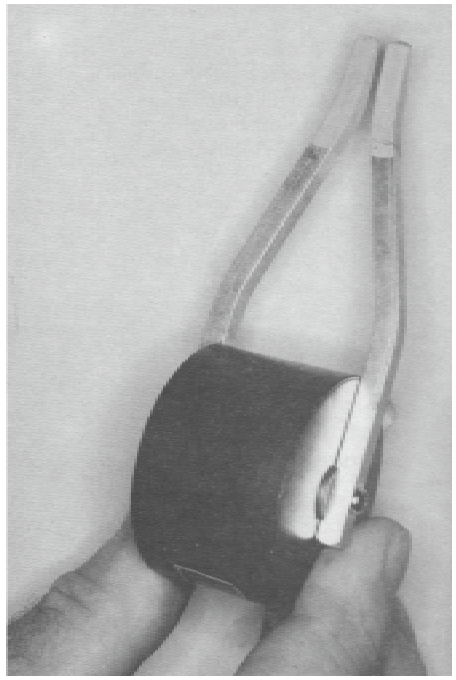

Figure 3-5.—Hand-held head degausser.

The procedure for demagnetizing a magnetic head is similar to the procedure for degaussing a magnetic tape. Here are the basic steps:

1. Remove the tape (reel or cartridge) from the magnetic recorder.

2. Holding the degausser an arm's length away from the magnetic head, energize the degausser.

3. *Slowly* bring the degausser closer and closer to the magnetic head. **Don't touch the head with the degausser**.

4. Move the degausser back and forth across the head for 15 to 30 seconds. Figure 3-6 shows how this looks.

5. *Slowly* move the degausser away from the magnetic head. When the degausser is an arm's length away, de-energize it.

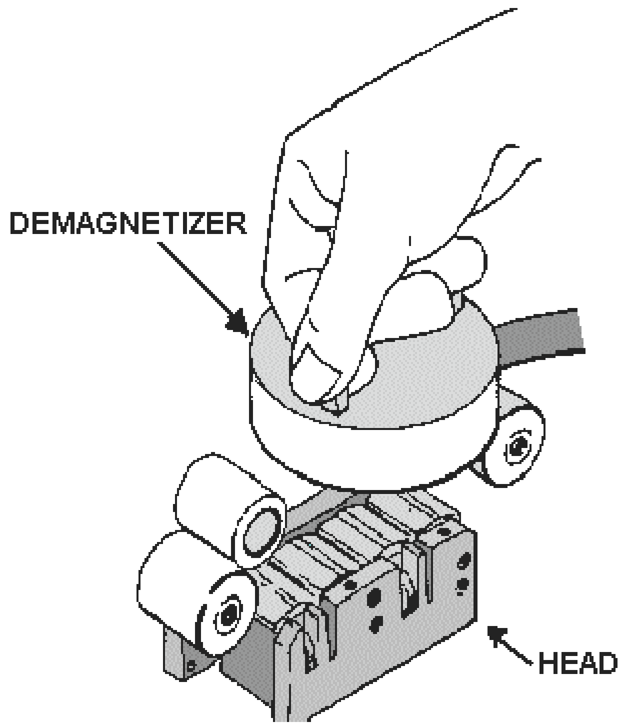

Figure 3-6.—Demagnetizing magnetic heads with a degausser.

That's all there is to it. It's hard to determine *exactly* how often magnetic heads should be de-magnetized. Manufacturer's recommendations vary from every 8 to 25 hours of operation. To be safe, check the equipment's technical manual.

Q-7. What two preventive maintenance actions must you do regularly to increase magnetic head life and to ensure good tape recording and playback?

Q-8. How should you clean your recorder's magnetic heads?

Q-9. What are four sources that can cause magnetic heads to become magnetized?

Q-10. What type of equipment should you use to demagnetize your recorder's magnetic heads?

Q-11. How often should you demagnetize a recorder's magnetic heads?

SUMMARY

Now that you've finished chapter 3, you should be able to (1) describe the construction of magnetic tape recorder heads; (2) describe the purpose and placement of record, reproduce, and erase heads; and (3) describe the preventive maintenance requirements for tape recorder heads. The following is a summary of important points in this chapter:

Magnetic tape recorders have up to **THREE MAGNETIC HEADS** to perform the erase, record, or reproduce function.

Three factors that determine the **CONSTRUCTION OF A MAGNETIC HEAD** are the (1) type of head, (2) frequencies it will record, reproduce, or erase, and (3) use on a single or multitrack recorder.

Most tape recorder heads are designed for **ONE OF THREE BANDWIDTHS**: (1) narrowband, (2) intermediate band, or (3) wideband.

A recorder's magnetic heads are in the following **SEQUENCE** on its record/reproduce track: (1) erase, (2) record, and (3) reproduce.

Two important **PREVENTIVE MAINTENANCE** requirements for magnetic heads are cleaning and demagnetizing.

ANSWER TO QUESTIONS Q1. THROUGH Q11.

A-1. Record, reproduce, and erase.

A-2.

a. Type of head (record, reproduce, or erase).

b. Frequencies it will record or reproduce.

c. Whether it will be used on a single or multitrack recorder.

A-3.

a. Size of the headgap.

b. Speed of the magnetic tape.

A-4.

a. Narrowband—100 Hz to 100 kHz.

b. Intermediate band—100 Hz to 500 kHz.

c. Wideband—400 Hz to 2 mHz.

A-5. Allow you to monitor the signals you're recording.

A-6. First, before the record and reproduce heads.

A-7.

a. Keep the heads clean.

b. Keep the heads demagnetized.

A-8. With a cotton-tipped applicator soaked in either isopropyl alcohol or a head cleaner recommended by the recorder's manufacturer.

A-9.

a. During ac power losses.

b. During testing.

c. Because of stray magnetic fields.

d. From normal use.

A-10. A hand-held degausser like the manual degaussers used for degaussing magnetic tape.

A-11. Every 8 to 25 hours depending on the manufacturer's recommendations.

CHAPTER 4

MAGNETIC TAPE RECORDER TRANSPORTS

LEARNING OBJECTIVES

After completing this chapter, you'll be able to do the following:

1. Describe the function and components of a basic magnetic tape transport system.
2. Describe the operating characteristics and parts of the three most common tape reeling systems.
3. Describe the physical characteristics of the two basic tape reeling configurations, *co-planar* and *co-axial*.
4. Describe the characteristics of *open-loop drive* and *closed-loop drive* tape transport configurations and the three most common *closed-loop* designs.
5. Describe the capstan speed control function of a tape transport system and the relationship of the six basic parts of a typical capstan speed control unit.
6. Explain why, and describe how, magnetic tape transports must be cleaned and degaussed.

INTRODUCTION

Magnetic tape recorder transports are precisely built assemblies that move the magnetic tape across the magnetic heads and hold and protect the tape. Figure 4-1 shows a basic tape transport assembly. Tape transports have four basic parts:

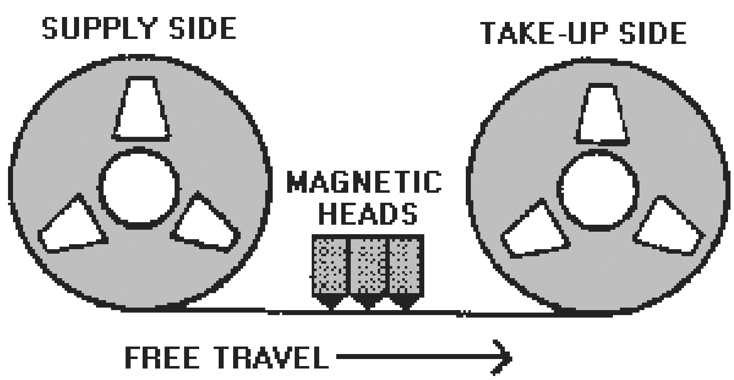

Figure 4-1.—Basic tape transport assembly.

1. A **tape reeling system** that, with the aid of tape guides, physically moves the tape across the magnetic heads.

2. A **tape speed control system** that monitors and controls the movement of the magnetic tape.

3. An **electronic subsystem** that activates the reeling device to move the magnetic tape.

4. A **basic enclosure** that holds and protects the reels or cartridges of magnetic tape.

This chapter describes these basic parts, tells how they work, and shows diagrams of the more common ones.

TAPE REELING SYSTEMS

A basic magnetic recorder tape reeling system (figure 4-1) has one supply reel and one take-up reel. Its job is to move the magnetic tape from one reel to the other. When this happens, four things occur:

1. The supply reel feeds out magnetic tape at a constant tension.

2. The tape passes the magnetic heads in a straight line.

3. The take-up reel accepts the magnetic tape at a constant tension.

4. Both the supply and take-up reels start and stop smoothly while maintaining the proper tape tension.

These four things must happen, or the magnetic tape could be damaged. Three of the most commonly used tape reeling systems are (1) take-up control, (2) two-motor reeling, and (3) tape buffering.

TAKE-UP CONTROL REELING SYSTEMS

This system uses a motorized take-up reel which pulls the magnetic tape off of a *free-spooling* supply reel. It maintains tape tension by using mechanical drag on the supply reel. As you might guess, this method has its disadvantages. It only works in one direction, and the tape tension doesn't remain constant throughout the reel. As the supply reel gives out tape, the tape tension varies. Uneven tape tension can cause stretched tape, poorly wound tape reels, and tape damage during starts and stops.

TWO-MOTOR REELING SYSTEMS

To overcome the problems of take-up control reeling systems, designers added a motor to the supply reel. By using two motors, the magnetic tape direction can be forward or reverse.

Two-motor reeling configurations usually use dc (direct current) motors, instead of ac (alternating current) motors, because dc motors run smoother and are easier to control. To help control tape tension, a small hold-back voltage is added to the motor for the supply reel.

Unfortunately, two-motor reeling systems do not properly control tape tension during starts and stops. Something called *tape buffering* must be added.

TAPE BUFFERING REELING SYSTEMS

Controlling a recorder's tape tension during starts and stops is a big problem. Tape buffering overcomes this problem by regulating the tape reel speed and by protecting against changes in tape tension.

Every manufacturer of high-quality, high performance magnetic tape recorders uses some sort of tape buffering. It's especially important in magnetic recorders that operate at many different speeds, where precise tape tension must be maintained.

Figure 4-2 shows the relationship between the tape reeling system and the tape buffering system. As you can see, the speed at which a tape reel will give up or take up magnetic tape is controlled by its respective speed control servo. Feedback from the supply and take-up buffers tells the servo to speed up or slow down.

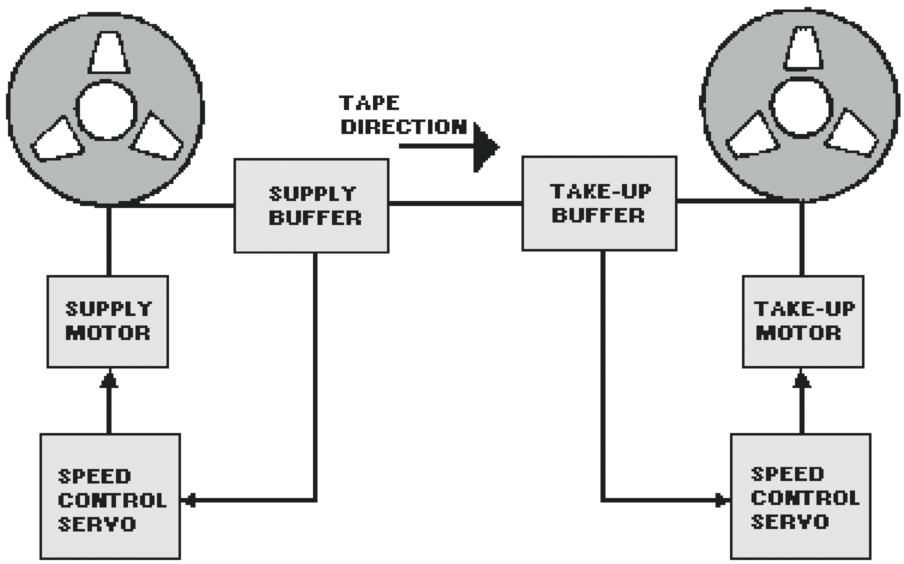

Figure 4-2.—Tape buffering arrangement.

There are two basic types of reeling system buffers: (1) spring-tension, and (2) vacuum-column.

1. **Spring-tension** buffering systems use an electro-mechanical device to sense changes in tape tension. These changes are *feedback* that the speed control servo needs to adjust the speed of the tape reels. Figures 4-3 and 4-4 show two of the more common arrangements for spring-tension buffers.

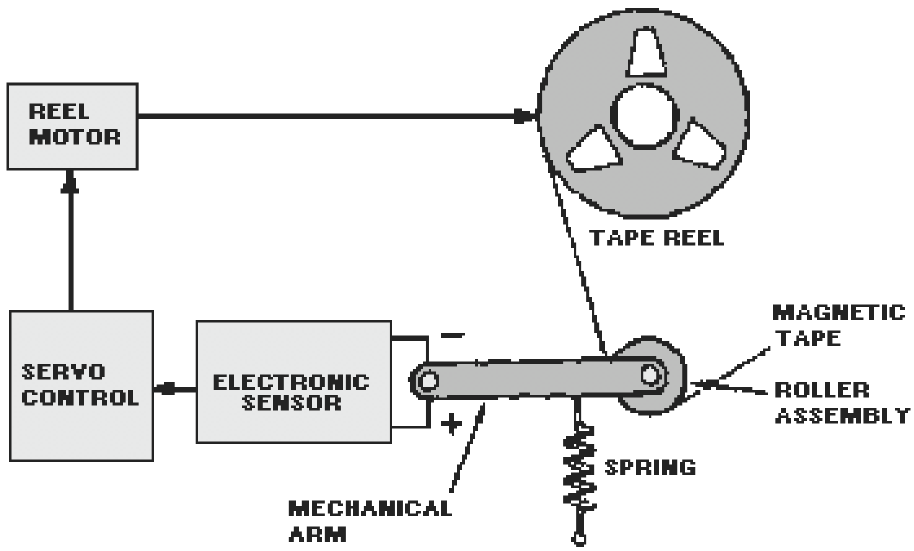

Figure 4-3.—Mechanical arm spring-tension tape buffering.

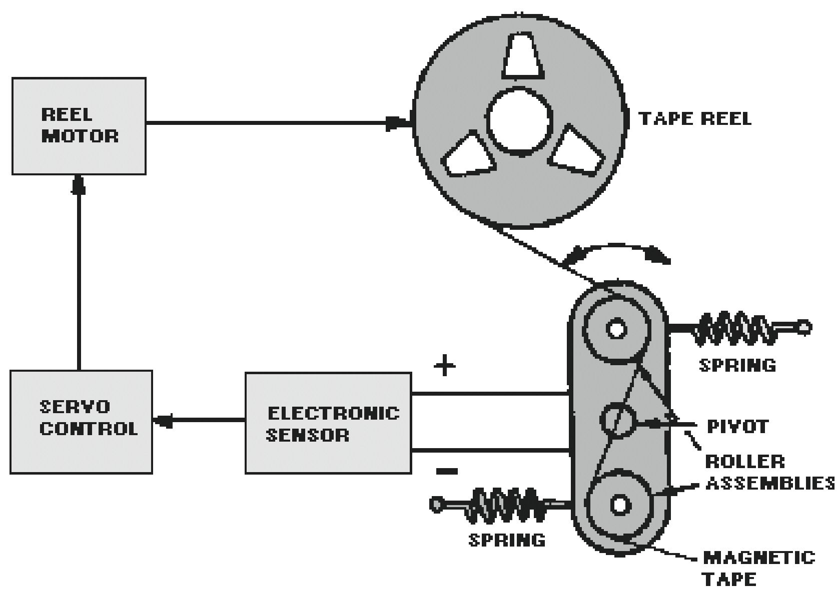

Figure 4-4.—Mechanical arm spring-tension tape buffering.

2. **Vacuum-column** buffering systems operate like the spring-tension systems. They also regulate the speed control servos that control tape reel speed. But, as shown in figure 4-5, the vacuum-column buffer system uses a vacuum chamber instead of a spring to hold a length of magnetic tape as *slack* during tape recorder starts and stops. An electronic sensor in the vacuum chamber helps to control how much tape is in the buffer.

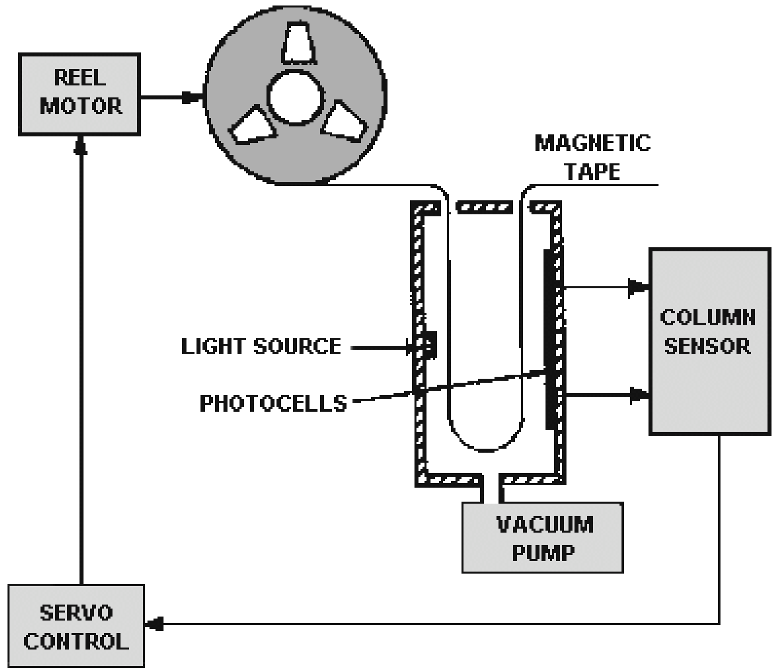

Figure 4-5.—Vacuum-column tape buffering system.

TAPE GUIDES

Another job of a tape reeling system is to make sure the magnetic tape is protected from damage during operation. To do this, tape reeling systems use tape guides. Tape guides come in two designs, *fixed* and *rotary*. Both of these are shown in figure 4-6. Each type of tape guide has its drawbacks. Fixed tape guides produce a lot more friction, and rotary tape guides are more likely to cause errors because of their moving parts.

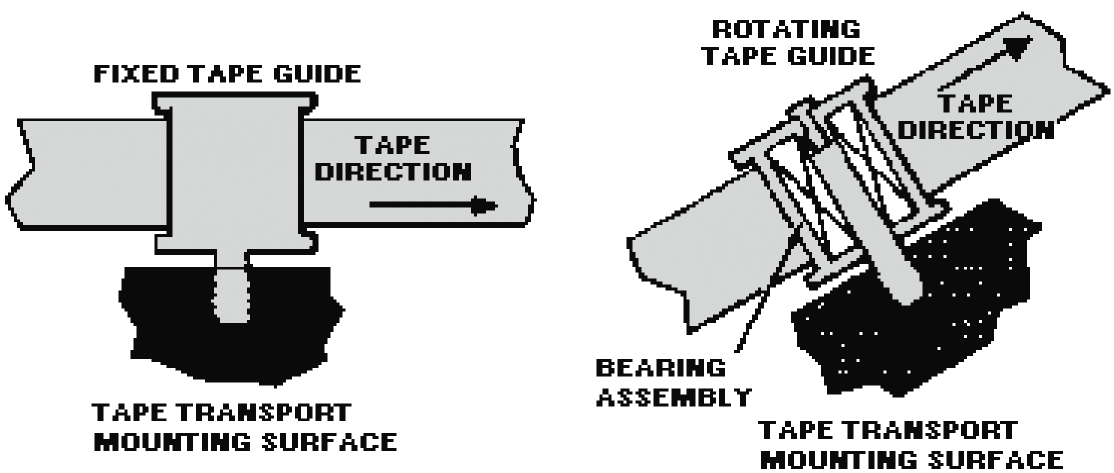

Figure 4-6.—Typical fixed and rotary tape guides.

Tape guides are strategically placed in a tape reeling system to make sure the magnetic tape is kept straight with respect to the supply and take-up reels and the magnetic heads. Some magnetic recorders use only fixed tape guides, some use rotary tape guides, and some use a combination of the two.

TAPE REELING CONFIGURATIONS

There are two basic tape reeling configurations: (1) co-planar, and (2) co-axial. Both of these describe the physical relationship between the supply reel and the take-up reel. The co-planar, which is used more often than the co-axial, has the supply reel and the take-up reel side by side. Figure 4-7 shows this configuration.

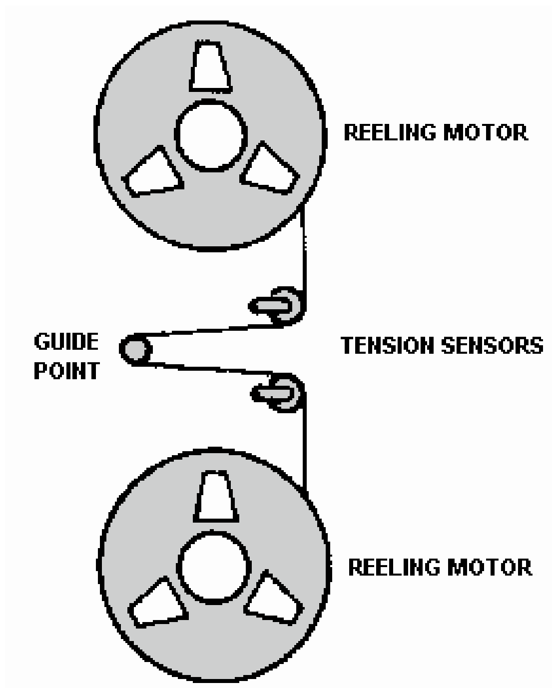

Figure 4-7.—Co-planar tape reeling configuration.

The co-axial configuration is used when physical space is limited. It places the supply and take-up reels on top of each other. Figure 4-8 shows this configuration.

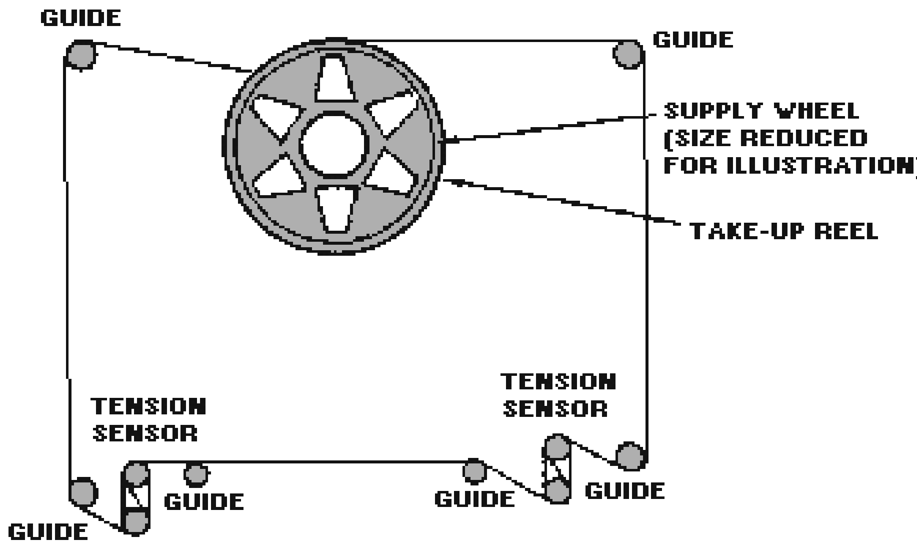

Figure 4-8.—Co-axial tape reeling configuration.

Q-1. What are the four basic parts of a magnetic tape recorder's tape transport system?

Q-2. What are the three most commonly used tape reeling systems?

Q-3. What are two disadvantages of the take-up control reeling system?

Q-4. What are two advantages of a two-motor reeling system over a take-up control reeling system?

Q-5. What type of reeling system best controls a tape recorder's tape tension during starts and stops?

Q-6. What are the two basic types of tape buffering reeling systems?

Q-7. How do the tape guides on a tape reeling system protect the tape from damage during operation?

TAPE TRANSPORT CONFIGURATIONS

There are two types of tape transport configurations: (1) *open-loop capstan drive*, and (2) *closed-loop capstan drive*. The following paragraphs describe each of these.

OPEN-LOOP CAPSTAN DRIVE

This is probably the simplest tape transport configuration. Figure 4-9 shows how the magnetic tape is pulled off of the supply reel, taken across the magnetic heads, and wound onto the take-up reel. The tape is *pulled* by sandwiching it between a single capstan and a pinch roller. As the capstan turns, the friction between it and the pinch roller pulls the tape across the magnetic heads. The magnetic tape is held against the magnetic heads by using tape guides.

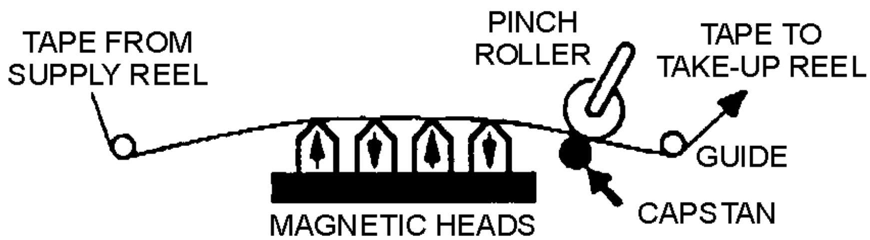

Figure 4-9.—Open-loop capstan drive tape transport.

The open-loop drive transport configuration has two major drawbacks:

1. It can only work in one direction. It can *pull* the tape, but it can't *push* it across the magnetic heads.
2. Tape tension and head-to-tape contact can vary. If the capstan motor hesitates or speeds up, the tape tension will vary.

CLOSED-LOOP CAPSTAN DRIVE

Closed-loop capstan drive tape transports were designed to overcome the drawbacks of the open-loop drive design. They use more than one capstan and/or pinch roller to *clamp* the magnetic tape in the area around the magnetic heads. This keeps tape tension constant and improves the quality of the recording or the playback. Figure 4-10 shows the basic arrangement of the closed-loop capstan drive.

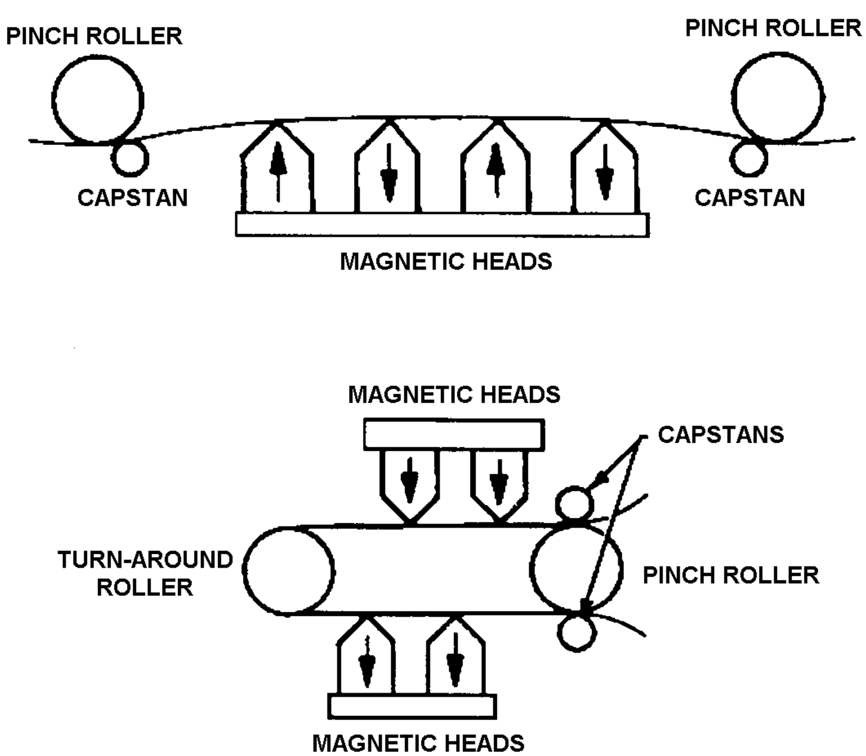

Figure 4-10.—Closed loop capstan drive tape transport.

The three most common closed-loop capstan drive designs are (1) *differential velocity capstans*, (2) *dual-motors dual capstans*, and (3) *peripheral drive capstans*.

Differential Velocity Capstans

Figure 4-11 shows a differential velocity capstan. In this design, the take-up capstan is made a little larger than the supply capstan. This causes the take-up capstan to pull the tape away from the heads slightly faster than the supply capstan feeds the tape to the heads. The result is a constant tape tension in the area around the magnetic heads.

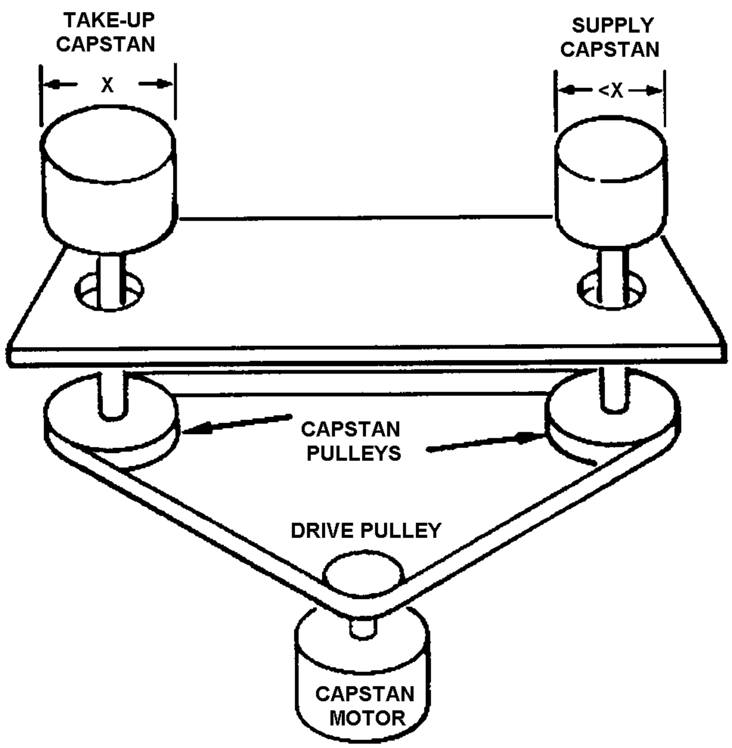

Figure 4-11.—Differential velocity capstan drive.

Both capstans are turned by a single motor which is coupled to the capstan pulleys by a belt. This arrangement is very efficient in one direction, but, unfortunately, differential velocity capstans don't work in reverse. If you reversed the tape direction, a negative tension would occur, and the tape would bunch up in the area around the magnetic heads.

Dual-Motors Dual Capstans

Figure 4-12 shows a dual-motor dual capstan drive. In this design, each capstan is driven by its own motor. Tape tension is maintained by slowing down one of the motors. When reverse tape motion is needed, the opposite motor is slowed down.

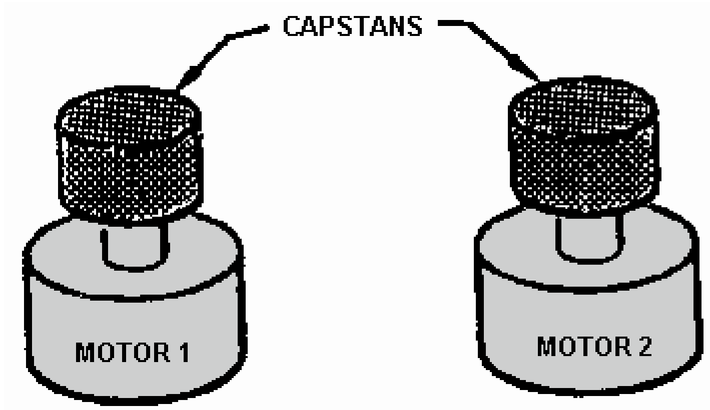

Figure 4-12.—Dual-motors dual capstans drive system.

Peripheral Drive Capstans

In this design, the magnetic tape is moved by a capstan placed directly against the tape reel or tape pack. Figure 4-13 shows two different peripheral drive capstan arrangements.

The first arrangement, figure 4-13A, shows a single capstan design. In this method, two tightly wound tape reels, without flanges, are pushed against the capstan. As the capstan turns, it forces the tape reels to turn in the appropriate direction. Magnetic tape tension is maintained by using either spring loading or servo control.

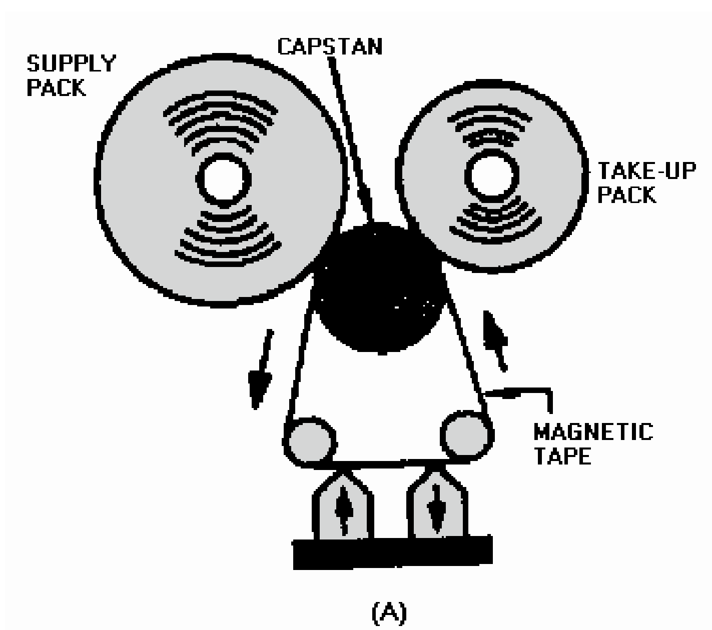

Figure 4-13A.—Peripheral drive capstans.

The second arrangement, figure 4-13B, uses two capstans. In this method, the two tightly wound tape reels, without flanges, are pressed directly against the capstans. Tension in the magnetic head area is maintained by controlling the speed of the individual capstans.

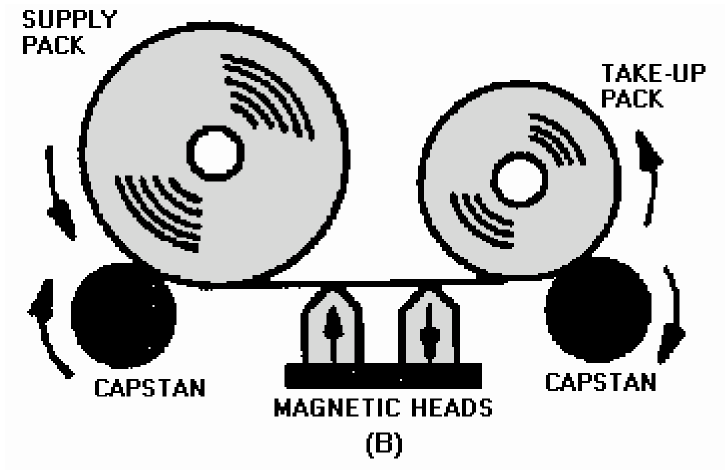

Figure 4-13B.—Peripheral drive capstans.

CAPSTAN SPEED CONTROL

Capstan speed control is an important part of the magnetic tape transport system. It makes sure the capstan is turning (1) at the right speed and (2) at a constant speed. This is important because errors in speed control can cause poor recordings and playbacks.

Capstans are turned either by a motor only, or by a motor, belt, and pulley arrangement. In either case, it's the motor that the capstan speed control function acts upon to do its job. A capstan speed control function typically consists of six basic parts. Figure 4-14 shows these six parts and how they're related. Each of the parts is described below.

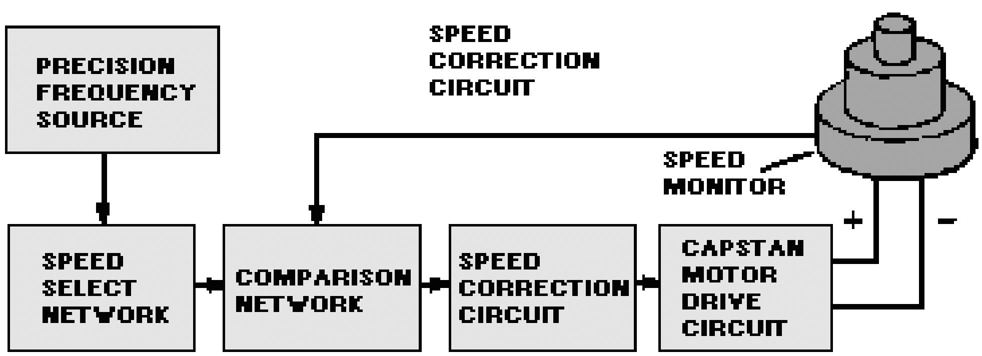

Figure 4-14.—Six parts of the capstan speed control function.

PRECISION FREQUENCY SOURCE

This part of the capstan speed control provides a reference frequency that the *speed select network* and the *comparison network* use to drive the capstan motor. The precision frequency source is usually a very-high-frequency crystal with an accuracy of at least .001 percent.

SPEED SELECT NETWORK

This network selects the desired operating tape speed. It takes the reference frequency from the *precision frequency source* and (depending on the desired operating tape speed) generates another specific reference signal that the *comparison network* uses to control the speed of the capstan. Table 4-1 is a list of the speed control reference signal frequencies for the various operating tape speeds.

Table 4-1.—Typical speed control reference signal frequencies

Operating Tape Speed (inches per second)	Speed Control Frequency (kilohertz)
15/16	1.5625
1 7/8	3.125
3 3/4	6.25
7 1/2	12.5
15	25
30	50
60	100
120	200
240	400

CAPSTAN SPEED MONITOR

This circuit monitors the true capstan motor speed. It sends the true speed to the *comparison network* circuit. Most capstan speed monitor circuits are made using a photo-optical tachometer that's directly attached to the shaft of the capstan motor. Figure 4-15 shows this.

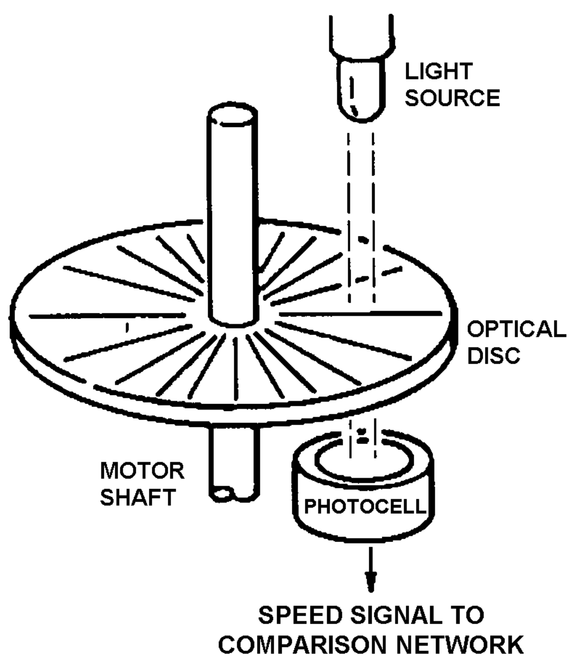

Figure 4-15.—Capstan speed monitor using a photo-optical tachometer.

COMPARISON NETWORK

This network takes the input signals from the *speed select network* and the *capstan speed monitor*, compares the two signals, and decides if the capstan is at the right speed. If not, it tells the speed *correction circuit*.

Sometimes, a third input signal, which comes from the magnetic tape itself, is supplied to the *comparison network.* It's called a *servo control from tape signal*. Tape recordings made on a specific recorder are sometimes shipped off for further analysis and played back on a different recorder. To help compensate for speed errors in the tape transport systems of the two recorders, the *precision reference frequency* of the originating recorder is recorded onto a track of the magnetic tape. During playback, this reference signal is also fed to the recorder's *comparison network* and is used to correct speed errors.

SPEED CORRECTION CIRCUIT

This circuit takes speed correction signals from the *comparison network* and tells the *capstan motor drive circuit* to either speed up or slow down the capstan motor.

CAPSTAN MOTOR DRIVE CIRCUIT

This circuit takes the speed-up or slow-down signals from the speed correction circuit and actually speeds up or slows down the capstan motor.

MAGNETIC TAPE TRANSPORT MAINTENANCE

If you want good recordings and playbacks, you must keep magnetic tape transports clean and demagnetized. The following paragraphs describe preventive maintenance procedures for magnetic tape transport systems.

MAGNETIC TAPE TRANSPORT CLEANING

You can clean most magnetic tape transports with isopropyl alcohol, cotton swabs, and lint-free cloths. (Caution: Cotton swabs <u>are not</u> lint free, so use them only in places you can't get to with the lint-free cloths.) Figure 4-16 shows a technician cleaning a capstan. Here are some other points to remember:

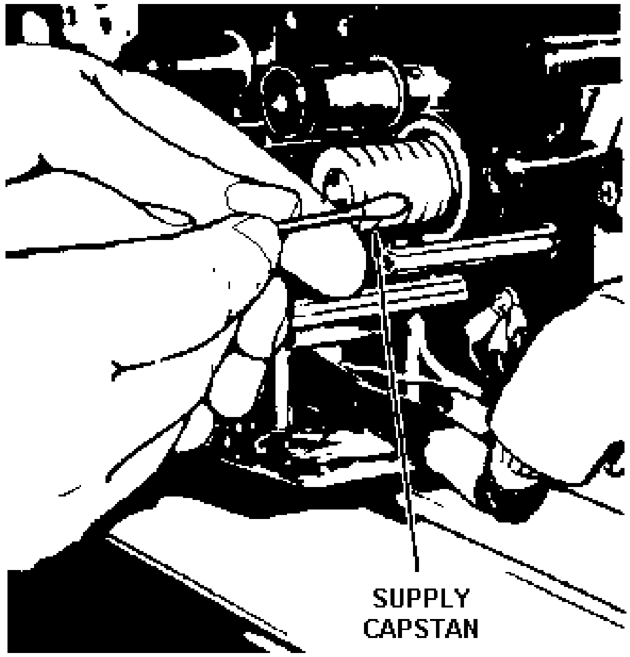

Figure 4-16.—Cleaning the capstan on a magnetic tape transport system.

- DO always remove the magnetic tape from the transport before cleaning it.
- DO apply the cleaner onto the lint free cloth or cotton swab; DON'T apply it directly onto the tape transport.
- DO pay extra attention to the flanged parts of tape guides. It's here that oxide particles collect the most.
- DON'T use the same lint-free cloth or cotton swab to clean many parts of the tape transport. Switch cloths and swabs often. If you don't, you may transfer dirt and oxide particles from one part of the tape transport to another.

MAGNETIC TAPE TRANSPORT DEMAGNETIZING

With use, tape transport parts become magnetized. It's hard to say *exactly* what will happen if the magnetic tape passes a magnetized part of the tape transport before the tape is recorded on. The effects can range from just a little more noise on the tape to a complete tape saturation. Either way, magnetized tape transport parts can ruin magnetic recordings.

To prevent this, you must periodically demagnetize the tape transport. The procedures for doing this are identical to those listed in chapter 2 for demagnetizing magnetic heads. You'll even use the same manual hand-held degausser you saw in figure 2-8 of chapter 2. Figure 4-17 shows a technician demagnetizing a tape guide.

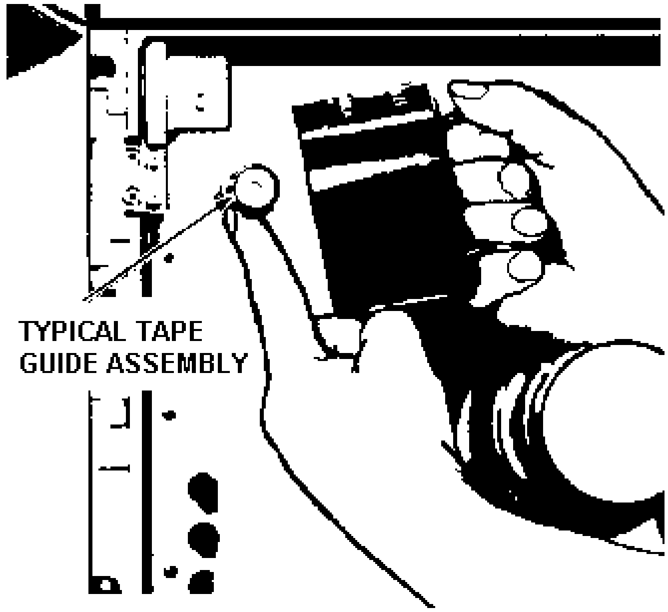

Figure 4-17.—Demagnetizing a tape guide with a hand-held degausser.

Q-8. There are two types of tape transport configurations, open-loop capstan drive and closed-loop capstan drive. What are two major disadvantages of open-loop capstan drive tape transports?

Q-9. How do closed-loop capstan drive tape transports overcome the disadvantages of the open-loop drive design?

Q-10. What are the three most common closed-loop capstan drive designs?

Q-11. How do tape transports with differential velocity capstans maintain a constant tape tension in the area around the magnetic heads?

Q-12. How do dual-motor dual capstan drives maintain a constant tape tension while operating in either a forward or reverse direction?

Q-13. What are the two critical functions of the capstan speed control part of a magnetic tape transport system?

Q-14. Which part of the capstan speed control function monitors the true capstan motor speed?

Q-15. Sometimes it's necessary, but why should you avoid using cotton swabs when cleaning a magnetic tape transport?

Q-16. When cleaning the parts of a tape transport, why should you switch lint-free cloths and swabs often?

Q-17. What equipment should you use to de-magnetize a magnetic tape transport?

SUMMARY

Now that you've finished chapter 4, you should be able to describe magnetic tape transport systems in terms of their operating characteristics, parts, and preventive maintenance requirements. The following is a summary of the important points in this chapter.

A **MAGNETIC TAPE RECORDER TRANSPORT** has four basic parts: (1) tape reeling system, (2) tape speed control system, (3) electronic subsystem, and (4) basic enclosure.

The **TAPE REELING SYSTEM** must move the tape in a straight line at a constant tension, and it must start and stop smoothly while maintaining the proper tension.

Three of the **MOST COMMON REELING SYSTEMS** are (1) take-up control, (2) two-motor reeling, and (3) tape buffering.

The two types of **TAPE TRANSPORT CONFIGURATIONS** are (1) *open-loop capstan drive* and (2) *closed-loop capstan drive*. The open-loop type works in only one direction, and the tape tension can vary. The closed-loop type keeps the tape tension constant.

Three types of **CLOSED-LOOP CAPSTAN DRIVES** are (1) differential velocity capstans, (2) dual-motors dual capstans, and (3) peripheral drive capstans.

The **CAPSTAN SPEED CONTROL** component of a tape transport keeps the capstan turning at the correct operating speed and at a constant speed. It has these six parts: (1) precision frequency source, (2) speed select network, (3) capstan speed motor, (4) comparison network, (5) speed correction circuit, and (6) capstan motor drive circuit.

You should **CLEAN** magnetic tape transports with isopropyl alcohol, cotton swabs, and lint free cloths and **DEMAGNETIZE** them using a hand-held degausser.

ANSWERS TO QUESTIONS Q1. THROUGH Q17.

A1.

- *a. Tape reeling system.*
- *b. Tape speed control system.*
- *c. Electronic subsystem.*
- *d. Basic enclosure.*

A2.

- *a. Take-up control.*
- *b. Two-motor reeling.*
- *c. Tape buffering.*

A3.

a. It only works in one direction.

b. The tape tension varies as the supply reel unwinds, which can cause damage during starts and stops.

A4. The two-motor configuration runs in both directions and a holdback voltage helps control tape tension, but it does not properly control tape tension during starts and stops.

A5. A tape buffering reeling system.

A6.

a. Spring-tension ***buffering systems****.*

b. Vacuum-column ***buffering systems****.*

A7. They keep the tape straight with respect to both the supply and take-up reels and the magnetic heads.

A8.

a. Only operates in one direction.

b. The tape tension and head-to-tape contact can vary.

A9. Closed loop capstan drive transports use more than one capstan to clamp the tape in the area around the magnetic head.

A10.

a. Differential velocity capstans.

b. Dual motors dual capstans.

c. Peripheral drive capstans.

A11. The supply capstan is slightly larger than the take-up capstan. This causes the take-up capstan to pull the tape slightly faster than the supply capstan feeds the tape.

A12. Each capstan is driven by its own motor. It maintains tape tension by slowing down one of the motors. When the tape motion is reversed, the opposite motor is slowed down.

A13. Makes sure the capstan turns at the right speed and at a constant speed.

A14. Capstan speed monitor.

A15. Cotton swabs are not lint free.

A16. You may transfer dirt or oxide particles from one part of the tape transport to another.

A17. A hand-held degausser.

CHAPTER 5

MAGNETIC TAPE RECORDER RECORD AND REPRODUCE ELECTRONICS

LEARNING OBJECTIVES

After completing this chapter, you'll be able to do the following:

1. State the two types of record and reproduce electronics used on magnetic tape recorders.
2. Describe the purpose and function of *direct record* electronics and the four main parts of a recorder's direct record component.
3. Describe the purpose and function of *direct reproduce* electronics and the three main parts of a recorder's direct reproduce component.
4. Describe the purpose and function of *frequency modulation* (FM) record electronics and the three main parts of a recorder's FM record component.
5. Describe the purpose and function of FM reproduce electronics and the four main parts of a recorder's FM record component.

RECORD AND REPRODUCE ELECTRONICS

There are two ways to record and reproduce analog signals. The first way is *direct record*. It's also called *amplitude modulation* (AM) electronics. The second way is *frequency modulation* (FM). Even though direct record and reproduce circuits are much different from FM record and reproduce electronics, they both share the same two very important jobs. They both must:

1. Take an input signal, process it as needed, and then send it to the record magnetic head for reproduction.
2. Take the reproduced signal from the reproduce magnetic head, process it as needed, and output it for listening or analysis.

DIRECT RECORD ELECTRONICS

Direct record electronics record input signals onto magnetic media just as the signals appeared at the recorder's input. The only processing an input signal receives is the adding of a bias signal. The added bias signal makes sure the signal stays away from the *steps* of the magnetism curve. Figure 5-1 shows a basic block diagram of a recorder's direct record electronics.

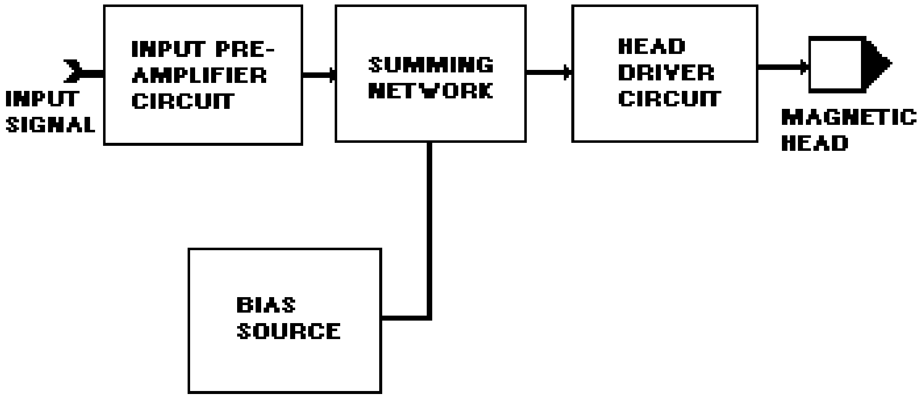

Figure 5-1.—Direct record electronics.

Direct record electronics has four main parts:

1. Input pre-amplifier circuit. This circuit takes the input signal, amplifies it, and sends it to the summing network. It also matches the impedance between the source of the input signal and the magnetic tape recorder.

2. Bias source. This circuit generates the high-frequency bias signal and sends it to the summing network. Normally, the frequency of the bias signal will be five to ten times higher than the highest frequency the tape recorder can record.

3. Summing network. This network takes the input signal and the bias signal, mixes them, and sends the resulting signal to the head driver circuit.

4. Head driver circuit. This circuit takes the signal from the summing network, amplifies it, and sends it to the record head for recording.

DIRECT REPRODUCE ELECTRONICS

Direct reproduce electronics amplify the *very* weak input signals from the reproduce head, and send them out for listening or analysis, as needed. Figure 5-2 shows a basic block diagram of direct reproduce electronics.

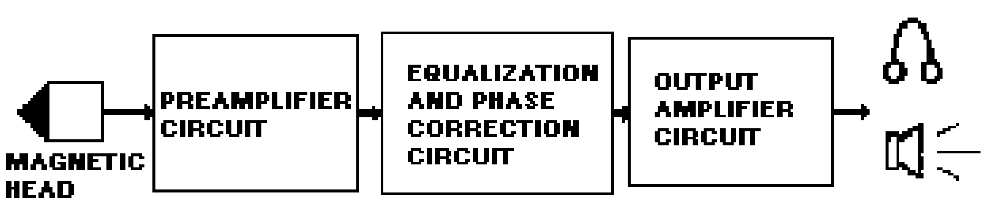

Figure 5-2.—Direct reproduce electronics.

Direct reproduce electronics consists of three main parts:

1. Pre-amplifier circuit. This circuit takes the very weak reproduced signal from the reproduce head and (a) amplifies the signal, (b) removes any bias signal that was used during the recording process, and (c) sends the signal to the equalization and phase correction circuit.

2. Equalization and phase correction circuit. This circuit takes the pre-amplified signal and fixes any frequency response problems that the reproduce magnetic head may have caused. To better understand this, look at the voltage *versus* frequency response graph in figure 5-3. The top of the graph shows the input signal that comes from the pre-amplifier and the bottom shows the *equalization* signal generated by the equalization circuit. In the top part of the graph, note how the output voltage level varies as the frequency of the signal varies. This isn't good. A good output voltage level is one that remains constant as the frequency changes. The equalization signal corrects this problem. Notice that when the input signal and the equalization signal are combined they cancel each other out. This allows a nice flat (voltage *versus* frequency) output signal to go to the output amplifier circuit.

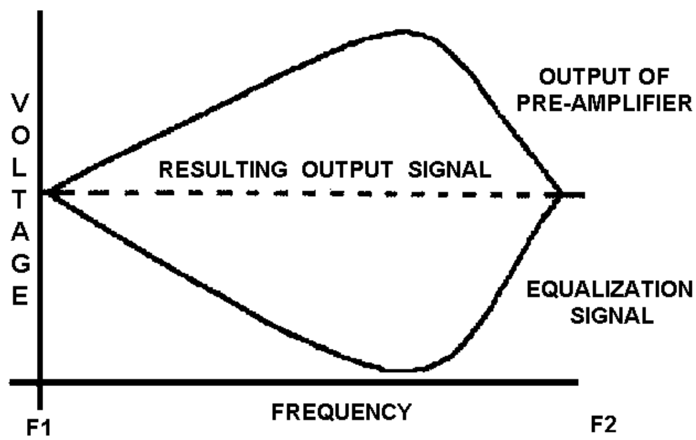

Figure 5-3.—Equalization process.

3. Output amplifier circuit. This circuit takes the signal from the equalization and phase correction circuit and amplifies it for output. It also matches the magnetic recorder's impedance to the output device that is used for listening or recording.

FM RECORD ELECTRONICS

FM record electronics process signals to be recorded differently than direct record electronics. Instead of recording the input signal just as it appears at the recorder's input, FM record electronics use the input signal to vary (modulate) the carrier frequency of a *record oscillator*. The frequency modulated output signal of the *record oscillator* then becomes the signal that's actually recorded onto the magnetic media. Figure 5-4 shows a block diagram of the FM record electronics.

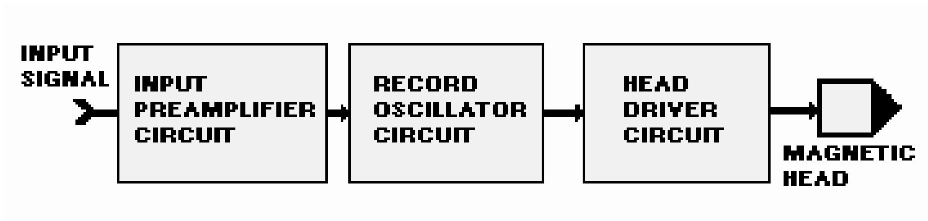

Figure 5-4.—FM record electronics.

FM record electronics consist of three main parts:

1. Input pre-amplifier circuit. This circuit does two things: (a) it serves as an impedance matcher between the signal source and the magnetic recorder, and (b) it pre-amplifies the input signal.

2. Record oscillator circuit. This circuit generates a carrier signal onto which the input signal will be modulated. The input signal is used to vary (frequency modulate) the carrier signal. This is how the input signal gets frequency modulated onto the carrier signal. The output of this circuit is the frequency-modulated carrier signal. The center frequency of the carrier depends on two things: (a) the bandwidth of the signal you're recording, and (b) the media onto which you're recording. For magnetic tape, the carrier frequency can be as low as 1.688 kHz for an operating tape speed of 1-7/8 inches per second, and as high as 900 kHz for 120 inches per second.

3. Head driver circuit. This circuit takes the frequency-modulated output from the record oscillator circuit, amplifies it, and sends it to the magnetic head for recording. The output level of this circuit is set to be *just below* the magnetic saturation point of the magnetic media.

FM REPRODUCE ELECTRONICS

The FM reproduce electronics work just like direct reproduce electronics, with one exception. FM reproduce electronics must first demodulate the original input signal from the carrier frequency before the intelligence can be sent to the output device for listening or analysis. Figure 5-5 shows a block diagram of the FM reproduce electronics.

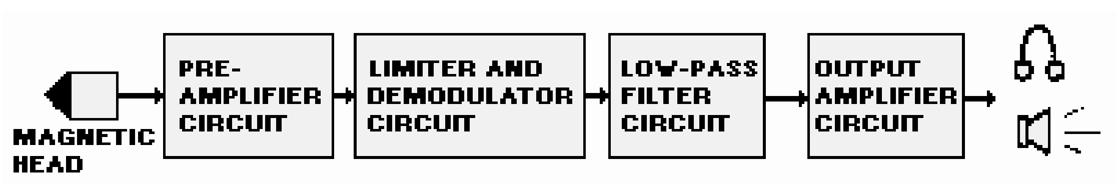

Figure 5-5.—FM reproduce electronics.

FM reproduce electronics consist of four main parts:

1. Pre-amplifier circuit. This circuit takes the frequency modulated carrier frequency from the reproduce head and amplifies it.

2. Limiter/demodulator circuit. This circuit takes the output of the preamplifier, stabilizes the amplitude level, and demodulates the signal intelligence from the carrier frequency.

3. Low-pass filter circuit. This circuit takes the signal intelligence from the limiter/demodulator circuit and cleans up any noise or left over carrier signal.

4. Output amplifier circuit. This circuit takes the output from the low-pass filter and amplifies it for output. It also matches the impedance of the magnetic recorder to the output device.

Q-1. What two types of record and reproduce electronics are used by magnetic tape recorders?

Q-2. The head driver circuit in a tape recorder's direct record electronics component (figure 5-1) performs what function?

Q-3. The equalization and phase correction circuit in a tape recorder's direct reproduce electronics (figure 5-2) performs what function?

Q-4. How do FM record electronics differ from AM (direct record) electronics?

Q-5. The head driver circuit of a tape recorder's FM record electronics (figure 5-4) performs what function?

Q-6. What is the major difference between direct reproduce electronics and FM reproduce electronics?

SUMMARY

Now that you've finished chapter 5, you should be able to (1) state the two types of record and reproduce electronics used on magnetic tape recorders and (2) describe the function and main parts of *direct record and reproduce electronics* and *FM record and reproduce electronics*. The following is a summary of important points in this chapter:

DIRECT RECORD (AM) and **FREQUENCY MODULATION (FM)** are the two types of record and reproduce electronics used by magnetic tape recorders.

The four main parts of **DIRECT RECORD ELECTRONICS** are the (1) input pre-amplifier circuit, (2) bias source, (3) summing network, and (4) head driver circuit.

The three main parts of **DIRECT REPRODUCE ELECTRONICS** are the (1) pre-amplifier circuit, (2) equalization and phase correction circuit, and (3) output amplifier circuit.

FM RECORD ELECTRONICS record a frequency modulated signal onto the magnetic tape. It has three main parts: (1) input pre-amplifier circuit, (2) record oscillator circuit, and (3) head driver circuit.

FM REPRODUCE ELECTRONICS must demodulate the original input signal from the carrier signal. It has four main parts: (1) preamplifier circuit, (2) limiter and demodulator circuit, (3) low-pass filter circuit, and (4) output amplifier circuit.

ANSWERS TO QUESTIONS Q1. THROUGH Q6.

A1.

a. Direct record (AM).

b. Frequency modulation (FM).

A2. It takes the signal from the summing network, amplifies it, and sends it to the record head for recording.

A3. It generates an equalization signal which corrects any frequency response problems in the input signal from the pre-amplifier circuit.

A4. Instead of recording the signal just as it appears at the recorder's input, FM record electronics records a frequency-modulated carrier signal from a record oscillator (figure 5-4) onto the magnetic tape.

A5. It amplifies the frequency-modulated output from the record oscillator and sends it to the record head.

A6. FM record electronics must use a limiter and demodulator circuit (figure 5-5) to demodulate the signal intelligence from the carrier frequency.

CHAPTER 6

MAGNETIC TAPE RECORDING SPECIFICATIONS

LEARNING OBJECTIVES

After completing this chapter, you'll be able to do the following:

1. Define the seven most common magnetic tape recording specifications.
2. Describe a magnetic tape recorder's *signal-to-noise ratio* (SNR) *specification*, how it's measured, and why a high SNR is important.
3. Describe a tape recorder/reproducer's *frequency-response* specification, how it's measured, and the three factors that can limit or degrade a recorder's frequency response.
4. Describe a tape recorder's *harmonic-distortion* specification, how it's measured, and how a recorder produces harmonic distortion.
5. Describe a recorder's *phase-response* specification, how it's measured, and why good phase response is important.
6. Describe a recorder's *flutter* specification, how it's measured, and why minimal flutter is important.
7. Describe a recorder's *time-base error* (TBE) specification, how it's measured, and why minimal TBE is important.
8. Describe a multi-track magnetic tape recorder's *skew* specification, how it's measured, and why minimal skew is important.

INTRODUCTION

Have you ever gone to a store to buy a magnetic tape recorder? Were you able to decide which of the displayed models was the *good* one to buy? Or, did you instead end up confused when the salesperson started spouting words like *SNR*, *flutter*, and *bandwidth.* If so, you weren't alone.

This chapter (1) defines the seven most common magnetic tape recording specifications, (2) describes their effect on the magnetic recording process, and (3) tells how to measure each specification. The remaining paragraphs in this chapter describe each of the following magnetic tape recorder specifications:

1. Signal-to-noise ratio
2. Frequency response
3. Harmonic distortion
4. Phase response

5. Flutter
6. Time-base error
7. Skew

SIGNAL-TO-NOISE RATIO

Signal-to-noise ratio (SNR) is the first magnetic tape recorder specification we'll describe. It's one of the most important specifications of a magnetic tape recorder.

SIGNAL-TO-NOISE RATIO DEFINITION

The SNR is *the ratio of the normal signal level to the magnetic tape recorder's own noise level.* It's measured in decibels (dB). In other words, the higher the SNR of a magnetic tape recorder, the wider the range of input signals it can properly record and reproduce.

The *noise* part of the signal-to-noise ratio is generated in the magnetic tape recorder itself. Although noise can be generated by almost any part of the magnetic tape recorder, it's usually generated by either the magnetic heads or the magnetic tape.

SIGNAL-TO-NOISE RATIO MEASUREMENT

You can measure the SNR with a vacuum tube voltmeter (VTVM) and a signal generator. The equipment set up for measuring the SNR is shown in figure 6-1. After equipment setup, measure the SNR as follows:

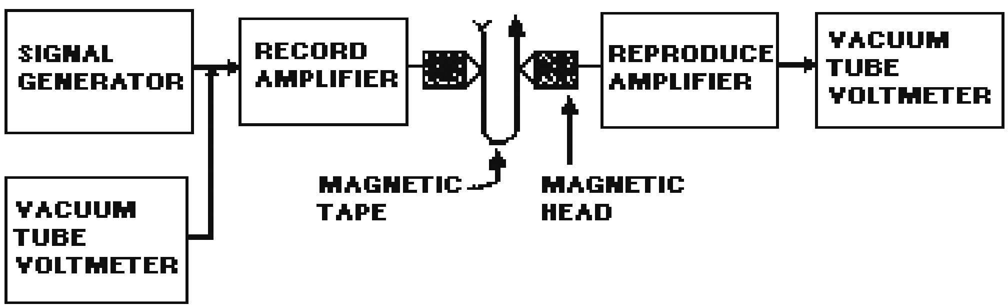

Figure 6-1.—Test equipment setup for measuring signal-to-noise ratio.

1. Set the signal generator to inject a test signal into the tape recorder. The technical manual for the tape recorder you're testing will tell you how to set up the signal generator.

2. While recording and reproducing, set the output level of the tape recorder's reproduce electronics to a level that displays 0-dB reference on the VTVM.

3. Disconnect the signal generator. The voltage displayed on the VTVM will drop from 0-dB to some *negative* dB level. This level is the magnetic tape recorder's SNR.

There are two things you should know when reading SNR specifications in technical manuals, equipment brochures, etc.

First, the SNR is stated in three ways. You'll see it as (1) *root-mean-square (RMS) signal-to-RMS noise*, (2) *peak-to-peak signal-to-RMS noise*, or (3) *peak signal-to-RMS noise*. If the SNR specification doesn't state which way it was measured, you could be mislead. For example, a 25-dB RMS SNR is equal to a 34-dB peak-to-peak signal-to-RMS noise ratio, or a 28-dB peak signal-to-RMS noise ratio.

Second, all SNR specifications should include the record level that was used. Since the SNR varies directly to the record level, you could be mislead by a SNR that doesn't include the record level of the test signal used when the SNR was measured.

FREQUENCY RESPONSE

The frequency-response specification of a magnetic tape recorder is sometimes called the *bandwidth*. A typical frequency-response specification might read *within* + / – 3 *db from 100 Hz to 100 kHz at 60 ips*. This means the magnetic tape recorder is capable of recording all frequencies between 100 Hz and 100 kHz at 60 inches per second (ips) without varying the output amplitude more than 3 dB.

FREQUENCY-RESPONSE DEFINITION

Frequency response is *the amplitude variation with frequency over a specified bandwidth*. Let's convert this to plain English. The frequency-response specification of a magnetic tape recorder tells you the range of frequencies the recorder can *effectively* record and reproduce. What exactly does the word *effectively* mean? That's hard to say because frequency response varies from recorder to recorder, and from manufacturer to manufacturer. But a good rule of thumb is that *an effective frequency-response specification tells the lowest and highest frequencies that the recorder can record and reproduce with no more than + / – 3-dB difference in output amplitude*.

FREQUENCY-RESPONSE MEASUREMENT

The equipment setup for measuring the frequency response of a magnetic tape recorder is the same as for measuring the signal-to-noise ratio. It's shown in figure 6-1. After equipment setup, measure a recorder's frequency response as follows:

1. Set the signal generator to output a test signal. The technical manual for the tape recorder will tell you how.

2. Set the recorder's reproduce electronics output level to a 0-dB reference on the VTVM.

3. While recording at a set speed, vary the frequency of the signal generator from the lowest to highest frequency you're checking. Make sure that the output level of the signal generator stays the same.

4. As you sweep through the frequencies, look at the VTVM. You'll see the amplitude rise and fall as you vary the output frequency of the signal generator. As you approach the lowest and the highest frequencies that the magnetic tape recorder can *effectively* record, you'll see the VTVM drop to less than – 3 dB. This determines the lower and upper limits of the frequency-response specification for that magnetic tape recorder.

FREQUENCY-RESPONSE LIMITING FACTORS

Four factors that can limit or degrade the frequency response of magnetic tape recorders are:

1. A too-high or too-low bias signal level setting for the record head.
2. An improper reproduce head.
3. An improper tape transport speed.
4. A poor magnetic tape-to-head contact.

The magnetic record head transforms the electrical signal into a magnetic field for recording onto magnetic tape. If the bias signal level is set to high, you might erase the higher frequencies. If it's too low, you'll get excessive tape distortion.

The reproduce head transforms the magnetic field from the magnetic tape back into an electrical signal. As explained in chapters 3 and 5, the head gap of a recorder's reproduce head and the operating speed of the magnetic tape transport determine the wavelength of the reproduce head. The wavelength determines the *center* frequency of a recorder's frequency-response specification. Once you pass this center frequency, both below and above, the output voltage level of the recorder's reproduce head will decrease. Figure 6-2 shows this. This is why the equalization circuits described in chapter 5, figure 5-3, are used.

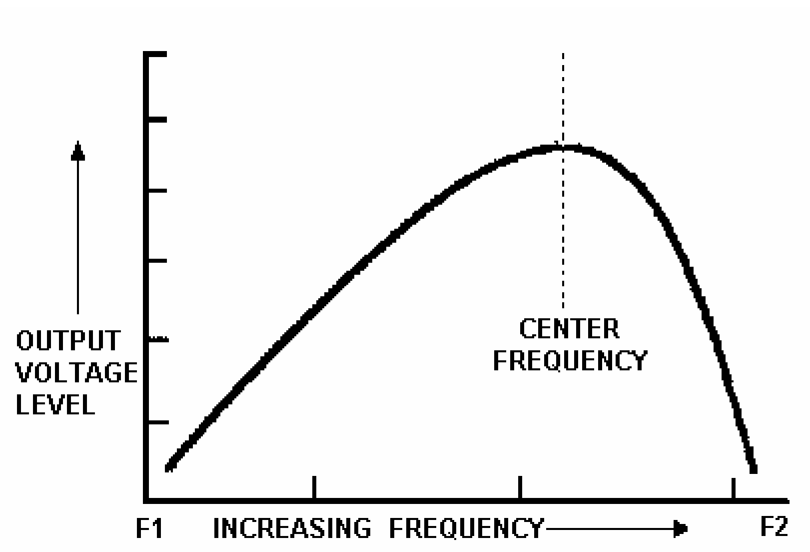

Figure 6-2.—Frequency response of a reproduce head.

Poor tape-to-head contact can seriously degrade the record and reproduce process. Magnetic heads are designed to reduce tape-to-head gap as much as possible. A tape-to-head gap is *extremely* degrading at the higher frequencies. Figure 6-3 shows this. Note how a .1-mil gap causes only a small loss at 10 kHz. But, at 1 MHz, it causes a 46-dB loss! <u>You must maintain tape-to-head contact.</u> Keeping the magnetic tape recorder heads and tape transport clean is the best way to do this.

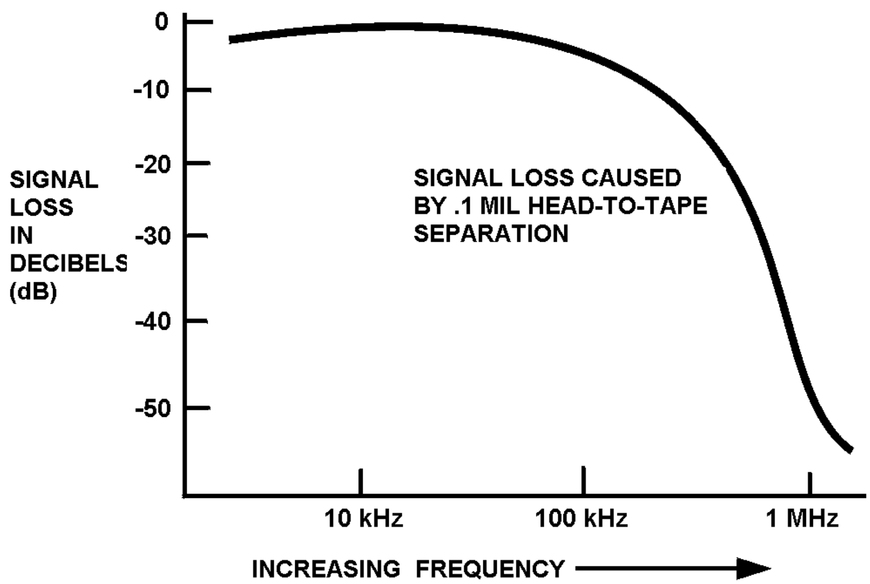

Figure 6-3.—Effects of poor tape-to-head contact.

Q-1. Two tape recorders have signal-to-noise ratios (SNRs) of 25-dB RMS and 35-dB RMS respectively. Which of the SNRs can record and reproduce the widest range of input signals and why?

Q-2. You plan to measure your tape recorder's SNR. What test equipment will you need?

Q-3. Technical manuals for tape recorders can state the SNR in what three different ways?

Q-4. The frequency-response specification of your tape recorder reads within +/– 3 dB from 150 Hz to 150 kHz at 60 ips. What does this mean?

Q-5. While measuring frequency response, as the signal generator approaches the lowest and highest frequency the recorder can effectively record, the VTVM reading drops to less than – 3 dB. What does this indicate?

Q-6. List four factors that can degrade the frequency response of magnetic tape recorders.

HARMONIC DISTORTION

A magnetic tape recorder's harmonic-distortion specification is very important. It usually determines where the record level of a recorder's electronics should be set. The record level is also used to determine the signal-to-noise ratio and frequency-response specifications. A typical harmonic-distortion specification might read "1% third harmonic of a 100-kHz signal at 60 ips." This means that the magnetic tape recorder has 1% third-harmonic distortion of a 100-kHz signal at 60 ips.

HARMONIC-DISTORTION DEFINITION

Harmonic distortion is *the production of harmonic frequencies by an electronic system when a signal is applied at the input.* When an input signal goes through nonlinear electronic circuitry, the output signal will include some harmonic distortion (or unwanted frequencies). If you analyzed this distortion, you'd see that a pattern exists. A pattern, whereby the frequency of each unwanted frequency is a multiple ($\times 1$, $\times 2$, $\times 3$, etc.) of the center frequency of the input signal.

There are two types of harmonic distortion: even-order and odd-order. If the frequencies of the distortion are 2, 4, 6, etc., times the center frequency, it's even-order harmonics. If the frequencies of the distortion are 3, 5, 7, etc., times the center frequency, it's odd-order harmonics.

Odd-order harmonics are normally caused by the magnetic tape itself. Even-order harmonics are normally caused by (1) permanently magnetized magnetic heads, (2) faulty circuits, or (3) asymmetrical or unbalanced bias signals. As you might guess, even-order harmonics can be reduced by doing the right maintenance and periodic performance tests.

The primary harmonic distortion in magnetic tape recorder systems is third-order harmonics. If the level of third-order harmonics in a recorder increases, the level of distortion will also increase (figures 6-4A and B show this relationship). Two things that determine the level of third-order harmonics in a recorder are (1) the signal bias level, and (2) the record level. Figure 6-4A shows how third-order harmonic distortion decreases as the signal bias level increases. Figure 6-4B shows how the third harmonic increases gradually at first and then abruptly as the record level increases. That's why the third harmonic is used to determine the normal record level.

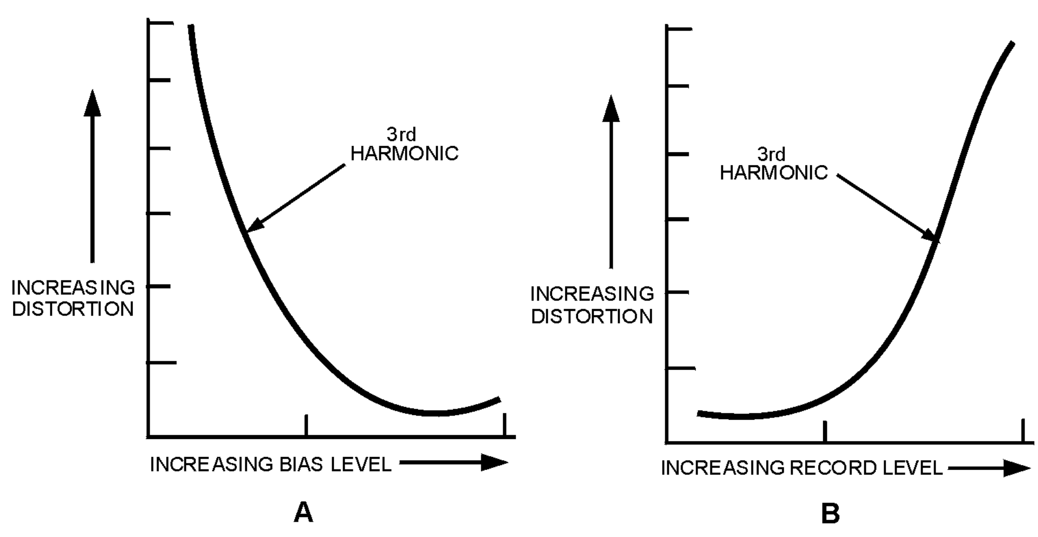

Figure 6-4 A & B.—Effect of signal bias level and record level on harmonic-distortion level.

HARMONIC-DISTORTION MEASUREMENT

Figure 6-5 shows a typical test equipment setup for measuring harmonic distortion. With this setup, the test signal from the signal generator is recorded and reproduced by the magnetic tape recorder at a normal record level. The amount of harmonic distortion is measured at the recorder's output on the wave analyzer.

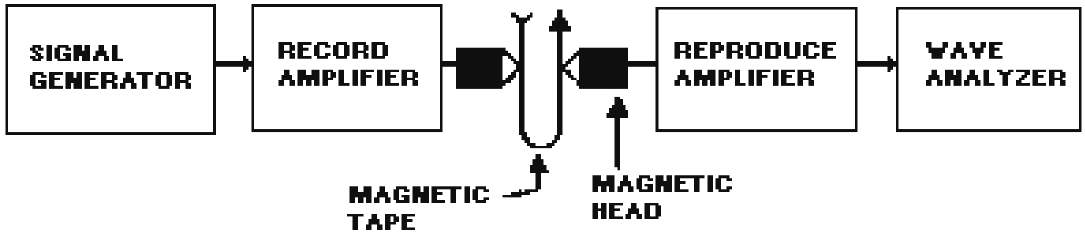

Figure 6-5.—Test equipment setup for measuring harmonic distortion.

The technical manual for the magnetic recorder you're testing will tell you how to set up the test equipment. It'll tell you to set up the wave analyzer to measure a specific frequency. This frequency will be one of the multiples (×1, ×2, ×3, etc.) of the frequency the signal generator is outputting.

For example, let's say the technical manual told you to set up the signal generator to input a 10-kHz test signal into the magnetic tape recorder. Since you want to measure third-order harmonics, the technical manual will tell you to set the wave analyzer to measure the amount of harmonic distortion at 30-kHz.

PHASE RESPONSE

It used to be thought that the only important specifications of magnetic tape recorders were signal-to-noise ratio and frequency response. But now, with the need to record and reproduce more complex waveforms, such as telemetry and computer data, the phase-response specification becomes as important as frequency response.

PHASE-RESPONSE DEFINITION

Phase response is *the expression of the variation of the phase shift with respect to frequency*. A good magnetic tape recorder will have linearly increasing phase response as frequency increases. In simpler terms, good phase response shows that a magnetic recorder can reproduce a complex waveform (such as a square wave which has an infinite number of sine waves) without distorting it. Figure 6-6 shows both good and bad phase response.

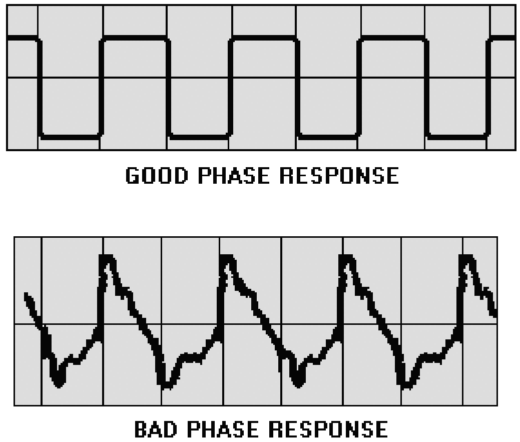

Figure 6-6.—Pictures showing the effect of good and bad phase response on square-wave reproduction.

PHASE-RESPONSE MEASUREMENT

You cannot *directly* measure phase response. The best way to check the phase response of a magnetic tape recorder is to record and reproduce a square wave and watch the output on an oscilloscope. If the output signal is symmetrical, like in figure 6-7, the recorder has good phase response.

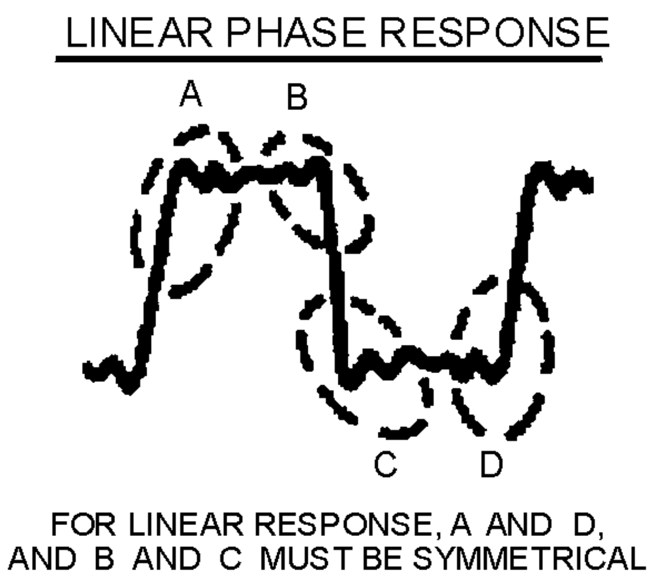

Figure 6-7.—An example of good linear phase response.

Q-7. A recorder's harmonic-distortion specification reads 2% third harmonic of a 100-kHz signal at 60 ips. What does this mean?

Q-8. What are three possible causes of even-order harmonics?

Q-9. What number harmonic is the primary harmonic distortion in magnetic tape recorders?

Q-10. When measuring harmonic distortion, you set the signal generator to input a 15-kHz test signal. To what frequency should you set the wave analyzer?

Q-11. How should a tape recorder with good phase response reproduce a complex waveform, such as a square wave?

Q-12. How could you check the phase response of a tape recorder?

FLUTTER

The general audio and broadcast field coined the term *flutter* to describe what you'll actually hear from the bad effects of this specification.

FLUTTER DEFINITION

Flutter is *the result of non-uniform tape motion caused by variations in tape speed that produces frequency modulation of signals recorded onto magnetic tape.*

Flutter is usually expressed as a *percent peak* or a *peak-to-peak* value for instrumentation recorders and as a *root-mean-square (RMS)* value for audio recorders. It's caused by magnetic tape transports. Low-frequency flutter (below 1000 Hz) is caused by the rotating parts of a tape transport such as:

- Irregular magnetic tape supply or take-up reels.
- Uneven or sticking guide rollers and pinch rollers.
- Capstans.

High-frequency flutter (above 1000 Hz) is caused by the *fixed* parts of a tape transport, such as fixed tape guides and magnetic heads. When the magnetic tape passes over a fixed tape guide or magnetic head, the transition from static to dynamic friction causes something called *stiction*. It's this stiction that causes the variations in tape speed which, in turn, cause the flutter.

As you might guess, it's hard to prevent flutter. The only way to lessen flutter is through skilled engineering, machining, and design of magnetic tape recorders.

FLUTTER MEASUREMENT

There are many ways to measure flutter. Most are based on the fact that tape speed variations cause frequency modulation of a recorded tone. Figure 6-8 shows a typical setup for measuring the peak-to-peak value of flutter with a frequency-modulation (FM) demodulator and an oscilloscope. The technical manual for the magnetic tape recorder you're testing will tell you how to set up the signal generator to output the test signal. After setting up the test equipment, follow these procedures:

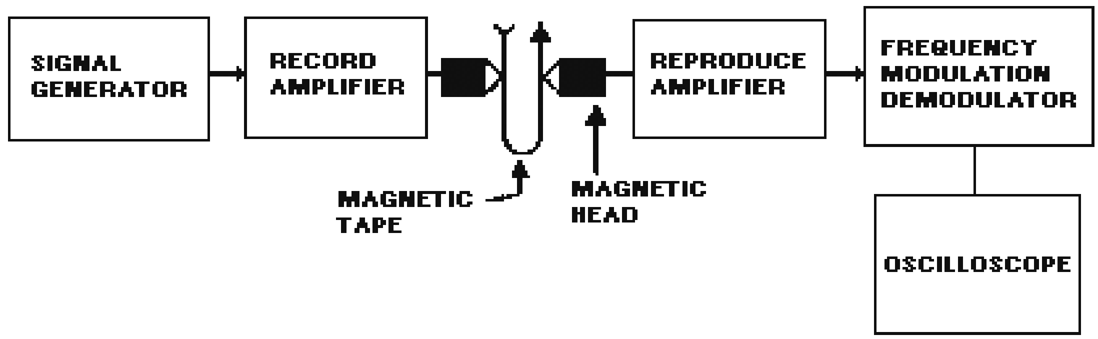

Figure 6-8.—Test equipment setup for measuring flutter.

1. Record the test signal onto magnetic tape; then rewind the magnetic tape. This is necessary because you can't measure flutter as you're recording. Since the tape-speed variation past the record head is almost the same as past the reproduce head, the flutter level is too small to see.
2. After you rewind the tape, play it back. During playback, the output signal from the tape recorder goes through the FM demodulator to remove the original test signal. The waveform you now see on the oscilloscope is the actual flutter signal that was modulated onto the test signal.
3. Using the oscilloscope display, measure the peak-to-peak value of the flutter signal.

TIME-BASE ERROR

The time-base error (TBE) specification of magnetic tape recorders is closely related to the flutter specification. In fact, the TBE is a direct measure of the effects of flutter on the stability of recorded data.

TIME-BASE ERROR DEFINITION

The TBE is *the time-relationship error between two or more events recorded and reproduced from the same magnetic tape.* It's also defined *as the displacement of a point on the magnetic tape from where it should have been, during a specific time interval.*

A typical TBE specification might read "+ / – 100 microseconds over a 10-millisecond time interval at a tape speed of 60 inches per second, referenced to a control tone." This means that the time-base error could cause a signal to *jitter* +/– 100 microseconds over a 10-millisecond period at a tape speed of 60 inches per second.

TBE jitter introduces noise or unwanted frequency modulation (when using FM recording techniques) into the magnetic tape recording process. It can also cause a loss of accuracy in pulse-duration modulation (PDM), pulse-coded modulation (PCM), or other magnetic recordings where precise timing relationships exist between two or more signals.

TIME-BASE ERROR MEASUREMENT

The simplest way to measure the TBE is with an oscilloscope. Figure 6-9 shows a typical test equipment setup for measuring TBE. After you set up the test equipment, measure the TBE as follows:

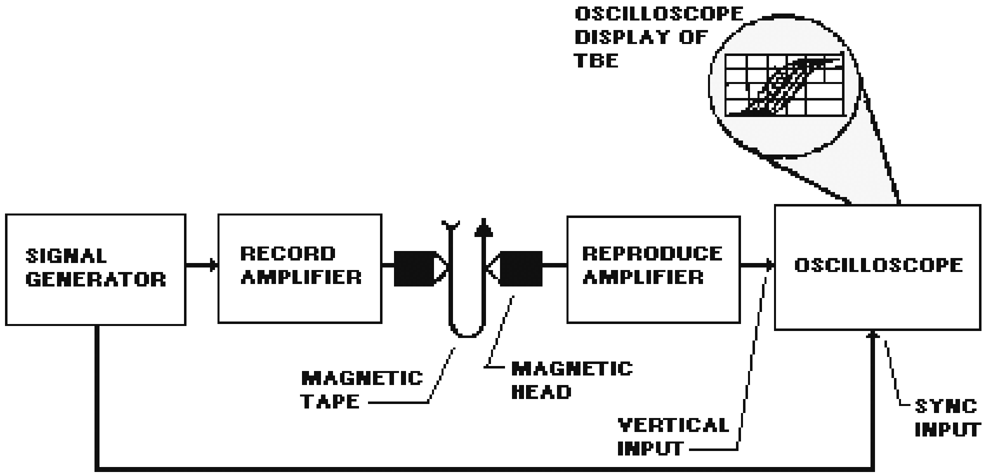

Figure 6-9.—Test equipment setup for measuring time-base error.

1. Set the signal generator to generate a test signal. The technical manual for the magnetic tape recorder you're testing will tell you how.
2. Connect the test signal output from the signal generator to both the recorder's input and the oscilloscope's trigger (sync) input.
3. Connect the output of the tape recorder to the oscilloscope's signal (vertical) input.
4. Record and reproduce the test signal.
5. Adjust the oscilloscope's intensity control until you can see the TBE on the oscilloscope's display. (Limit glare by using a hood on the oscilloscope's display.)

SKEW

This magnetic tape recording specification only applies to multi-tracked magnetic tape recorders.

SKEW DEFINITION

Skew is *the inter-track fixed and dynamic displacement, or change in azimuth, encountered by different tracks across the width of the magnetic tape as it passes the magnetic heads*. In other words, it's the time difference between the tracks on a multi-tracked magnetic head.

A typical skew specification might read "+/– 0.15 microseconds between adjacent tracks on the same head stack at 120 inches per second." This means that one of the tracks on a magnetic head could lead, or lag, the track next to it by as much as 0.15 microseconds at 120 ips. This specification applies to both fixed and dynamic skew.

Fixed skew can be caused by

- magnetic tape recorder electronics,

- gap scatter in the magnetic head stack,
- azimuth alignment of the magnetic head stack, or
- fixed difference in tension along the tape path

You can minimize most fixed skew by adjusting the magnetic recorder's electronics or by realigning the magnetic heads.

Fixed skew errors usually do not show up when magnetic tapes are recorded and reproduced on the same tape recorder. Since fixed skew errors are additive, they'll usually show up when you record on one magnetic tape recorder and then reproduce on another.

Dynamic skew errors are caused by either the magnetic tape transport or the magnetic tape itself. If the tape transport guides are worn or sticking, the magnetic tape won't properly pass over the magnetic heads. It'll *drift* and pass the magnetic head at an angle (like a car skidding on an icy road). If the magnetic tape itself is warped or isn't uniform across its width it, too, will cause dynamic skew.

SKEW MEASUREMENT

Skew is best measured with an oscilloscope. Figure 6-10 shows a typical test equipment setup for measuring skew. The technical manual for the magnetic tape recorder you're testing will tell you how to set up the signal generator. After test equipment setup, measure the skew as follows:

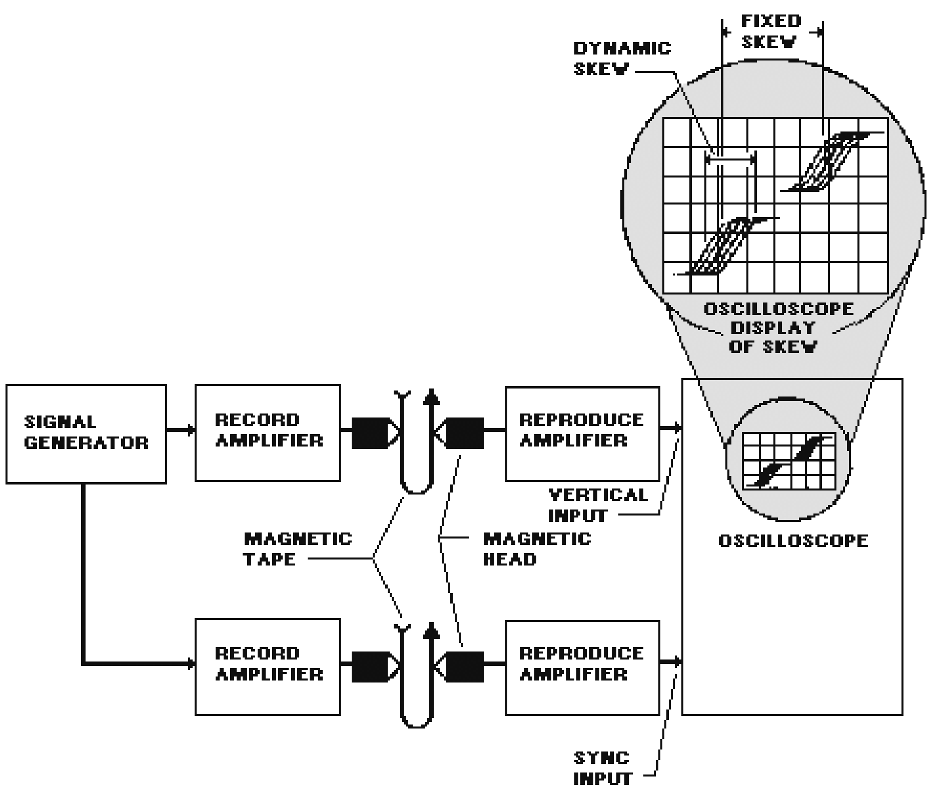

Figure 6-10.—Test equipment setup for measuring skew.

1. Inject the test signal into a reference track and one other track of the multi-track magnetic tape recorder. (The reference track should be one of the two *outside* tracks of the magnetic head.)

2. Connect the output from the reference track to the *sync* input of the oscilloscope to trigger the horizontal sweep.

3. Connect the output from the other track to the *vertical* input of the oscilloscope.

4. While recording and reproducing the test signal, measure the fixed and dynamic skews which are displayed on the oscilloscope. Figure 6-10 shows how this looks.

Q-13. What causes flutter in a tape recorder's output?

Q-14. What causes low-frequency flutter (below 1000 Hz)?

Q-15. What causes high-frequency flutter (above 1000 Hz)?

Q-16. Your recorder's TBE specification reads " +/− 80 microseconds over a 10 millisecond time interval at a tape speed of 60 ips, referenced to a control tone." What does this mean?

Q-17. Why is it important to minimize TBE jitter in magnetic tape recordings where precise timing relationships exist between two or more signals?

Q-18. The skew specification of your multi-tracked tape recorder reads " +/− 0.20 microseconds between adjacent tracks on the same head stack at 120 ips." What does this mean?

Q-19. How can you minimize fixed skew?

Q-20. When are fixed skew errors most likely to show up?

Q-21. How do worn or sticking tape transport guides cause dynamic skew on a multi-track recorder?

SUMMARY

Now that you've finished chapter 6, you should be able to describe the seven most common magnetic tape recording specifications and how to measure each specification. The following is a summary of important points in this chapter:

The **SIGNAL-TO-NOISE RATIO (SNR)** is the ratio of the normal signal level to the tape recorder's own noise level measured in dB. The higher a recorder's SNR, the wider the range of signals it can record and reproduce.

SNR IS STATED IN ONE OF THREE WAYS based on how it was measured. If you don't know the way it was measured, you could be misled.

A recorder's **FREQUENCY-RESPONSE** specification is sometimes called its *bandwidth*. It tells the range of frequencies a recorder can effectively record and reproduce. Factors that can degrade a recorder's frequency response are an improper *bias level setting, reproduce head gap*, or *tape transport speed.* Also, failure to clean the heads and the tape transport can cause poor *tape-to-head contact.*

HARMONIC DISTORTION is the production of unwanted harmonic frequencies when a signal is applied at the recorder's input. The primary harmonic distortion in tape recorders is third order harmonics. It's measured with a wave analyzer. You can reduce this distortion with proper preventive maintenance and periodic performance tests.

Good **PHASE RESPONSE** means the recorder can reproduce complex waveforms such as square waves without distortion. The best way to check a recorder's phase response is by recording and reproducing a square wave and checking the output on an oscilloscope.

FLUTTER results from non-uniform tape motion caused by variations in tape speed. The tape speed variations are caused by design and machining deficiencies in the rotating and fixed parts of the tape transport.

TIME-BASE ERROR (TBE) is the time-relationship error between two or more events recorded on and reproduced from the same magnetic tape. It causes TBE jitter, which introduces noise or loss of accuracy where precise timing relationships exist between two or more signals.

SKEW is the time difference in microseconds between the tracks on a multi-tracked tape recorder. *Fixed* or *dynamic* skew can happen when one of the tracks on the multi-track head leads or lags the track next to it. *Fixed skew* errors only show up when you record on one recorder and reproduce on a different recorder. You can minimize fixed skew by adjusting the recorder's electronics and aligning the heads. *Dynamic skew* errors are caused by worn or sticking tape transport guides or by warped magnetic tape.

ANSWERS TO QUESTIONS Q1. THROUGH Q21.

A1. 35-dB RMS because the highest SNR can always record and reproduce the widest range of input signals.

A2. A VTVM and a signal generator. (See figure 6-1.)

A3.

- *a. Root-mean-square (RMS) signal-to-RMS noise.*
- *b. Peak-to-peak signal-to-RMS noise.*
- *c. Peak signal-to-RMS noise.*

A4. The recorder can record all frequencies between 150 Hz and 150 kHz at 60 ips without varying the output amplitude more than 3 dB.

A5. The upper and lower limits of the frequency response specification for that tape recorder.

A6.

- *a. A too-high or too-low bias signal level setting for the record head.*
- *b. An improper reproduce head gap.*
- *c. An improper tape transport speed.*
- *d. Poor tape-to-head contact.*

A7. The recorder has 2% third-harmonic distortion of a 100-kHz signal at 60 ips.

A8.

a. Permanently magnetized heads.

b. Faulty circuitry.

c. Asymmetrical bias signal.

A9. Third-order harmonic.

A10. 45 kHz.

A11. With no distortion.

A12. Record and reproduce a square wave and see if the output on an oscilloscope is symmetrical.

A13. Non-uniform tape motion caused by variations in tape speed.

A14. Rotating parts of a tape transport, such as irregular tape reels, sticking guides and pinch rollers, and capstans.

A15. Fixed parts of a tape transport, such as fixed tape guides and magnetic heads.

A16. The TBE could cause a signal to jitter +/− 80 microseconds over a 10-millisecond period at a tape speed of 60 ips.

A17. The jitter could cause noise and a loss of accuracy.

A18. One of the tracks on a magnetic head could lead or lag the track next to it by as much as 0.20 microseconds at 120 ips.

A19. Adjust the recorder's electronics or realign the magnetic heads.

A20. When you record on one tape recorder and then reproduce on a different recorder.

A21. The tape drifts past the multi-track head at an angle.

CHAPTER 7

DIGITAL MAGNETIC TAPE RECORDING

LEARNING OBJECTIVES

After completing this chapter, you'll be able to do the following:

1. Describe the characteristics of digital magnetic tape recording and the difference between *analog* and *digital* recording.

2. Describe each of the three *formats* for digital magnetic tape recording (serial, parallel, and serial-parallel).

3. Define the following terms as they apply to digital magnetic tape recording: *mark, space, bit-cell period, packing density,* and *bit-error rate (BER)*.

4. Describe the eight most common methods for encoding digital data onto magnetic tape.

5. Describe the characteristics and use of the following categories of digital magnetic tape recorders: (1) computer-compatible, (2) telemetry, and (3) instrumentation.

INTRODUCTION TO DIGITAL MAGNETIC TAPE RECORDING

This chapter introduces you to digital magnetic tape recording. It describes (1) the three formats for digital magnetic tape recording, (2) the eight methods of encoding digital data onto magnetic tape, and (3) the configuration differences between the three types of digital tape recorders.

Until now, you've learned about magnetic tape recording from an *analog* point-of-view. That is, the signal you record and reproduce is the actual analog input signal waveform. In digital magnetic tape recording, the signal you record and reproduce is, instead, a series of *digital* pulses. These pulses are called binary *ones* and *zeros*. These *ones* and *zeros* can represent one of three types of data: (1) data used by digital computers, (2) pulsed square-wave signals, or (3) digitized analog waveforms.

The digital magnetic tape recording process stores data onto tape by magnetizing the tape to its saturation point in one of two possible polarities: positive (+) or negative (–). The *saturation* point of magnetic tape is the point where the magnetic tape is magnetized as much as it can be.

DIGITAL MAGNETIC TAPE RECORDING FORMATS

There are three digital magnetic tape recording formats: *serial, parallel*, and *serial-parallel*. Each of these is described below. Figure 7-1 shows each of the three formats as they apply to recording an eight-bit binary data stream.

SERIAL DIGITAL MAGNETIC TAPE RECORDING FORMAT

This is the simplest of the three digital magnetic tape recording formats. It's usually used when recording instrumentation or telemetry data. In this format, the incoming data pulses are recorded onto a single recorder track of the magnetic tape in a single, continuous stream. Figure 7-1A shows how this looks.

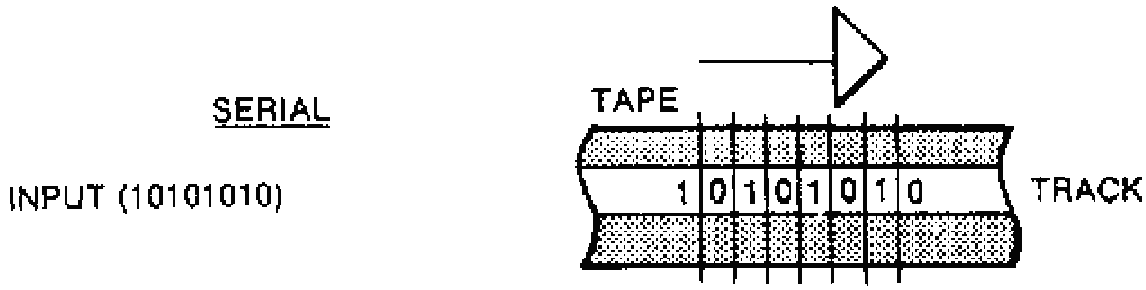

Figure 7-1A.—Digital magnetic tape recording formats.

PARALLEL DIGITAL MAGNETIC TAPE RECORDING FORMAT

In this format, the incoming data pulses come in on more than one input channel and are recorded *side-by-side* onto more than one tape track. The data pulses across the width of the magnetic tape are *related* to each other. Figure 7-1B shows how this looks. This format is usually used to store computer data.

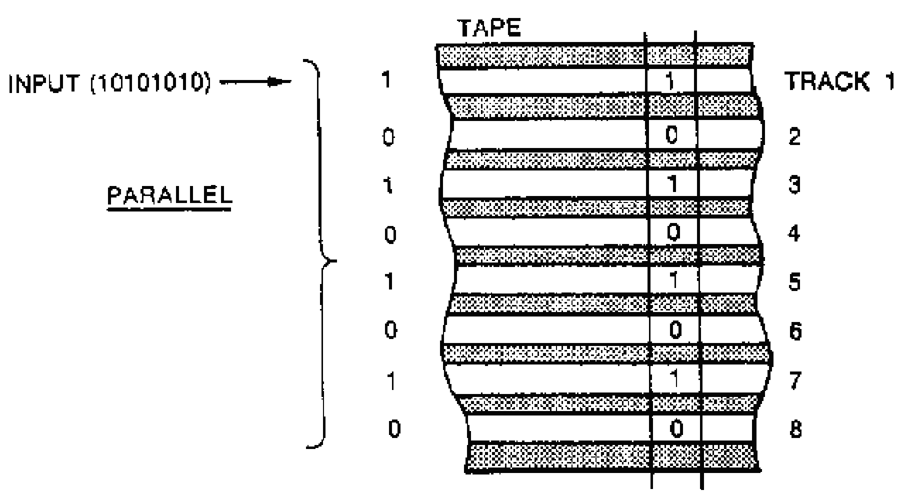

Figure 7-1B.—Digital magnetic tape recording formats.

SERIAL-PARALLEL DIGITAL MAGNETIC TAPE RECORDING FORMAT

This format is more complex. It takes a serial input stream of data pulses, breaks them up, and records them on more than one recorder track. When the tape is reproduced, the recorder recombines the broken-apart data into its original form. Figure 7-1C shows how this looks. The serial-parallel format is usually used in instrumentation recording when the input data rate is high.

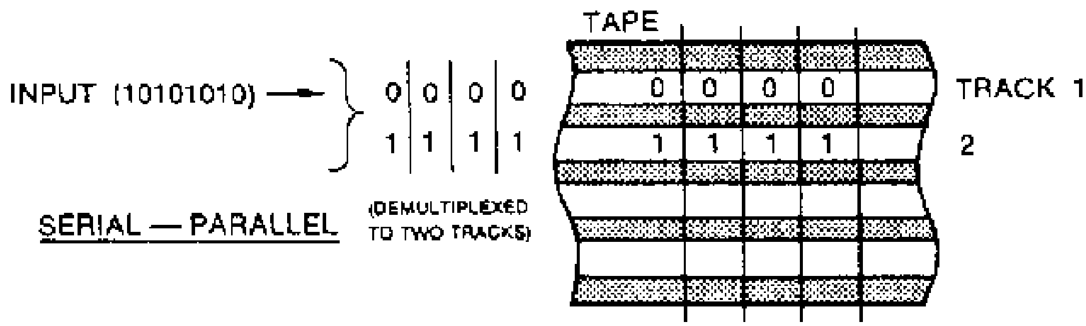

Figure 7-1C.—Digital magnetic tape recording formats.

DIGITAL MAGNETIC TAPE RECORDING DEFINITIONS

Before we describe the methods for encoding digital data onto magnetic tape, let's define the following terms:

Mark: The voltage state of a digital *one (1)* data bit. It's also sometimes called *true*.

Space: The voltage state of a digital *zero (0)* data bit. It's also sometimes called *false*.

Bit-cell period: The time occupied by a single digital bit.

Packing density: The number of bits per fixed length of magnetic tape per track. There are three categories of packing density:

1. Low density—200 to 1,000 bits per inch (bpi).
2. Medium density—1,000 to 8,000 bpi.
3. High density—8,000 to 33,000 bpi.

Bit-error rate: The number of bits within a finite series of bits that will be reproduced incorrectly.

Q-1. In digital magnetic tape recording, the series of recorded digital pulses can represent what three types of data?

Q-2. What three formats are used for digital magnetic tape recording?

Q-3. What format of digital tape recording is normally used to store computer data?

Q-4. What format of digital tape recording takes a serial input stream of data pulses, breaks them up, and records them on more than one data track?

Q-5. What format of digital tape recording is normally used to record instrumentation or telemetry data?

DIGITAL MAGNETIC TAPE RECORDING ENCODING METHODS

This section describes how digital data is *electrically* encoded onto the magnetic tape. The following paragraphs describe the eight most common digital data encoding methods.

1. Return to bias (RB)
2. Return to zero (RZ)
3. Non-return to zero (NRZ) and these four variations of the NRZ method:
    a. Non-return-to-zero level (NRZ-L)
    b. Enhanced non-return-to-zero level (E-NRZ-L)
    c. Non-return-to-zero mark (NRZ-M)
    d. Non-return-to-zero space (NRZ-S)
4. Bi-phase level

RETURN-TO-BIAS (RB) ENCODING

The RB encoding method uses magnetic tape that is *pre-set* to one of the two polarities (+ or –). This pre-sets the magnetic tape to *all zeros.* Digital *ones* are then recorded onto the magnetic tape by magnetizing the tape in the opposite polarity. After each *one* pulse, the tape returns to its original bias condition. Figure 7-2 shows the magnetic tape *preset* to a negative bias condition. It also shows how the digital data word 0100110001 is stored onto the magnetic tape using the RB encoding method.

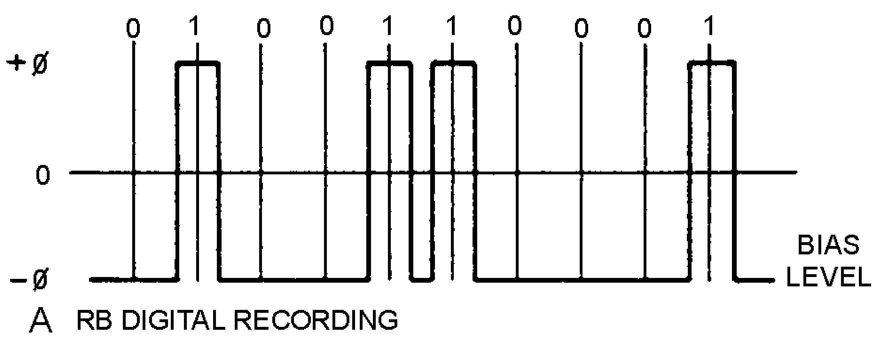

Figure 7-2.—Return-to-bias (RB) digital encoding method.

This method has a serious drawback: It requires an external clocking signal to read the zeros stored on the tape.

RETURN-TO-ZERO (RZ) ENCODING

The RZ encoding method uses magnetic tape that is normally in a *neutral* condition (the tape is not biased positively or negatively). A digital *one* is recorded as a positive-going pulse: a digital *zero* is recorded as a negative-going pulse. The magnetic tape returns to its *neutral* state in between pulses. Figure 7-3 shows the magnetic tape in its neutral state. It also shows how the digital data word 0100110001 is stored onto the magnetic tape using return-to-zero encoding.

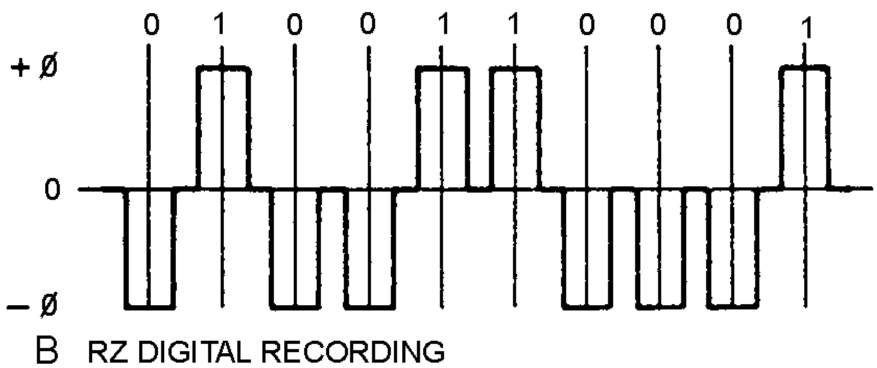

Figure 7-3.—Return-to-zero (RZ) digital encoding method.

NON-RETURN-TO-ZERO (NRZ) ENCODING

The NRZ encoding method is, by far, the most widely used. It's accurate, simple, and reliable. It does <u>not</u> return the magnetic tape to its *neutral* state in between pulses. The magnetic tape is always in saturation, either positively or negatively. The polarity of the saturating signal only changes when incoming data changes from a *zero* to a *one* and vice versa. Figure 7-4 shows how the digital data word 101100011010 is stored onto the magnetic tape using the NRZ encoding method.

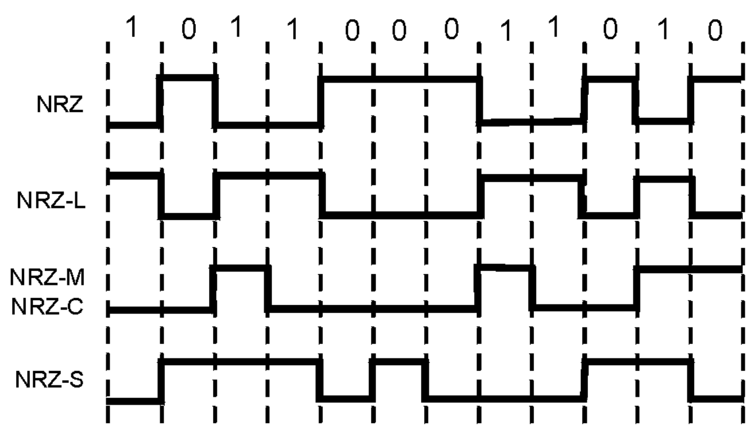

Figure 7-4.—Non-return-to-zero (NRZ) digital encoding method.

There are four widely used variations to the basic NRZ encoding method. Each of these is described in the following paragraphs.

Non-Return-To-Zero-Level (NRZ-L) Encoding

In NRZ-L encoding, the polarity of the saturating signal changes only when the incoming signal changes from a *one* to a *zero* or from a *zero* to a *one*. Figure 7-4 also shows how the digital data word 101100011010 is stored onto the magnetic tape using the NRZ-L encoding method. Note that the NRZ-L method looks just like the NRZ method, except for the first input *one* data bit. This is because NRZ does not consider the first data bit to be a polarity change, where NRZ-L does.

The NRZ-L encoding method isn't normally used in higher density (over 20,000 bpi) digital magnetic recording. This encoding method is sometimes called the non-return-to-zero-change (NRZ-C) encoding method.

Enhanced Non-Return-to-Zero-Level (E-NRZ-L) Encoding

This encoding method takes the basic NRZ-L data and adds a parity bit to it after every seven incoming data bits. The polarity of the parity bit is such that the total number of *ones* in the eight-bit data word will be an *odd* count. Figure 7-5 shows how the digital data word 0100010 is stored onto the magnetic tape using the E-NRZ-L encoding method.

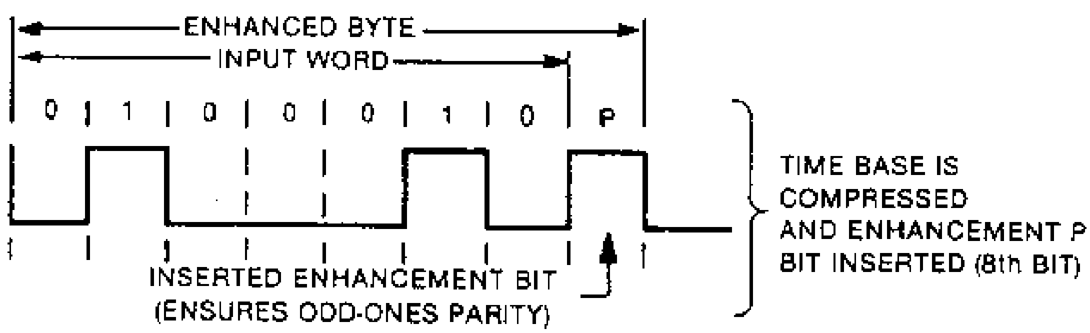

Figure 7-5.—Enhanced non-return-to-zero-level (E-NRZ-L) digital encoding method.

Before the parity bit is added, the original incoming data is compressed in time. This is done so that when the parity bit is added, the eight-bit data word takes up the same amount of time as the original-seven bit data word. When the tape is reproduced, the parity bit is taken out.

This encoding method works very well in high density (up to 33,000 bpi) magnetic tape recording. And, it offers an extremely good bit-error rate of 1 error per 1 million bits.

Non-Return-to-Zero-Mark (NRZ-M) Encoding

The NRZ-M encoding method is probably the most widely used encoding method for 800-bpi digital magnetic tape recording. In this method, the polarity of the saturating signal changes when the incoming signal is a *one.* An incoming *zero* would not change the polarity of the saturating signal.

NRZ-M offers better protection from error than straight NRZ. In NRZ-M, there's a one-to-one relationship between incoming data and polarity changes. If one data bit is lost, only that one bit is lost.

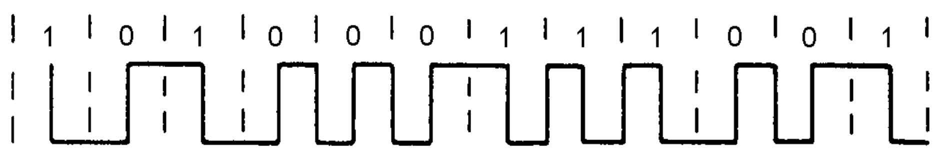
Whereas, in straight NRZ, if one bit is lost, all of the bits that follow will be exactly the opposite in polarity from what they should be. Figure 7-4 also shows how the digital data word 101100011010 is stored onto the magnetic tape using the NRZ-M encoding method.

Non-Return-to-Zero-Space (NRZ-S) Encoding

The NRZ-S encoding method works just like NRZ-M encoding, with one exception. Instead of the saturating signal changing polarity when the incoming data signal is a *one*, it changes when the incoming data signal is a *zero*.

BI-PHASE LEVEL ENCODING

The bi-phase level encoding method records two logic levels for each incoming data bit. When an incoming data bit is a *one*, bi-phase level recording records a *zero-one*. When an incoming data bit is a *zero*, bi-phase level recording records a *one-zero.* This encoding method helps to overcome any low-frequency response problems that the magnetic tape recorder may have. Figure 7-6 shows how the digital data word 101000111001 is stored onto magnetic tape using the bi-phase encoding method.



Courtesy of DATATAPE Incorporated, Copyright © All rights reserved

Figure 7-6.—Bi-phase level digital encoding method.

Bi-phase encoding requires exactly twice the bandwidth of NRZ-L. That's why it's mostly used in medium-density digital magnetic tape recording. In fact, this encoding method is probably the most widely used encoding method for 1600-bpi digital magnetic tape recording.

DIGITAL MAGNETIC TAPE RECORDER USES

As you already know, digital magnetic tape recorders are used to store and retrieve *digital* data. These recorders fall into one of three categories, (1) computer compatible, (2) telemetry, and (3) instrumentation.

COMPUTER-COMPATIBLE DIGITAL TAPE RECORDERS

Computer-compatible digital tape recorders store and retrieve computer programs and data. They're usually multi-tracked tape recorders with at least two, and up to nine, tracks for data. They use either 1/4" or 1/2" magnetic tape on either reels or cartridges.

TELEMETRY DIGITAL TAPE RECORDERS

Telemetry digital magnetic tape recorders are more commonly called *wideband* recorders. They're used for recording radar signals and other pulsed square-wave type signals with a bandwidth of 500 kHz to 2 MHz. They're also multi-tracked tape recorders that have either 14 or 28 tracks for data. They use 1" magnetic tape on either aluminum or glass reels.

INSTRUMENTATION MAGNETIC TAPE RECORDERS

Instrumentation digital magnetic tape recorders are used to record other special signals with a bandwidth of less than 500 kHz. They, too, are multi-tracked recorders, normally with 7 tracks for data. They use 1/2" magnetic tape on metal or glass reels.

Q-6. Which of the eight methods for encoding digital data onto magnetic tape is most widely used because it's accurate, simple, and reliable?

Q-7. Which digital data tape encoding method presets the magnetic tape to all zeros and then records digital ones onto the tape?

Q-8. Which digital data encoding method records a digital one as a positive pulse and a digital (zero) as a negative pulse and returns the tape to neutral between pulses?

Q-9. Which method of digital data encoding does NOT return the tape to neutral between pulses but, instead, saturates the tape positively or negatively as the incoming data changes between zero and one?

Q-10. What are the four widely used variations of the NRZ encoding method?

Q-11. Which digital data encoding method helps overcome a tape recorder's low-frequency response problems by recording two logic levels for each incoming data bit?

Q-12. Digital magnetic tape recorders used to store and retrieve digital data fall into what three categories?

Q-13. What category of digital tape recorder is used for recording pulsed square-wave signals with a bandwidth of 500 kHz to 2 MHz?

Q-14. What category of digital tape recorder is used to record special signals with a bandwidth of less than 500 kHz?

SUMMARY

Now that you've finished chapter 7, you should be able to describe (1) the characteristics of digital magnetic tape recording, (2) the three *formats* for digital magnetic tape recording, (3) the eight *methods* for encoding digital data onto magnetic tape, and (4) the characteristics and uses of the three types of digital magnetic tape recorders. The following is a summary of important points in this chapter:

Digital magnetic tape recorders record a SERIES OF DIGITAL PULSES called binary *ones* and *zeros*. These digital pulses can represent (1) data used by digital computers, (2) pulsed square-wave signals, or (3) digitized analog waveforms.

Three **FORMATS FOR DIGITAL MAGNETIC TAPE RECORDING** are *serial, parallel,* and *serial-parallel*.

There are **EIGHT COMMONLY USED METHODS FOR ENCODING** digital data onto magnetic tape. The non-return-to-zero (NRZ) method and the four variations of the NRZ method are most commonly used.

THREE CATEGORIES OF DIGITAL MAGNETIC TAPE RECORDERS are (1) computer-compatible, (2) telemetry, and (3) instrumentation.

ANSWERS TO QUESTIONS Q1. THROUGH Q14.

A1.

a. *Data used by digital computers.*

b. *Pulsed squarewave signals.*

c. *Digitized analog waveforms.*

A2. (1) Serial, (2) parallel, and (3) serial-parallel.

A3. Parallel digital magnetic tape recording.

A4. Serial-parallel digital magnetic tape recording.

A5. Serial digital magnetic tape recording.

A6. Non-return-to-zero (NRZ) encoding.

A7. Return-to-bias (RB) encoding.

A8. Return-to-zero (RZ) encoding.

A9. Non-return-to-zero (NRZ) encoding.

A10.

a. *Non-return-to-zero level (NRZ-L).*

b. *Enhanced non-return-to-zero level (E-NRZ-L).*

c. *Non-return-to-zero mark (NRZ-M).*

d. *Non-return-to-zero space (NRZ-S).*

A11. Bi-phase level encoding.

A12.

a. *Computer-compatible digital tape recorders.*

b. *Telemetry digital tape recorders.*

c. *Instrumentation digital tape recorders.*

A13. Telemetry digital tape recorders.

A14. Instrumentation digital tape recorders.

CHAPTER 8

MAGNETIC DISK RECORDING

LEARNING OBJECTIVES

After completing this chapter, you'll be able to do the following:

1. Describe how flexible (floppy) disks are constructed; how data is organized on them; how they are handled, stored, and shipped; and how they are erased.
2. Describe how fixed (hard) disks are constructed; how data is organized on them; how they are handled, stored, and shipped; and how they are erased.
3. Describe each of the following methods for recording (encoding) digital data onto magnetic disks: *frequency-modulation* encoding, *modified frequency-modulation* encoding, and *run length-limited* encoding.
4. Describe the characteristics of *floppy disk drive transports* and *hard disk drive transports* and describe the preventive maintenance requirements of each type.
5. Describe the following parts of the *electronics* component of a magnetic disk drive: control electronics, *write/read* electronics, and *interface* electronics.
6. Describe the five most common types of disk drive interface electronics.
7. Define the following magnetic disk recording *specifications:* seek time, latency period, access time, interleave factor, transfer rate, and recording density.

INTRODUCTION

Magnetic disk recording was invented by International Business Machines (IBM) in 1956. It was developed to allow mainframe computers to store large amounts of computer programs and data. This new technology eventually led to what's now known as the computer revolution.

This chapter introduces you to the following aspects of magnetic disk recording:

- Disk recording mediums
- Disk recording methods
- Disk drive transports
- Disk drive electronics
- Disk recording specifications

MAGNETIC DISK RECORDING MEDIUMS

There are two types of disk recording mediums: *flexible diskettes* and *fixed (hard) disks.* The following paragraphs describe (1) how flexible and fixed disks are made; (2) how data is organized on them; (3) how to handle, store, and ship them; (4) and how to erase them.

FLEXIBLE MAGNETIC RECORDING DISKETTES

Flexible diskettes, or *floppy disks* as they're more commonly called, are inexpensive, flexible, and portable magnetic storage mediums. They have the following characteristics.

Floppy Disk Construction

Floppy disks are made of round plastic disks coated with magnetic oxide particles. The disks are enclosed in a plastic jacket which protects the magnetic recording surface from damage.

Floppy disks come in three sizes: 8 inch, 5 1/4 inch, and 3 1/2 inch. Figure 8-1 shows each size. All disk sizes can either be *single-sided* or *double-sided.* Single-sided disks store data on only one side of the disk; double-sided disks store data on both sides.

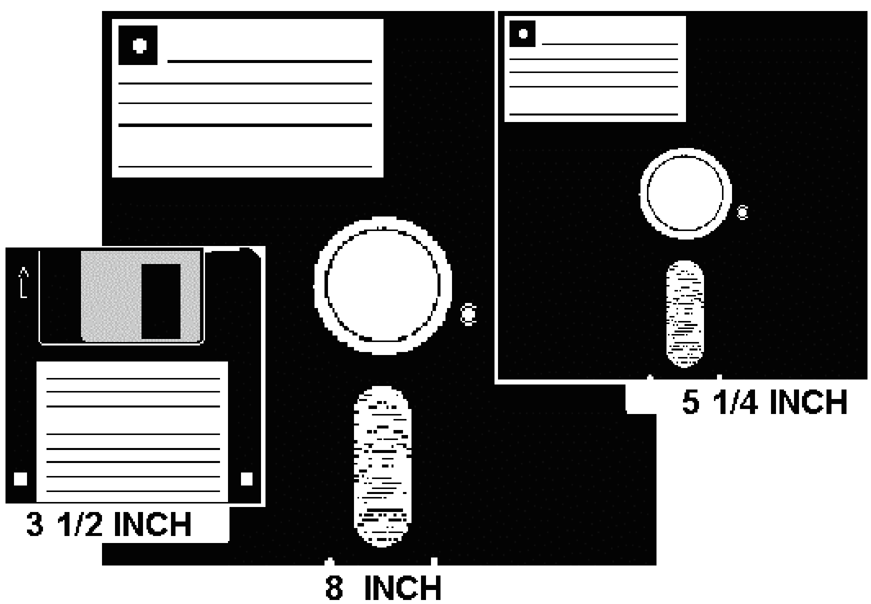


Figure 8-1.—Floppy disk construction.

When floppy disks are manufactured, the magnetic oxide coating is applied to both sides. Each disk is then checked for errors. Disks certified as single-sided, are checked on only one side; disks certified as double-sided are checked on both sides.

Floppy disks are also classified by how much data they can store. This is called a disk's *density*. There are three levels of floppy disk density: *single-density, double-density*, and *high-density*.

Some of the more common types of floppy disks and their storage capacity are listed below:

TYPE OF FLOPPY DISK	STORAGE CAPACITY
5-1/4" double-sided, double-density	360,000 bytes
5-1/4" double-sided, high-density	1,200,000 bytes
3-1/2" double-sided, double-density	720,000 bytes
3-1/2" double-sided, high-density	1,400,000 bytes

Floppy Disk Data Organization

Data is stored on a floppy disk in circular *tracks*. Figure 8-2 shows a circular track on a floppy disk. The total number of tracks on a floppy disk is permanently set by (1) the number of steps the disk drive's magnetic head stepper motor can make, and (2) whether the disk drive has a magnetic head for one or both surfaces of the floppy disk. These two things will also determine the type of floppy disk that's needed. Each type of disk is rated with a number that represents how many *tracks per inch (TPI)* it can hold. Some common track capacities are 40, 48, 80, and 96 TPI.

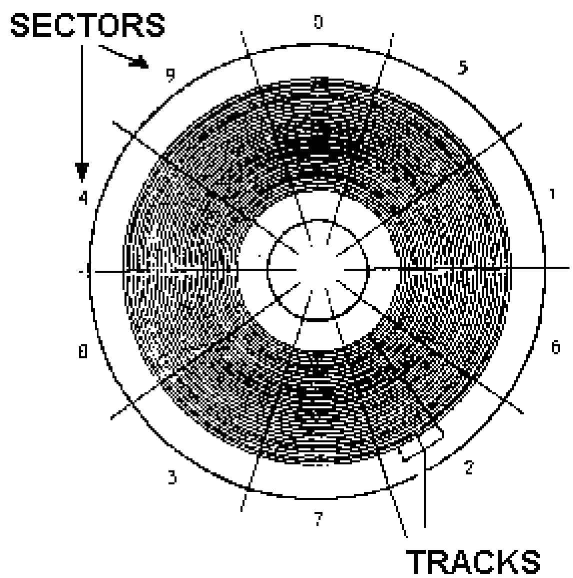

Figure 8-2.—Tracks and sectors of a magnetic disk.

Each track of a floppy disk is broken up into arcs called *sectors*. A disk is sectored just as you'd slice an apple pie. Figure 8-2 shows the sectors of a floppy disk. How many slices are made? That depends on who made the disk and in what host computer the disk is used.

There are two methods for *sectoring* a floppy disk:

1. <u>Hard Sectoring</u>: This method sectors the disk *physically.* The disk itself will have marks or sensor holes on it that the floppy disk drive hardware can detect. This method is seldom used today.

2. <u>Soft sectoring:</u> This method sectors the disk *logically*. The computer software determines the sector size and placement, and then *slices* the disk into sectors by writing codes on the disk. This

is called *formatting* or *initializing* a floppy disk. During formatting, if the computer software locates a bad spot on the disk, it locks it out to prevent the bad spot from being used. Soft sectoring is by far the most popular method of sectoring a floppy disk.

Once a floppy disk is *formatted*, the computer uses the disk's side number, a track number, and a sector number (together) as an *address*. It's this address that locates where on the disk the computer will store the data.

Floppy Disk Handling, Storage, and Shipping

Floppy disks hold a lot of data. Even disks with only a 360,000-byte storage capacity can hold 180 pages of data! That's why it's important to handle, store, and ship floppy disks properly. One hundred and eighty pages of data is a lot of data to retype just because of carelessness.

Before we get into disk handling and storage procedures, let's first learn about head-to-disk contact. Do you remember reading in chapter 2 that the quality of magnetic tape recording is seriously degraded when dust, dirt, or other contaminates get between the magnetic head and the tape? Well, the same is true for magnetic disk recording. In fact, head-to-disk contact is extremely important with floppy disks. This is because floppy disk drives, unlike magnetic tape drives, spin at very high speeds — 300 to 600 revolutions-per-minute (RPM). If anything gets between the head and the recording surface, you can lose data, or even worse, you can damage the magnetic head and the disk's recording surface. Figure 8-3 shows the size relationship between a disk drive's magnetic head, the disk recording surface, and some common contaminants.

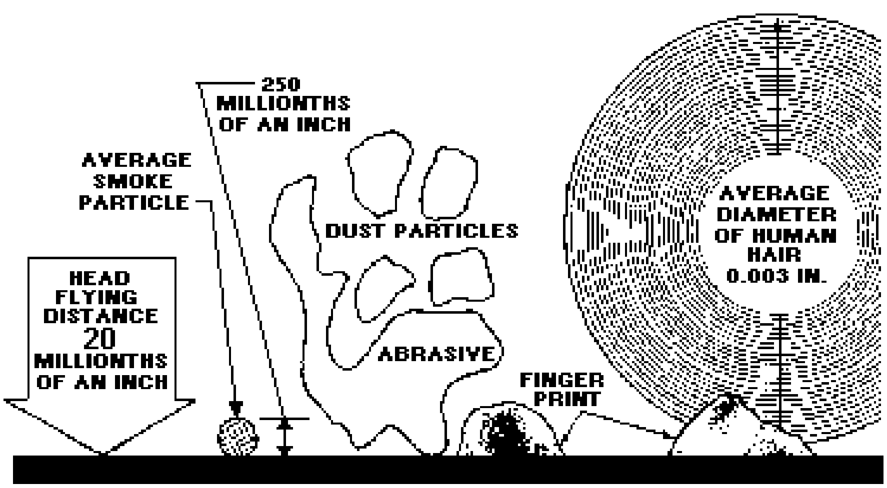

Figure 8-3.—Size relationship of distance between head and disk to contaminants.

You must handle, store, and ship floppy disks with great care if you want them to stay in good condition. Here's some specific precautions you should take:

- DO always store 8" and 5-1/4" floppy disks in their envelopes when not in use. Dirt, dust, etc., can get on the recording surface through the magnetic head read/write access hole if you leave it exposed for any length of time.

- DO always write on a floppy disk label first, and then place the label on the disk. NEVER write directly on a floppy disk. If you absolutely must write on a disk, use a felt-tip marker.

- DO hold floppy disks by their outside corners only. DO NOT bend them. And NEVER, NEVER paper clip them to anything, or anything to them.

- DO always store floppy disks in an upright position. Laying them on their side can cause them to warp.

- DO always keep floppy disks away from food, liquids, and cigarette smoke. All of these can easily damage floppy disks.

- DO always ship floppy disks in appropriate shipping containers. When shipping only a few disks, use the specially designed cardboard shipping envelopes. If you must ship a large number of disks, make sure the box you use is sturdy enough to protect the disks from damage. A good rule of thumb is to use a shipping box that allows you to place 2 inches of packing material around the disks.

- DO NOT touch any exposed recording surfaces. Something as simple as a fingerprint can destroy the data on a floppy disk.

- DO NOT expose a floppy disk to magnetic fields. Telephones, magnetic copy holders, printers, and other electronic equipment generate magnetic fields that can destroy the data on a floppy disk.

- DO NOT expose floppy disks to extreme heat or cold. Floppy disks will last longer if they're stored in an environment that stays around 70-80 degrees Fahrenheit and 30-60 percent relative humidity.

Floppy Disk Erasing

There are two ways to erase a floppy disk: (1) degauss it and then reformat it, or (2) just reformat it. The process for degaussing floppy disks is the same as for degaussing magnetic tape. Refer back to chapter 2 for the details on this.

If the floppy disks were used to store classified, or unclassified but *sensitive* information, they can't be de-classified by erasing them. This is because, with the right equipment and software, the data that was on the disk can be reconstructed. Floppy disks are cheap and easy to replace. If you can't re-use the floppy disks to store other classified data, just destroy them, using the procedures in OPNAVINST 5510.1, *DON Information and Personnel Security Program Regulation.*

Q1. Floppy disks are manufactured in what three sizes?

Q2. What type of floppy disk is made to store data on both sides of the disk?

Q3. What are the three levels of floppy disk density?

Q4. What is the storage capacity of a 5-1/4" double-sided, high-density floppy disk?

Q5. The floppy disks you are using have a rating of 96 TPI. What does this mean?

Q6. The process of formatting a floppy disk is called what type of sectoring?

Q7. What three components determine the address that locates where on a floppy disk the computer will store the data?

Q8. Why should you always store floppy disks in their envelopes?

Q9. Why should you never place floppy disks near telephones or other electronic equipments that generate magnetic fields?

Q10. What are the two ways to erase floppy disks?

FIXED MAGNETIC RECORDING DISKS

Fixed disks, or *hard disks* as they're more commonly called, are expensive, rigid, semi-portable, magnetic storage mediums. They have the following characteristics:

Hard Disk Construction

Most hard disks are made of aluminum platters coated on both sides with either *iron oxide* or *thin-film metal* magnetic coatings. The first type, iron oxide, is the most common (you can recognize this coating by its rust color). This is the same oxide coating that's used on magnetic tape. The second type of coating, thin-film metal, is the newer and better of the two. This coating is a microscopic layer of metal that's bonded to the aluminum platter. You can recognize it by its shiny silver color. Thin-film metal-coated hard disks are becoming more and more popular because they allow more data to be stored in less space.

Hard disks can hold a lot of data, the smallest disk being 10,000,000 bytes, and the largest being about 2,500,000,000 bytes (and they're working on larger ones).

Hard disk platters come in many sizes, ranging from 14" to 2". The most common sizes are 3-1/2", 5-1/4" and 14". The first two sizes are usually used with smaller personal computers. The 14" size is usually used with the larger *mini* and *mainframe* computers.

Most hard disk drives use more than one hard disk platter to store data. These are called *disk packs*. Some hard disk drives use removable hard disk platters. These can use just one platter, or they can use disk packs containing many platters. Most of the multi-platter *removable* hard disk drives in use today use 14" hard disk platters. Figure 8-4 shows a hard disk-pack.

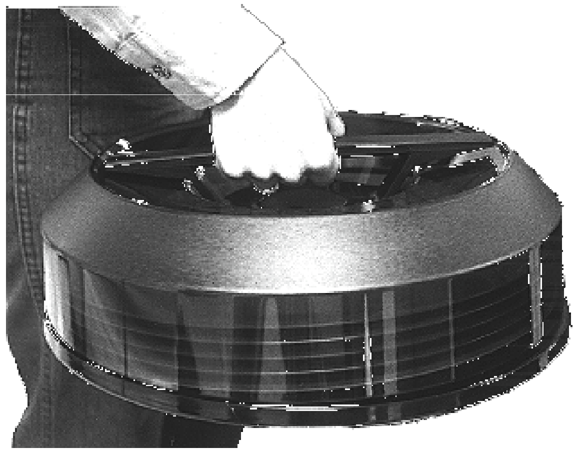

Figure 8-4.—Magnetic hard disk pack.

Hard Disk Data Organization

Data is stored on a hard disk the same way it's stored on a floppy disk, in circular tracks. The total number of tracks on a hard disk is set, just like floppy disk, by (1) the number of steps the disk drive's magnetic head stepper motor can make, and (2) whether the disk drive has a magnetic head for one or both surfaces of the hard disk platter.

A computer places data on a hard disk using one of two methods, either (1) the *cylinder* method, or (2) the *sector* method. The manufacturer of the hard disk drive decides which method to use.

THE CYLINDER METHOD.—This method uses a *cylinder* as the basic reference for placing data on a hard disk. Look at figure 8-5 view A. This is a picture of a disk pack containing six hard disk platters. Notice that this particular disk drive uses only 10 out of the 12 available recording surfaces. If you imagine that you're looking down through the disk pack from above, the tracks with the same number on each of the 10 recording surfaces will line up. Put together, these tracks make up a *cylinder*. Each of these 10 tracks with the same number, one on each recording surface, can be read from and written to by one of the disk drive's 10 read/write magnetic heads that are positioned by the five access arms.

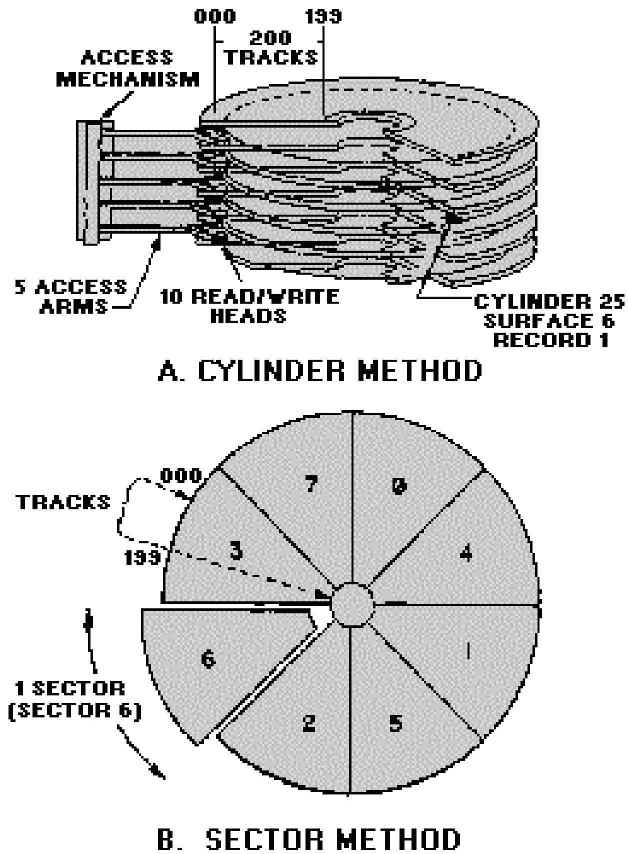

Figure 8-5.—Cylinder and sector method of organizing data on a hard disk pack.

So, to locate a place to store data using the cylinder method, a computer must specify the *cylinder number*, the *recording surface number*, and the *record number.* Figure 8-5 view A shows record number 1 stored on cylinder 25 of recording surface number 6. Special data is stored on each track to tell the computer where the start of a track is.

THE SECTOR METHOD.—Although we talked about this method earlier under the heading "Floppy Disk Data Organization," we need to repeat it here as it also applies to hard disks.

The sector method of organizing data on a hard disk is actually a variation of the *cylinder* method. As you already know, the sector method slices up a hard disk into *pie-shaped* slices (just like floppy disks). The total number of slices is set by the hard disk drive manufacturer. Figure 8-5 view B shows an example of the sector method.

Unlike a floppy disk drive, which locates a place on the disk using the *surface number, track number*, and *sector number,* a hard disk drive locates a place on the disk by using the *surface number, cylinder number,* and *sector number*. This is true even if the hard disk has only one platter. That's because both surfaces of that one platter still form a cylinder.

Hard Disk Handling, Storage, and Shipping

Hard disks hold a lot more data than floppy disks; even the lowest capacity hard disk can hold 5,000 pages of data! That's why it's important to handle, store, and ship hard disks properly. If you think 180 pages of data is a lot to retype, just think of retyping 5,000 pages!

Hard disk drives spin at a very high speed of about 3600 RPM. It is extremely important that nothing gets between the head and the recording surface. If it does, you can lose data and you can damage both the magnetic head and the disk's recording surface.

Most hard disk failures involve a *head-crash*. It's the worst thing that can happen to a hard disk. A head-crash is the result of the disk drive's magnetic heads *crashing* into the recording surface and grinding into the hard disk platter. Figure 8-6 shows a good hard disk platter and a bad hard disk platter that was the victim of a head-crash.

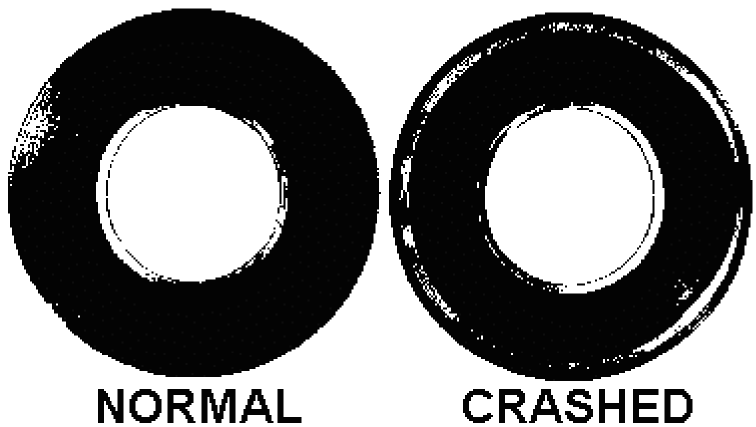

Figure 8-6.—Example of a hard disk crash.

You must handle, store, and ship hard disks with extreme care if you want them to stay in good condition. Here are some specific precautions you should take:

- DO always store removable hard disks in their storage cases when not in use. Dirt, dust, etc., can get on the recording surface through the magnetic head read/write access hole if you leave it exposed for any length of time.
- DO always handle hard disks with extreme care. DO NOT drop them. Even a small drop of 2" can warp a hard disk platter enough to cause a head crash.
- DO always keep removable hard disks away from food, liquids, and cigarette smoke. All of these can easily cause damage.
- DO always ship hard disks in their proper shipping containers. If you don't have the original shipping container, make sure the shipping box is sturdy and big enough to allow 2" of packing material around the disk. Save the original packing material for the hard disk just in case you need to ship it somewhere.
- DO NOT touch any exposed recording surfaces. Something as simple as a fingerprint can cause a head crash and destroy a hard disk platter.
- DO NOT expose hard disks to extreme heat or cold. Hard disks will last longer if they're stored in an environment that stays around 70-80 degrees Fahrenheit and 30-60 percent relative humidity.

Hard Disk Erasing

There are two ways to erase a hard disk: (1) degauss it and then reformat it, or (2) just reformat it. As you might guess, the first method can only be used for removable hard disk platters. The second method (reformatting) is the most common. If you must degauss a removable hard disk, the process is the same as degaussing magnetic tape. Refer back to chapter 2 for the details on this.

If the hard disks were used to store classified information or unclassified but *sensitive* information, you can't de-classify the hard disks by erasing them. This is because with the right equipment and software, the data that was on the disk can be reconstructed. If you can't re-use the hard disks to store other classified data, you must sanitize or destroy them, using the procedures in OPNAVINST 5510.1.

Q11. What are the three most common sizes of hard disk platters?

Q12. Computers use what two methods to place data on a hard disk?

Q13. Which method for placing data on hard disks divides a hard disk into pie shaped slices?

Q14. When computers use the cylinder method to store data on a hard disk pack, what three items make up the address that tells the computer where on a specific disk to store the data?

Q15. What is the most common type of hard disk failure?

Q16. Hard disks should be stored in an environment that stays within what relative humidity and temperature range?

Q17. What is the most common method for erasing a hard disk?

RECORDING DIGITAL DATA ON MAGNETIC DISKS

Digital data is stored on a magnetic disk using magnetic pulses. These pulses are generated by passing a frequency modulated (FM) current through the disk drive's magnetic head. This FM current generates a magnetic field that magnetizes the particles of the disk's recording surface directly under the magnetic head. The pulse can be one of two polarities, *positive* or *negative*.

Digital data isn't just recorded onto a magnetic disk as-is. Instead, it's encoded onto the disk. Three of the most popular encoding methods are (1) *frequency modulation (FM),* (2) *modified frequency modulation (MFM)*, and (3) *run length limited (RLL)*. The following paragraphs describe each of these encoding methods.

FREQUENCY MODULATION (FM) ENCODING

The FM method of encoding digital data onto a disk uses two pulse periods to represent each bit of data (a pulse period is the time span of one pulse). The first pulse period <u>always</u> contains a *clock* pulse. The second pulse-period may, or may not, contain a *data* pulse. If the digital data is a "1," a data pulse will be present in the second pulse-period. But, if the digital data is a "0," then there's no pulse present. Figure 8-7 shows this. The clock pulse, which is always present, tells the disk drive's interface that the next pulse is a data pulse. It is used to compensate for changes in the disk's rotation speed.

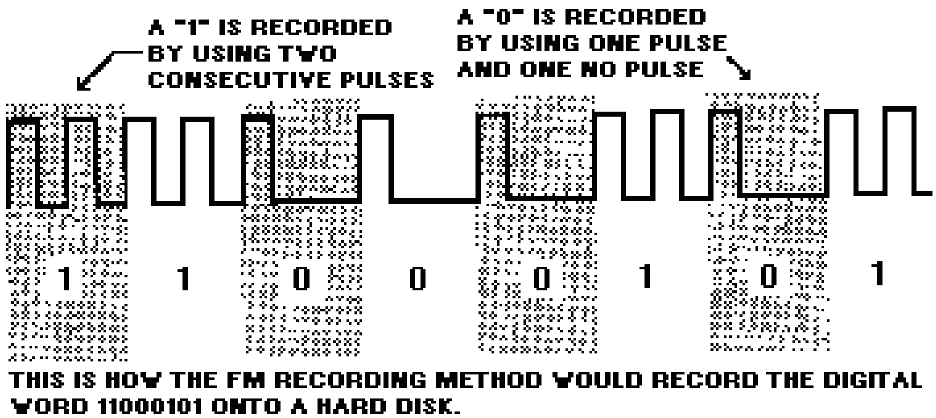

Figure 8-7.—Frequency-modulation (FM) encoding.

The FM method of encoding is old, and isn't used much anymore. You'll only see it in some of the older single-sided, single-density floppy disk drives, and in some of the older military hard disk drives.

MODIFIED FREQUENCY-MODULATION (MFM) ENCODING

The MFM method of encoding digital data onto a disk is more popular because it is more efficient and more reliable than straight FM encoding.

MFM encoding still uses two pulse periods, but uses a lot fewer pulses to store the digital data onto the disk. It does this in two ways:

1. It does away with the clock pulse that the FM method uses.

2. It stores a digital "1" by generating a *no-pulse* and a *pulse* in the two pulse periods. It stores a digital "0" as either a *pulse and a no-pulse* if the last bit was a "0," or as two no-pulses if the last bit was a "1." Figure 8-8 shows this.

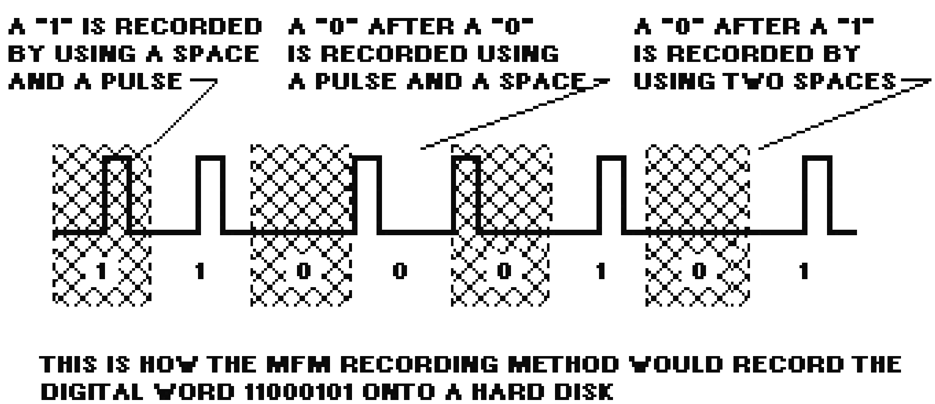

Figure 8-8.—Modified frequency-modulation (MFM) encoding.

RUN LENGTH-LIMITED (RLL) ENCODING

The RLL method of encoding digital data onto a disk is actually a refinement of the MFM encoding method. As its name implies, RLL *limits* the *run length* (distance) between pulses (also called *flux reversals*) on a hard disk. The basic theory of RLL encoding is that you can store more data in less space if you reduce the number of flux reversals (or pulses) that you must record.

There are several versions of the RLL encoding method, the most popular version being the 2,7 RLL. This means that no fewer than 2 *no-pulses* and no more than 7 *no-pulses* can occur between pulses.

MAGNETIC DISK DRIVE TRANSPORTS

Magnetic disk drive transports, like magnetic tape drive transports, move the magnetic disks across the magnetic heads and protect the disks from damage. The following paragraphs will (1) introduce you to the characteristics of both floppy and hard disk drive transports, and (2) describe their preventive maintenance requirements.

FLOPPY DISK DRIVE TRANSPORTS

Floppy disk drive transports contain the electromechanical parts that (1) rotate the floppy disk, (2) write data to it, and (3) read data from it. Figure 8-9 shows a typical floppy disk drive transport. Four of the drive transport's more important parts are the

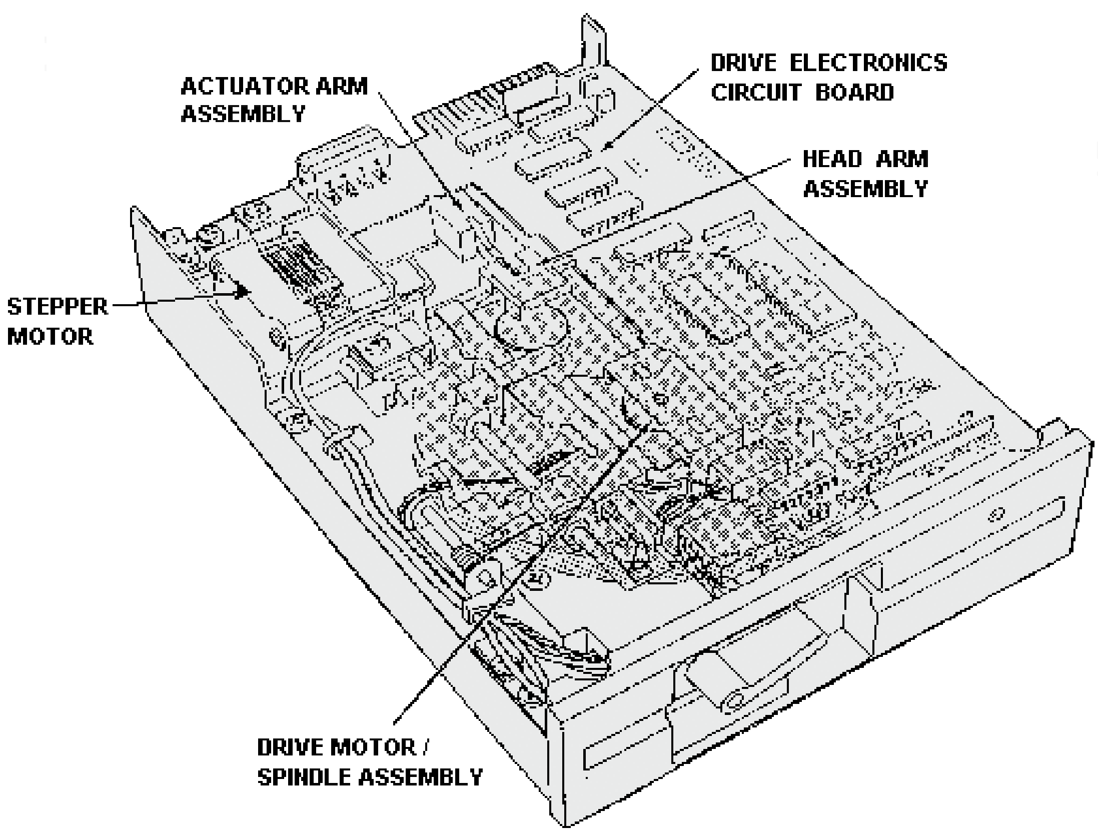

Figure 8-9.—Typical floppy disk drive transport.

1. drive motor/spindle assembly,
2. head arm assembly,
3. actuator arm assembly, and
4. drive electronics circuit board.

Drive Motor/Spindle Assembly

The spindle in this assembly holds the floppy disk in place while it spins. The drive motor spins the spindle at 300 to 600 RPM, depending on the type of floppy disk drive. The following is a list of the types of floppy disk drives and the spinning speeds of their spindles.

FLOPPY DISK DRIVE TYPE	SPINNING SPEED
5-1/4" 360-KB storage	300 RPM
5-1/4" 1.2-MB storage	360 RPM
3-1/2" 720-KB storage	600 RPM
3-1/2" 1.44-MB storage	600 RPM

The spindle of a 5-1/4" disk drive is activated and released by a small arm that's mounted on the front of the disk drive. You must turn the small arm to *lock* and *release* the floppy disk.

The spindle of a 3-1/2" disk drive is activated when the floppy disk is inserted into the disk drive. It's released by a push-button that's located on the front of the disk drive. When you push this button, the floppy disk is released and pops out of the disk drive.

Head Arm Assembly

This part of a floppy disk drive transport holds the magnetic read/write heads. There are four heads on a head arm assembly, two *write* heads and two *read* heads - one of each for each recording surface. The head arm assembly is attached to the actuator arm assembly.

Actuator Arm Assembly

The actuator arm assembly *positions* the magnetic heads over the recording surface of the floppy disk. It does this by using a special type of dc motor called a *stepper motor.* This motor, which can be moved in very small *steps*, allows the read/write heads to be moved from track to track as needed to write data onto and read data off of the floppy disk.

Drive Electronics Circuit Board

This circuit board contains the circuitry which (1) controls the electromechanical parts of the disk drive transport, (2) writes data to and reads data from the floppy disk, and (3) interfaces the floppy disk drive to the host computer.

HARD DISK DRIVE TRANSPORTS

Hard disk drive transports contain the electromechanical parts that (1) rotate the hard disk platter, (2) write data to it, and (3) read data from it.

There are two types of hard disk drive transports, *fixed disk* and *cartridge disk.* Fixed disk drive transports use *non-removable* hard disk platters. Cartridge-disk drive transports use *removable* hard disk platters that are built into protective cartridges. These two transports serve very different purposes, but they each contain the same basic parts. Figure 8-10 shows a typical hard disk drive transport. Four of the more important parts of a hard disk drive transport are the

1. drive motor/spindle assembly,

2. head arm assembly,

3. actuator arm assembly, and

4. drive electronics circuit board.

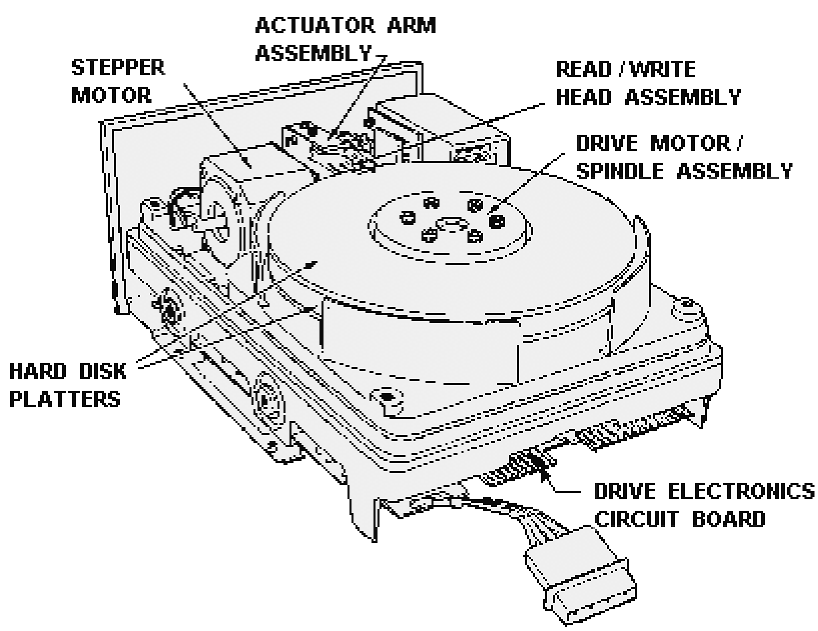

Figure 8-10.—Typical hard disk drive transport.

Drive Motor/Spindle Assembly

This assembly holds and spins the hard disk pack. The spindle assembly holds the hard disk pack in place and the drive motor spins the spindle at 3600 RPM. On cartridge disk drives, the spindle is *electronically* disengaged to release the disk pack so it can be removed.

Head Arm Assembly

This part of the hard disk drive transport holds the magnetic read/write heads. There is a separate head arm assembly for each of the hard disk platters in the disk pack. Each assembly has four magnetic heads, two *write* heads and two *read* heads-one pair of heads for each surface of the hard disk platter. The head arm assembly is attached to the actuator arm assembly.

Actuator Arm Assembly

This part of the hard disk drive transport *positions* the magnetic heads so they can write data to and read data from the correct track of the hard disk. It does this by using either a *stepper motor* or a *voice coil* servo. A stepper motor is a special type of dc motor which can be moved in very small *steps* to accurately position the magnetic heads. A voice coil servo by itself cannot move the magnetic heads from track to track. Instead, it must use special signals called *servo signals* to make sure it's positioning the heads where they should be. The *servo signals* are pre-recorded signals which are stored on either the same hard disk platter as the data or on a separate hard disk platter.

The voice coil servo method of moving the magnetic heads to the correct track of the hard disk is also called *embedded servo control.* This type of control is becoming very popular because voice coil actuator assemblies can position the magnetic heads much quicker and more accurately than dc stepper motors.

Drive Electronics Circuit Board

This circuit board contains the circuitry which (1) controls the electromechanical parts of the hard disk drive transport, (2) writes data to and reads data from the hard disk, and (3) interfaces the hard disk drive to the host computer.

Q18. What are the three most popular methods for encoding digital data onto magnetic disks?

Q19. Older, single-sided, single-density floppy disk drives would probably use what method for encoding digital data onto the floppy disk?

Q20. What method for encoding digital data enables you to store more data in less space by limiting the distance between pulses on a hard disk?

Q21. What are the four most important parts of a floppy disk drive transport?

Q22. The drive motor of a 3-1/2", 1.44-MB floppy disk drive spins the disk at what RPM?

Q23. The head arm assembly of a floppy disk drive transport has how many read heads and how many write heads?

Q24. What part of a floppy disk drive transport uses a dc stepper motor to position the magnetic heads over the recording surface of a floppy disk?

Q25. What part of a floppy disk drive transport contains the circuitry which controls the electromechanical parts of the transport?

Q26. Hard disk drive transports contain the electromechanical parts that perform what three functions?

Q27. In the actuator arm assembly of a hard disk drive transport, what device can position the magnetic heads to the correct track of a hard disk more accurately than a dc stepper motor?

MAGNETIC DISK DRIVE PREVENTIVE MAINTENANCE

Like magnetic tape recorders, if you want a magnetic disk drive to continue storing and retrieving data without errors, you must periodically perform preventive maintenance. Fortunately, disk drives require less maintenance than magnetic tape drives. The following paragraphs describe the preventive maintenance requirements for both *floppy* and *hard* disk drives.

FLOPPY DISK DRIVE PREVENTIVE MAINTENANCE

Of all of the magnetic disk drives in use today, floppy disk drives require the most maintenance. This is because they are not sealed units like most hard drives and because they use flimsy plastic disks that are coated with the same type of oxide as magnetic tape.

It's this oxide that causes most of the problems you'll have with floppy disk drives. Just as with magnetic tape, the oxide coating wears off of the plastic backing and sticks (mainly) to the magnetic heads. This contamination causes dropout errors which have much graver consequences than with magnetic tape. It can cause a program to crash, or even worse — it can destroy your valuable data.

To prevent this, you must *periodically* clean the floppy disk drive's magnetic heads. There are many kits available to do the job. A kit has a cleaning disk and a bottle of cleaning solution. A cleaning disk looks just like a regular disk, except that instead of an oxide-coated disk, it has a cloth or fiber cleaning disk inside the protective jacket. The instructions that come with the cleaning kit will lead you through the cleaning process. Here is an example of the cleaning procedures for a floppy disk drive's magnetic heads:

1. Pour some of the cleaning solution onto the cleaning disk through the access hole in the protective jacket.
2. Insert the cleaning disk into the disk drive.
3. Exercise the disk drive for at least 30 seconds.
4. Remove the disk from the disk drive.

There are also some cleaning kits that use disposable cleaning disks. These kits will instruct you to clean the heads as follows:

1. Open the scaled envelope that contains a cleaning disk soaked in cleaning solution.
2. Insert the cleaning disk into the protective jacket provided.
3. Insert the cleaning disk (with protective jacket) into the disk drive.
4. Exercise the disk drive for 30 seconds.
5. Remove the disk from the disk drive.
6. Remove the cleaning disk from the protective jacket and throw it away.

Now comes the question "How often must I clean the heads?" That's hard to say. It depends on the type of disk drive, the quality of the floppy disks you use, and how much you use the disk drive. On the average, you should clean a floppy disk drive

- once a month if it gets heavy use,
- once every 6 months if it gets moderate use, or

- once a year if it gets very little use.

HARD DISK DRIVE PREVENTIVE MAINTENANCE

Hard disk drives need little or no preventive maintenance. If it's a *fixed* hard disk drive, it doesn't need preventive maintenance because it's a sealed unit that you must not open for any reason. If it's a *cartridge* disk drive, the manufacturer will have a special cleaning disk with instructions for doing the preventive maintenance. The Navy uses some larger cartridge disk drives, such as the 14" disk pack drives, that require some other preventive maintenance. This could include the following:

- Cleaning air filters.
- Cleaning spindles, rails, and slides.
- Cleaning and buffing read and write heads.

The technical manual for the disk drive will guide you through this type of preventive maintenance.

Q28. Why do floppy disk drives require more preventive maintenance than hard disk drives?

Q29. A kit for cleaning floppy disk drives contains what two items?

Q30. Approximately how often should you clean a floppy disk drive that gets heavy use?

Q31. Cartridge hard disk drives with 14" disk packs may require what additional types of preventive maintenance?

MAGNETIC DISK DRIVE ELECTRONICS

Magnetic disk drive electronics consist of three main parts:

1. Control electronics to control the electromechanical parts of a disk drive.
2. Write/read electronics to write data to and read data from a disk drive.
3. Interface electronics to interface the disk drive to the host computer.

Some disk drives require a separate *controller card*. When this is true, some of the drive electronics are part of the disk drive itself, and some are part of the host computer's controller card.

As different as disk drives can be (floppy, fixed, cartridge, etc.), their electronics is surprisingly similar. That's why the following paragraphs will only *very basically* describe these three main parts.

CONTROL ELECTRONICS

The main functions of a disk drive's control electronics are to:

- Spin the disk at the proper speed.
- Move the magnetic heads across the recording surface.
- Tell write/read heads when to write data and when to read data.

WRITE/READ ELECTRONICS

The write/read electronics consists of the *write* part and the *read* part. The *write* part takes incoming data from the interface electronics, formats it as needed, and writes it onto the disk. The *read* part reads the data off of the disk, formats it as needed, and sends it to the interface electronics for output to the host computer. The write/read electronics also performs the initial disk formatting function.

INTERFACE ELECTRONICS

Interface electronics do two things:

1. Receive control signals from the host computer that tells them to spin the disk, move the magnetic heads, write/read data, format a disk, etc.

2. Convert the incoming and outgoing data as needed.

A disk drive is a *serial* device. This means the data stored on the disk is stored in a serial pulse-train format. But the data coming from the disk drive and going to the host computer needs to be in a *parallel* data format. The interface electronics converts the data from parallel to serial, and vice versa, as needed.

There are many types of disk drive interfaces in use today. The five most common ones are the:

1. Naval Tactical Data System (NTDS) interface.

2. ST-506/412 interface.

3. Enhanced small device interface (ESDI).

4. Small computer systems interface (SCSI).

5. Integrated drive electronics (IDE).

The following paragraphs describe each of these interfaces.

Naval Tactical Data System (NTDS) Interface

The NTDS interface is used by many naval electronic warfare systems. There are three versions of this interface:

1. NTDS FAST: A parallel interface that can transfer data at a rate of 250,000 32-bit words per second.

2. NTDS SLOW: A parallel interface that can transfer data at a rate of 41,667 32-bit words per second.

3. NTDS SERIAL: A serial interface that can transfer data at a rate of 10 million bits (Mbits) per second.

ST-506/412 Interface

The ST-506/412 interface was developed by Seagate Technology, Inc. It's often used in the hard disk drives installed in older IBM-compatible desktop computers that have a maximum capacity of 125 MB. It's also the interface used to control most floppy disk drives in use today.

This is one of the interfaces where most of the electronics is actually on a *controller card* mounted in the host computer. With this interface, the controller card does most of the work (moving the magnetic head, spinning the disk, etc.). The controller card also cleans any data coming from the disk drive by stripping off the formatting and control signals that were used to store the data onto the hard disk.

A hard disk drive is connected to the controller card in the host computer via two ribbon cables (a 34-pin control cable and a 20-pin data cable). Floppy drives use only the 34-pin control cable to transfer both data and control signals.

When this interface was originally developed in 1981, it's 5-Mbits per second transfer rate was considered *too fast*. They actually slowed it down by using a 6:1 interleave factor (we'll define this later) so it could operate with the computers being built at that time. With today's transfer rates pushing the envelope at 24 Mbits per second, you can see that it's now one of the slowest interfaces.

Enhanced Small Device Interface (ESDI)

The ESDI is an optimized version of the ST-506/412 interface. The main difference is that with ESDI, most of the disk drive's interface electronics is located in the disk drive itself, rather than on a controller card in the host computer. The result is a much faster transfer rate and more hard disk capacity. ESDIs have a transfer rate of up to 24 MB per second. And, they can handle disk drives with a maximum capacity of 1.2 GB (gigabytes).

The ESDI uses the same interface cables as the ST-506/412 interface, but that's where the similarity ends. With ESDI drives, only the *clean* data is sent to the controller card in the host computer. All formatting and control signals are stripped off at the hard disk drive.

Small Computer Systems Interface (SCSI)

The SCSI (pronounced *skuzzy)* is very different from both the ST-506/412 and the ESDI. The SCSI is an 8-bit, parallel, high-level interface. *High-level* means that instead of a host computer asking for data by specifying a track, cylinder, and sector number, all it asks for is a logical sector number. The SCSI then translates the logical sector number into the actual disk location.

The SCSI also has other improvements over the previous disk drive interfaces. For example, it can:

- Transfer data at rates of up to 4 MB per second.
- Handle hard disk drives of almost any size.
- *Disconnect* itself from a host computer's bus while it processes requests. This frees-up the host computer to do other things.
- *Daisy-chain* up to eight units off of one controller.

The SCSI interface uses one 50-pin ribbon cable to connect the hard disk drive(s) to the controller card mounted in the host computer. Some computer manufacturers include the SCSI electronics in their motherboards and do away with a separate controller card altogether. This interface got its big break when Apple Computer Corporation used the SCSI as its hard disk drive interface in its MacIntosh computers.

Integrated Drive Electronics (IDE)

The IDE is the newest interface available. It was developed as a result of trying, to find a cheaper way to build computer systems. It includes all of the controller card electronics in the hard disk drive itself, thus, the hard drive does all the work.

The hard disk drive connects to the host computer's bus with a 40-pin ribbon cable. The ribbon cable connects directly to either a 40-pin connector on the host computer's motherboard or a 40 pin connector on a small interface card that plugs into the host computer's motherboard. This interface offers a transfer rate of up to 1 MB and can handle hard drives with a maximum capacity of 300 MB.

MAGNETIC DISK RECORDING SPECIFICATIONS

Think back to the chapter 6 on "Magnetic Tape Recording Specifications." Do you remember how to measure and adjust them if needed? Well, magnetic disk recording specifications are a little different. They're set by the manufacturer and you can't change them. All you can do is measure them. The following paragraphs describe six of the most common specifications.

SEEK TIME

The *seek time* is the amount of time it takes for the magnetic head to position itself over a specific track of a magnetic disk. It's usually stated in milliseconds.

LATENCY PERIOD

The *latency period* is the amount of time it takes for a specific sector of a specific track to position itself under the magnetic head. It too, is usually stated in ms.

ACCESS TIME

The *access time* is the sum of the seek time and the latency period. It's the total amount of time in ms that it takes a disk drive to retrieve a sector of data from the magnetic disk. Access time is stated in one of the following three ways:

1. Track-to-track seek time: This is the amount of time it takes a disk drive to access data from a track next to the track it's presently over.

2. Average seek time: This is the amount of time it takes a disk drive to access data that's located one-third of the way across the magnetic disk.

3. Maximum seek time: This is the amount of time it takes a disk drive to access data from the last track of a magnetic disk when it's presently on the first track of the magnetic disk.

INTERLEAVE FACTOR

The *interleave factor* applies only to hard disk drives. They spin at 3600 RPM, a very fast speed compared to floppy disk drives which only spin at 300-600 RPM. Interleave indicates how many physical sectors are between sequentially numbered logical sectors on a hard disk. It's used when the magnetic heads and the control circuitry can't process the data fast enough to sequentially number the sectors on a hard disk platter. With interleave, the magnetic head is told to *skip* X number of sectors to get to the *next* one. For example, a hard disk with 17 sectors per track and no interleave is numbered 1, 2, 3, 4.... 17. The same hard disk with an interleave factor of 3 is numbered 1, 7, 13, 2, 8, 14, 3, 9, 15, 4, 10, 16, 5, 11, 17, 6, 12, and then back to 1. If you count every third sector, they're sequential. The most efficient hard disk drives have *no* interleave.

TRANSFER RATE

The *transfer rate* states how fast a disk drive and a disk drive controller (working together) can transfer data to the host computer. An example of a transfer rate specification is "2 Mbits/sec," or two million bits per second. The higher the number, the faster the data transfer rate.

RECORDING DENSITY

The *recording density* states how close together bits can be stored on the recording surface of a magnetic disk. It determines two things: (1) How close together the tracks on the disk will be, and (2) how close together the bits on each track will be. An example of a recording density specification is "12 Mbits/in^2," or 12 million bits per square inch.

Q32. The control electronics component of a floppy or hard disk drive performs what three main functions?

Q33. The write/read electronics of a disk drive performs what three functions?

Q34. The interface electronics of a disk drive performs what three functions?

Q35. What type of interface electronics is used in many naval electronic warfare systems?

Q36. What type of disk drive interface has most of the electronics on a controller card mounted in the host computer?

Q37. The SCSI is a high level disk drive interface. What does this mean?

Q38. What type of hard disk drive interface has all of the controller card electronics included in the disk drive itself?

SUMMARY

Now that you've finished chapter 8, you should be able to describe the (1) characteristics of floppy and hard disks, (2) methods for encoding digital data onto magnetic disks, (3) disk drive transports and their preventive maintenance requirements, (4) parts of a disk drive's electronics component, and (5) common types of disk drive interface electronics. The following is a summary of important points in this chapter:

FLOPPY DISKS are single-sided or double-sided plastic disks coated with oxide particles. The disks can be *single-density, double-density*, or *high density*.

Data is stored on floppy disks in **CIRCULAR TRACKS**. The tracks are divided into arcs called **SECTORS**.

HANDLE, SHIP, and **STORE** floppy disks carefully. Contaminates between the heads and the disk surface can cause serious damage.

FIXED (HARD) DISKS are aluminum platters coated on both sides with iron oxide or thin-film metal. Most hard disk drives use *disk packs* which are several disk platters stacked together. Some hard disk drives use removable disk platters.

Either the **CYLINDER** OR **SECTOR METHOD** is used to place data on hard disks.

HANDLE, STORE, AND **SHIP HARD DISKS** with extreme care. Contaminates on the heads or the disk surface can cause *head-crash*.

ERASE HARD AND FLOPPY DISKS by reformatting or degaussing.

Three popular **METHODS FOR ENCODING DIGITAL DATA ONTO DISKS** are frequency modulation, modified frequency modulation, and run length limited.

FLOPPY DISK DRIVE TRANSPORTS contain the parts that (1) spin the floppy disk, (2) write data to the disk, and (3) read data from it.

The **DRIVE MOTOR/SPINDLE ASSEMBLY** of a floppy disk drive transport holds and spins the floppy disk. The transport's **HEAD ARM ASSEMBLY** holds the read/write heads and its ACTUATOR ARM ASSEMBLY positions the heads over the disk's recording surface.

HARD DISK DRIVE TRANSPORTS contain the parts that (1) rotate the hard disk platter, (2) write data to the disk, and (3) read data from the disk.

The **DRIVE MOTOR/SPINDLE ASSEMBLY** of a hard disk drive transport holds the disk pack in place while the drive motor spins the spindle at 3600 RPM. The transport's HEAD ARM ASSEMBLY holds the read/write heads and its ACTUATOR ARM ASSEMBLY positions the heads over the correct track of the hard disk.

FLOPPY DISK DRIVES REQUIRE PREVENTIVE MAINTENANCE at regular intervals because they are not sealed units and the disks use an oxide coating that wears off and sticks to the heads and other parts.

HARD DISK DRIVES REQUIRE VERY LITTLE PREVENTIVE MAINTENANCE. Cartridge disk drives will have a special cleaning kit for doing the preventive maintenance.

Magnetic **DISK DRIVE ELECTRONICS** consist of (1) *control electronics* to control the electromechanical parts of a disk drive, (2) *write/read electronics* to write data to and read data from a disk drive, and (3) *interface electronics* to interface the disk drive to the host computer.

MAGNETIC DISK RECORDING SPECIFICATIONS are set by the manufacturer; all you can do is measure them. Six of the most common specifications are *seek time, latency period, access time, interleave factor, transfer rate,* and *recording density.*

ANSWERS TO QUESTIONS Q1. THROUGH Q38.

A1. 8 inch, 5 1/4 inches, 3 1/2 inches.

A2. Double-sided.

A3.

- *a.* *Single-density,*
- *b.* *double-density, and*
- *c.* *high-density.*

A4. 1,200,000 bytes or 1.2 megabytes.

A5. The disks can hold 96 tracks per inch.

A6. Soft sectoring.

A7.

- *a.* *disk side number,*
- *b.* *track number, and*
- *c.* *sector number.*

A8. Dust and other contaminates can get on the recording surface through the read/write hole.

A9. Magnetic fields can destroy the data on a disk.

A10.

- *a.* *Degauss the disk and then reformat it.*
- *b.* *Reformat the disk.*

A11. 3-1/2 inches, 5-1/4 inches, and 14 inches.

A12. (1) Cylinder method and (2) sector method.

A13. Sector method.

A14.

- *a.* *Cylinder number.*
- *b.* *Recording surface number.*
- *c.* *Record number.*

A15. Head-crash.

A16.

- *a.* *30-60 percent relative humidity.*
- *b.* *70-80 degrees Fahrenheit.*

A17. Reformat the disk.

A18. Frequency modulation (FM).

a. Modified frequency modulation (MFM).

b. Run length limited (RLL).

A19. Frequency-modulation encoding.

A20. Run length-limited (RLL) encoding.

A21.

a. Drive motor/spindle assembly.

b. Head arm assembly.

c. Actuator arm assembly.

d. Drive electronics circuit board.

A22. 600 RPM.

A23. Two read heads and two write heads.

A24. Actuator arm assembly.

A25. Drive electronics circuit board.

A26.

a. Rotates the hard disk platters.

b. Writes data to and reads data from the disk platters.

A27. Voice coil servo.

A28. They are not sealed units, and they use flimsy plastic disks with an oxide coating that wears off and sticks to the heads.

A29.

a. A cloth or fiber cleaning disk.

b. A bottle of cleaning solution.

A30. Once a month.

A31.

a. Cleaning with a special cleaning disk.

b. Cleaning air filters.

c. Cleaning spindles, rails, and slides.

d. Cleaning and buffing read/write heads.

A32.

a. Spins the disk at the correct speed.

b. Moves the heads across the recording surface.

c. Tells the write/read heads when to write data and when to read it.

A33.

a. Formats and writes incoming data from the interface electronics onto the disk.

b. Reads data off the disk, formats it, and sends it to the interface electronics for output.

c. Performs the initial disk formatting.

A34.

a. Receives control signals from the host computer and sends them to the control electronics or write/read electronics.

b. Receives data from the write/read electronics and outputs it to the host computer.

c. Converts incoming and outgoing data from parallel to serial, and vice versa, if needed.

A35. NTDS interface.

A36. ST-506/412 interface.

A37. The host computer asks for data by specifying a logical sector number. The SCSI translates the sector number into the actual disk location.

A38. Integrated drive electronics (IDE).

APPENDIX I

GLOSSARY

ABRASIVITY—The ability of the magnetic tape to wear the head.

ADDITIVE—Any material in the coating of magnetic tape other than the oxide and binder resins. (Examples: plasticizers (to soften an otherwise hard or brittle binder), lubricants (to lower the coefficient of friction of an otherwise high-friction binder), fungicides (to prevent fungus growth), dispersants (to uniformly distribute the oxide particles), and dyes.)

ALTERNATING CURRENT (ac) BIAS—(1) The alternating current, usually of a frequency several times higher than the highest input signal frequency, that is fed to a record head in addition to the input signal current. (2) Linearizes the recording process. (3) Is universally used in direct analog recording.

AMPLITUDE/FREQUENCY RESPONSE—(See frequency response.)

ANALOG RECORDING—A method of recording in which some characteristic of the record current, such as amplitude or frequency, is continuously varied in a manner similar to the variations of the original signal.

AZIMUTH ALIGNMENT—The alignment of the recording and reproducing gaps so their center lines lie parallel with one another. Misalignment of the gaps causes a loss in output at short wavelengths.

BACKINGS—(See base film.)

BANDWIDTH—The frequency within which the performance of a recorder with respect to some characteristic (usually frequency response) falls within specified limits, or within which some performance characteristic (such as noise) is measured.

BASE FILM—The plastic substrate material used in magnetic tape that supports the coating.

BER—(See bit error rate.)

BIAS-INDUCED NOISE (See noise.)

BINARY—(1) Two values ("O" or "1") or states (ON or OFF). (2) The number systems used in computers.

BINDER—A compound consisting of organic resins used to bond the oxide particles to the base material, the actual composition being considered proprietary information by each magnetic tape manufacturer. The binder is required to be flexible but still maintain the ability to resist flaking or shedding during extended wear passes.

BIT—(1) The acronym binary digit. (2) The smallest unit of data, either "O" or "1". (3) One recorded information cell, as applied in magnetic recording.

BIT DENSITY—(See packing density.) bit error rate (BER).—(1) The number of errors a specific magnetic tape may contain, as used in high-density recording. (2) Is expressed in errors per data bit, such as 1 in 10^6, or one error in one million data bits.

BREAK ELONGATION—The relative elongation of a specimen of magnetic tape of base film at the instant of breaking when it has been stretched at a given rate.

BROWN STAIN—(1) A thin discoloration of the head's top surface, usually a chemical reaction between the head's surface materials and the tape binder, the tape lubricant, or the head's bonding materials. (2) Its origin is not well understood, but is known to occur in low humidity.

BUCKLING—(1) A deformation of the circular form of a tape pack. (2) Caused perhaps by a combination of improper winding tension, adverse storage conditions, and/or poor reel hub configuration.

BUILD-UP—(1) A snowballing effect started by debris and tape magnetic particles embedded in the contamination. (2) The thickness of this build-up can cause an intense in head-to-tape separation, as well as an increase in the coefficient of friction. (3) Solvent cleaning of the head's top surface will usually remove the build-up.

BULK-ERASED NOISE—See noise.

BULK ERASER (DEGAUSSER)—An equipment for erasing a full reel of previously recorded signals on tape.

BYTE—A group of bits (next to each other) that are considered a unit (example, an 8-bit byte).

CERTIFIED TAPE—A tape that is electrically tested on a specified number of tracks and is certified by the supplier to have less than a certain total number of permanent errors.

CERTIFIER—(1) An equipment that tests the ability of magnetic tape to record and reproduce. (2) Counts and charts each error on the tape, including the level and duration of dropouts. (3) In the certify mode, stops the tape at an error to allow for visual inspection of the tape to see if the cause of the error is correctable or permanent.

CHICKEN TRACKS—(1) A line of small craters in the head's top surface running in the direction of tape motion. (2) Usually caused by a loose, small, hard particle moving with the tape over the head.

CINCHING—(1) The tape folds resulting from longitudinal slippage between the layers of tape in a tape pack. (2) Caused by uneven tension when the roll is accelerated or decelerated.

CLEAN ROOMS—The rooms of which their cleanliness is measured by the number of particles of a given size per cubic foot of room volume. (Examples (1) A class 100,000 clean room may have no more than 100,000 particles 0.5 fm or larger per cubic foot, and so on for class 10,000 and class 100 rooms. (2) A class 10,000 room may have no more than 65 5-fm particles per cubic foot, while class 100,000 may have no more than 700 5-fm particles per cubit foot.)

CLEANER—(See winder/cleaner.)

COATING—The magnetic layer of a magnetic tape consisting of oxide particles held in a binder that is applied to the base film.

COATING RESISTANCE—(1) The electrical resistance of the coating measured between two parallel electrodes spaced a known distance apart along the length of the tape. (2) Called resistivity on specification sheets.

COATING THICKNESS—The thickness of the magnetic coating applied to the base film.

COATING-TO-BACKING ADHESION—(See anchorage.)

CONTAMINATION—(1) A thick, tacky (viscous) deposit on the head's top surface, which causes a large increase in the effective head-to-tape coefficient of friction. (2) May not be removable by solvent cleaning.

CORE MATERIAL—(1) hard core material.—(a) Hard metal laminations bonded together to form the core, with a typical thickness of 0.005 to 0.004 inch. (Hard metal wears much more slowly than soft laminations.) (b) Hard solid metal, such as alphenol or sendust. (Wear rates are much lower than those of soft metal laminations.) (2) soft core material.—(a) Soft metal laminations bonded together to form the core, with a typical thickness of 0.0005 to 0.004 inch. (b) Usually, a high nickel/iron alloy, such as Hy Mu 800. (c) These materials have a relatively poor wear rate.

CRACK—A narrow, deep break in the head's surface material.

CREEP—The time-dependent strain at a constant stress (tape deformation).

CROSSFEED—See crosstalk and write feedthrough.

CROSSPLAY—The ability to interchange recordings between recorders while maintaining a given level of performance.

CROSSTALK—(1) The magnetic coupling from one track to another in the tape's read/write head. (2) See also write feedthrough.

CUPPING—(1) The curvature of a magnetic tape pack in the lateral direction. (2) May be caused by differences between the coefficients of thermal or hygroscopic expansion of coating and base film.

db—See decibel.

dc NOISE—(See noise.)

DECIBEL (db)—A dimensionless unit for expressing the ratio of two powers or voltages or currents on a logarithmic scale. If A and B represent two voltages or currents, the ratio A/B corresponds to 20 log A/B decibels. One decibel represents a ratio of approximately 1.1 to 1 between A and B. Other values are as follows:

RATIO	DECIBEL
1	0
1.4	3
2	6
4	12
10	20
100	40
1000	60

DEFECT—(1) An imperfection in the tape leading to a variation in output or a dropout. (2) The most common defects are surface projections of oxide agglomerates, embedded foreign matter, and redeposited wear products.

DEGAUSSER—See bulk eraser.

DELAY MODULATION—(See modified frequency modulation.)

DIGITAL RECORDING—(1) A method of recording in which the information is first coded in a digital form. (2) Usually, a binary code is used, with recording taking place in two discrete values/polarities of residual flux.

DIRECT RECORDING—An analog recording that records and reproduces data in the electrical form of its source.

DISK—(1) A disk-drive storage device on which information is magnetically recorded and retrieved. (2) Can be either hard (rigid) or floppy (flexible).

DISK DRIVE—A storage device for recording and retrieving data on hard or floppy disks.

DISK PACK—A portable, interchangeable device that contains more than one hard-disk platter and is used in hard-disk drives.

DISPERSION—The distribution of the oxide particles within a tape's binder.

DISTORTION—(see harmonic distortion.).

DRAG—The fractional tension differential across the contact area caused when the tape contacts some element in the tape path (such as the head, tape guides, tape bearings, or column walls).

DROPOUT—(1) A temporary reduction in the output of a magnetic tape of more than a certain predetermined amount. (2) Expressed in terms of the percentage reduction or decibel loss.

DROPOUT COUNT—The number of dropouts detected in a given length of magnetic tape.

DURABILITY—The number of passes that can be made before a significant degradation of output occurs, divided by the corresponding number that can be made using a reference tape.

DYNAMIC—(See tape skew.)

DYNAMIC RANGE—(1) The bandwidth within which a satisfactory signal-to-noise ratio is obtained. (2) See also resolution.

DYNAMIC SKEW—The change in skew caused by tape motion.

DYNAMIC TAPE SKEW—(See tape skew.)

EQUIPMENT NOISE—(See noise.)

ERASURE—A process by which a signal recorded on a tape is removed and the tape made ready for rerecording. May be accomplished in two ways. (1) In ac erasure, the tape is demagnetized by an alternating magnetic field that is reduced in amplitude from an initially high value. May be accomplished by passing the tape over an erase head fed with high-frequency ac, or by placing the whole roll of tape in a decreasing ac field (bulk erasure). (2) In dc erasure, the tape is saturated by applying a primarily unidirectional field. May be accomplished by passing the tape over a head fed with dc or over a permanent magnet. Additional stages may be included in dc erasure to leave the tape in a more nearly unmagnetized condition.

FERRITE—A powdered and compressed ferric-oxide material that has both magnetic properties and light resistance to current flow.

FLOPPY DISK—(See disk.)

FLUTTER—(See wow.)

FLUX—A term, with reference to electrical or electromagnetic devices, that designates collectively all the electric or magnetic lines of force in a region.

FLUX DENSITY—The number of magnetic lines of force passing through a given area.

FM—(See frequency modulation.)

FREQUENCY MODULATION (FM)—(1) A flux reversal at the beginning of a cell time represents a clock bit. (2) A "1" bit is a flux reversal at the center of the cell time. (3) A "0" bit is an absence of a flux reversal.

FREQUENCY RESPONSE—(1) The variation of sensitivity with signal frequency. (2) The frequency response of a tape is usually given in decibels relative to a referenced frequency-output level. (3) Also called amplitude/frequency response.

GAMMA-FERRIC OXIDE—The common magnetic constituent of magnetic tapes in a dispersion of fine, needle-like particles within the coating.

GAP EROSION—(1) The read or write gap increased in length and retreated below the head surface. (2) Usually due to deterioration of core material at the edges of the gap.

GAP LOSS—(1) The loss in output due to the finite gap length of the reproduce head. (2) The loss increases as the wavelength decreases.

GAP WIDTH—The dimension of the gap of a magnetic head measured in the direction perpendicular to the direction of the tape path.

GAUSS—The metric unit of the magnetic flux density equal to 1 Mx/CM^2.

HARD DISK—(See disk.)

HARD FERRITE—A ferrite with a very low wear rate when compared with the soft metal laminations.

HARD METAL LAMINATIONS—(See core material, hard.)

HARD SOLID METAL—(see core material, hard.)

HARMONIC DISTORTION—A signal non-linearity with harmonics of the fundamental in the output when the input signal is sinusoidal.

HEAD CONTAMINATION—(See tape-to-head separation.)

HEAD CONTOUR—(1) The complex shape of the contacting surface of a head as a result of manufacture, head lapping, or wear. (2) The contour of a head is always changing throughout the head's life and, in many cases, is responsible for retiring the head.

HEAD CRASH—A term used for the damage to a hard disk caused by the physical contact made between the magnetic read/write heads and the surface of the hard-disk platter.

HEAD STICK—(1) A common word for a large increase in head-to-tape friction caused by (a) a stick by-product exuded by conditions due to tape age, temperature/humidity, and head-to-tape pressure, and (b) very smooth tapes coupled with large area heads. (2) See also sticktion and stick-slip.

HEAD-TO-TAPE CONTACT—The degree that a tape's magnetic coating approaches the surface of the record or reproduce head during normal operation.

INTERLAYER TRANSFER—Any loose material, such as oxide, generated by tape wear or a head-stick condition which is transferred from the oxide to the back of the tape, or from the back side to the oxide when the tape is wound on a reel.

INTERMODULATION DISTORTION—(1) A signal non-linearity with frequencies in the output equal to sums and differences of integral multiples of the component frequencies present in the input signal. (2) Harmonies are usually not included as part of the intermodulation distortion.

INTERSYMBOL INTERFERENCE—(1) An interference resulting in a phase shift of the cell playback crossover point with respect to the data clock. (2) When a recording system has limited record resolution, a flux transition being recorded will extend beyond its cell boundaries, adding or subtracting from the flux in the adjacent bit cells of symbols.

IRON OXIDE—(See gamma-ferric oxide.)

LAMINATIONS—(see core material.)

LATERAL DIRECTION—The direction across the width of the tape.

LAYER-TO-LAYER ADHESION—The tendency for adjacent layers of tape in a roll to adhere to one another.

LAYER-TO-LAYER TRANSFER—The magnetization of a layer of tape in a roll by the field from a nearby recorded layer, sometimes referred to as print through.

LBE—(See lower band edge.)

LINEARITY—The extent to which the magnitude of the reproduced output is directly proportional to the magnitude of the signal applied to the input of the recorder.

LONG-TERM TAPE SPEED—(See tape speed.)

LONGITUDINAL CURVATURE—Any deviation from the straightness of a length of tape.

LOOSE DEBRIS—Any material that is very lightly bonded to the tape or the head's top surface, removable by tape motion.

LOWER BAND EDGE (LBE)—The lower band edge of the recorder/reproducer response (usually at the −3-dB point).

LUBRICANT—(See additive.)

MAGNETIC INSTABILITY—(1) The property of a magnetic material that causes variations in the residual flux density of a tape to occur with temperature, time, and/or mechanical flexing. (2) A function of particle size, magnetizing field strength, and anisotropy.

MAGNETIC MEDIA—A base film, coated with magnetic particles held in a binder. (The magnetic particles are usually needle-like, single-domain, gamma-ferric oxide.)

MAGNETIZING FIELD STRENGTH—The instantaneous strength of the magnetic field applied to a sample of magnetic material.

MFM—(See modified frequency modulation.)

MODIFIED FREQUENCY MODULATION (MFM)—(1) A code that has a "1" and a "O" corresponding to the respective presence or absence of a transition in the center of the corresponding bit cell. (2) Additional transitions at the cell boundaries occur only between bit cells that contain consecutive "0" values. (3) Also called delay modulation.

MODULATION NOISE—(See noise.)

NOISE—Any unwanted electrical disturbances other than crosstalk or distortion components that occur at the output of the reproduce amplifier. (1) System noise is the total noise produced by the whole recording system, including the tape. (2) Equipment noise is produced by all the components of the system, with the exception of the tape. (3) Tape noise can be specifically ascribed to the tape. The following are typical sources of tape noise: (a) Bulk-erased noise arises when a bulk-erased tape with the erase and record heads completely deenergized is reproduced. (b) Zero-modulation noise arises when an erased tape with the erase and record heads energized as they would be in normal operation, but with zero input signal, is reproduced. This noise is usually 3 to 4 dB higher than the bulk-erased noise. The difference between bulk-erased and zero-modulation noise is sometimes termed bias-induced noise. (c) Saturation noise arises when a uniformly saturated tape is reproduced. This is often some 15 dB higher than the bulk-erased noise and is associated with imperfect particle dispersion. (d) Dc noise arises when a tape that has been non-uniformly magnetized by energizing the record head with dc, either in the presence or the absence of bias, is reproduced. This noise has pronounced, long, wavelength components that can be as much as 20 dB higher than those obtained from a bulk-erased tape. At very high values of dc, the dc noise approaches the saturation noise. Dc noise is actually the low-frequency component of modulation noise. (e) Modulation noise is essentially a modulation of the desired signal by noise that is caused by non-uniform dispersion of elementary magnetic particles in the tape’s coating material. This noise, which occurs only when a recorded tape is reproduced, increases with the intensity of the reproduced signal. Dc noise is actually the low-frequency component of modulation noise.

NOISE PULSE—(1) A short-duration false signal occurring during the reproduction of a tape. (2) A signal that is of a magnitude considerably in excess of the average peak value of the ordinary system noise.

NOMINAL BIT TIME—(1) The average bit time of recording at continuous maximum-flux reversals. (2) Also called cell time.

NON-RETURN-TO-ZERO (NRZ0)—The flux reversal for a "0"; no flux reversal for a "1."

NON-RETURN-TO-ZERO INVERTED (NRZI)—The flux reversal for a "1"; no flux reversal for a "0."

NON-RETURN-TO-ZERO (NRZ) RECORDING—(See digital recording.)

OERSTED—A unit of magnetic field strength.

OUTPUT—The magnitude of the reproduced signal voltage, usually measured at the output of the reproduced amplifier.

OXIDE BUILD-UP—The accumulation of oxide or wear products as deposits on the surface of heads and guides.

OXIDE LOADING—(1) A measure of the density with which oxide is packed into a coating. (2) The weight of the oxide per unit volume of the coating.

OXIDE SHED—The loosening of particles of oxide from the tape coating during use.

PACKING DENSITY—The amount of digital information recorded along the length of a tape, measured in bits per inch.

PARTICLE ORIENTATION—The rotation of needle-like particles so that their longest dimensions tend to lie parallel to one another.

PARTICLE SHAPE—The needle-like particles of gamma-ferric oxide used in conventional magnetic tape, with a dimensional ratio of about 6 to 1.

PARTICLE SIZE—The physical dimensions of magnetic particles used in a magnetic tape.

PERMANENT ELONGATION—The percentage of elongation remaining on a tape or a length of base film after a given load applied for a given time has been removed.

PLASTICIZER—(See additive.)

POLYESER—(1) An acronym for polyethylene glycol terephthalate. (2) The material most commonly used as a base film for precision magnetic tape.

READ/WRITE ERASE HEAD—A three-gap head (read, write, erase) on one body. Sometimes the erase head is bolted to the read/write head.

READ/WRITE HEAD—A two-gap head (read, write) on one body.

REEL—The metal-, glass-, or plastic-flanged hub on which magnetic tape is wound.

REFERENCE TAPE—A tape used as a reference against which the performances of other tapes are compared.

REMANENCE—(1) The magnetic flux density that remains in a magnetic circuit after removal of applied magnetomotive force. (2) Is not necessarily equal to residual flux density.

REMOVABLE FIXED DISK—A hard-disk device (usually) with only one hard-disk platter that's used to record and retrieve data.

RESISTIVITY—(See coating resistance.)

RESOLUTION (DYNAMIC RANGE)—The average peak-to-peak signal amplitude at the maximum flux reversal divided by the average peak-to-peak signal amplitude at the minimum flux reversal at the desired recording method.

RETENTIVITY—The maximum value of residual flux density corresponding to saturation flux density.

RZ RECORDING—(See digital recording.)

SATURATION FLUX DENSITY—(1) The maximum intrinsic flux density possible in a sample of magnetic material. (2) The intrinsic flux density asymptotically approaches the saturation flux density as the magnetizing field strength increases.

SATURATION NOISE—(See noise.)

SCRATCH—A long, narrow, straight defect in the top surface of a head track or a tape.

SENSITIVITY—The magnitude of the output when reproducing a tape recorded with a signal of given magnitude and frequency.

SEPARATION LOSS—The loss in output that occurs when the surface of the coating of a magnetic tape fails to make perfect contact with the surface of the record or reproduce head.

SHEDDING—The loss of oxide or other particles from the coating or backing of a tape, usually causing contamination of the tape transport and, by redeposit, of the tape itself.

SHORT-TERM TAPE SPEED—(See tape speed.)

SIGNAL-TO-NOISE RATIO—(1) The ratio of the power output of a given signal to the noise power in a given bandwidth. (2) Is usually measured by the corresponding root mean square signal and noise voltages appearing across a constant output resistance.

SKEW—A deviation of a line connecting the average displacement of the read or write track gaps from a line perpendicular to the reference edge of the tape in the direction of tape motion.

SKEW TAPE—(1) The continuous strings of "1" values written on a properly adjusted tape drive for the entire recoverable length of the tape. (2) An "all '1' pattern" on all tracks. (3) The write head, the write delays, and the tape drive adjusted to write with minimum physical skew and gap scatter.

SOFT METAL LAMINATIONS—(See core material, soft.)

SPOKING—A buckling in which the tape pack is deformed into a shape that approximates a polygon.

SPOOL—(See reel.)

SQUEAL—(See stick-slip.)

STANDARD REFERENCE TAPE—A tape intended for daily calibration, the performance of which has been calibrated to the amplitude reference tape.

STATIC—(See tape skew.)

STICK-SLIP—(1) A low-speed phenomenon. (2) A relationship between tension, temperature, humidity, wrap angle, head material, tape binder, and elastic properties. (3) When detected audibly, it is a squeal.

STICKTION—The tape's adhering to transport components, such as heads or guides.

STIFFNESS—(1) The resistance to bending the tape. (2) A function of tape thickness. (3) A modulus of elasticity.

SURFACE TREATMENT—Any process by which the surface smoothness of the tape coating is improved after it has been applied to the base film.

SYSTEM NOISE—(See noise.)

TAPE CONTAMINATION—(See tape-to-head separation.)

TAPE NOISE—(See noise.)

TAPE PACK—The form taken by the tape wound on a reel.

TAPE SKEW—(1) The tape's deviation from following a linear path when transported across the heads. (2) The terms static and dynamic distinguish between the physically fixed components and the fluctuating components of total tape skew.

TAPE SPEED—(1) The speed at which the tape is transported across the read/write head during normal recording or reproduction. (2) Long-term speed is averaged over a minimum of 15 inches of tape (in inches per second). (3) Short-term speed is the instantaneous (dynamic) tape speed (in inches per second).

TAPE-TO-HEAD SEPARATION—(1) Separation.—The separation between a magnetic head and the magnetic tape caused by the (a) foil-bearing effect, (b) improper head contour, which generates standing waves in the tape, and (c) surface roughness of the tape. These conditions are interrelated and are greatly influenced by tape tension and tape compliancy. In a properly designed system, tape roughness is the limit of head-to-tape separation, usually <10 fm. (2) Changes.—(a) Head contamination is the debris attached to the head, which causes the tape to lift away from the head, forming a tent-like deformation of the tape. This tent does not move or change shape until the contamination is removed. (b) Tape contamination includes particles attached to the tape, resulting in a tent that moves across the head with the tape. (3) Effective.—(a) The actual distance from the magnetic storage material on the tape to the top of the active magnetic core material at the read or write gape. (b) The effective head-to-tape separation is usually somewhat larger than the mechanical head-to-tape separation.

TAPE TRANSPORT—(1) The mechanism that extracts magnetic tape from a storage device, moves it across magnetic heads at a controlled speed and then feeds it into another storage device. (2) Typical storage devices are tape loops, bins, reels, cassettes, and cartridges. (3) The tape transport is the part of a magnetic tape recorder/reproducer system that normally consists of magnetic heads, magnetic tape, transport, record electronics, and reproduce electronics.

TEAR STRENGTH—The force required to initiate and/or propagate a tear in a specially shaped specimen of tape or base film.

TOTAL THICKNESS—The sum of the thicknesses of the base film and the magnetic coating, as well as back coating, when applied. The total thickness governs the length of tape that can be wound on a given reel.

TRACK—An area of the tape's surface that coincides with the location of the recorded magnetization produced by one record gap.

TRACK WIDTH—The width of the track corresponding to a given record gap.

UBE—(See upper band edge.)

UNDERCUT—(See washout.)

UNIFORMITY—The extent to which the output remains free from variations in amplitude. Uniformity is usually specified as the positive and negative deviations from the average output within a roll of tape.

UPPER BAND EDGE (UBE)—The upper band edge of the recorder/reproducer response (usually at the −3dB point).

VOID—An area where material is missing on the surface of a tape or on a head's track.

WASHOUT—(1) A hard-coated head whose magnetic core material has a much higher wear rate than the coating. (2) The radius of curvature of the core material will be larger than the surrounding coating of the softer material, which could even be undercut, possibly causing an increase in the head-to-tape separation. (3) Also called undercut.

WAVELENGTH—The distance along the length of a sinusoidally recorded tape corresponding to one cycle.

WAVINESS—(1) A non-flat head's top surface perpendicular to the tape motion due to different wear rates in top surface materials. The harder material will be up. The head core is usually the harder material; therefore, there will be increased head-to-tape contact pressure at the cost of tape life. (2) Can occur during break-in or field use.

WEAR ABILITY—(See durability.)

WEAR PRODUCT—Any material that is detached from the tape during use.

WEAR TEST—(See durability.)

WIND—The way in which tape is wound onto a reel. An A-wind is one in which the tape is wound so that the coated surface faces toward the hub.

WINDER/CLEANER—A device that winds and cleans magnetic tape to restore it to a near-new condition, providing the tape has not been physically damaged.

WOW AND FLUTTER—(1) The changes in signal-output frequency caused by tape-speed variations occurring at relatively low and relative high rates, respectively. (2) Wow is no longer used, but is incorporated into the flutter measurement.

WRITE FEEDTHROUGH—(1) The magnetic coupling from the write track to a read track in the read/write head. (2) Also called crossfeed and crosstalk.

ZERO-MODULATION NOISE—(See noise.)

Assignment Questions

<u>Information</u>: The text pages that you are to study are provided at the beginning of the assignment questions.

ASSIGNMENT 1

Textbook assignment: Chapter 1, "Introduction to Magnetic Recording," pages 1-1 through 1-7. Chapter 2, "Magnetic Tape," pages 2-1 through 2-158. Chapter 3, "Magnetic Tape Recorder Heads," pages 3-1 through 3-9. Chapter 4 "Magnetic Tape Recorder Transports," pages 4-1 through 4-17.

1-1. In what year did Oberlin Smith originate the idea of using permanent magnetic impressions to record sound?

1. 1880
2. 1888
3. 1900
4. 1908

1-2. In 1925, magnetic recording began receiving attention when what device was invented?

1. Magnetic tape
2. Magnetic disk
3. Electronic amplifiers
4. Video recorders

1-3. In 1907, Mr. Poulsen discovered dc bias. How did adding dc bias to the input signal solve the distortion problem for magnetic recording?

1. It moved the input signal away from the step in the magnetism curve
2. It moved the input signal directly onto the step in the magnetism curve
3. It moved the output signal directly over the step in the magnetism curve
4. It straightened the step in the magnetism curve

1-4. After 1925, the Naval Research Laboratory greatly improved the signal-to-noise ratio of magnetic recording by adding what component?

1. Ac bias
2. Electronic amplifiers
3. Transistors
4. Dc motors

1-5. In what year was plastic based tape introduced?

1. 1900
2. 1925
3. 1939
4. 1947

1-6. In 1956, IBM introduced what major contribution to magnetic recording?

1. The magnetic tape drive
2. The floppy disk drive
3. The hard disk drive
4. Each of the above

1-7. In 1966, IBM introduced the first removable-pack hard disk drive.

1. True
2. False

1-8. In what year was the 5 1/4" floppy disk drive invented?

1. 1956
2. 1976
3. 1980
4. 1988

1-9. Which of the following is a prerequisite for magnetic recording?

1. An input signal
2. A recording medium
3. A magnetic head
4. Each of the above

1-10. A magnetic recording medium is any material that has the ability to become magnetized, in set amounts, in large sections along its entire length.

1. True
2. False

1-11. Magnetic heads are transducers that convert the electrical variations of your input signal into what type of variations that are stored on a recording medium?

1. Magnetic
2. Electrical
3. Electrical and magnetic combined
4. Direct current

1-12. What factor determines the number of turns of wire placed on the core of a magnetic head?

1. The size of the magnetic head
2. The size of the head-gap
3. The purpose of the magnetic head
4. Each of the above

1-13. All magnetic heads operate the same way. An electric current passes through the coil. Magnetic field lines associated with the electric current follow paths through the core material. When the magnetic field lines get to the head-gap, some of them spread outside the core to form a fringing field. When a recording medium is passed through this fringing field, magnetic recording happens.

1. True
2. False

1-14. Which of the following materials is used to make magnetic tape?

1. Base material
2. Magnetic oxide coating
3. Glue
4. Each of the above

1-15. The base material of magnetic tape is made with what material?

1. Plastic
2. Metal
3. Either 1 or 2
4. Paper

1-16. Which of the following can happen if the magnetic particles used to make magnetic tape aren't uniform in size?

1. The tape's surface will be abrasive which reduces the magnetic head's life
2. The frequency response of the tape will be distorted
3. The glue will not hold the particles in place
4. The oxide coating cannot be magnetized

1-17. Generally, short magnetic oxide particles are used on magnetic tape to record low-frequency signals and long particles are used to record high-frequency signals.

1. True
2. False

1-18. Why does digital magnetic tape use a base material about 50 percent thicker than analog magnetic tape?

1. Thicker tape is needed to hold the long magnetic oxide particles
2. Thicker tape allows the tape to withstand the more strenuous starts and stops
3. Thicker tape is needed for instrumentation type signals
4. Thicker tape can store more digital data

1-19. There are four types of tape errors that can degrade the performance of a magnetic recording system. Which of the following tape errors is the most common and causes a 50% or more drop in signal strength?

1. Noise
2. Skew
3. Signal dropout
4. Level

1-20. Which of the following contaminants can cause signal dropouts?

1. Dust
2. Lint
3. Oil
4. Each of the above

1-21. Which of the following items on magnetic tape will cause noise errors?

1. Dust or lint
2. A cut
3. A scratch
4. Both 2 and 3 above

1-22. Brand "X" magnetic tape is rated for 5 volts (± 10%). Which of the following minimum and maximum voltage levels is what the output signal level could vary before it is considered a level error?

1. 4.95/5.05
2. 4.75/5.25
3. 4.5/5.5
4. 4/6

1-23. Magnetic tape can eventually become unusable when it comes in contact with the fixed surfaces of a recorder over long periods of time. What causes this type of tape failure?

1. Environmental damage
2. Normal wear
3. Winding errors
4. Accidental damage

1-24. Ideally, magnetic tape should be used and stored within what temperature and humidity range?

1. 40 - 80º F, 60 - 80% humidity
2. 50 - 70º F, 60 - 80% humidity
3. 60 - 80º F, 60 - 80% humidity
4. 60 - 80º F, 40 - 60% humidity

1-25. Using magnetic tape in a workplace that exceeds the ideal temperature and humidity ranges can cause which of the following types of environmental damage to the tape?

1. Dirt build-up
2. Layer-to-layer sticking
3. Tape deformation
4. Each of the above

1-26. At temperatures above 130 degrees, what happens to a tape's oxide coating?

1. Becomes soft
2. Separates from the base material
3. Both 1 and 2 above
4. Becomes brittle

1-27. What causes head-to-tape sticking?

1. Temperatures below 2º F
2. Dirty record/reproduce heads
3. The tape binder glue softens
4. Static electricity

1-28. Which of the following environmental conditions could create static electricity which attracts dirt build-up on the tape and tape recorder parts?

1. Relative humidity of 5%
2. Temperature of 28º F
3. Relative humidity of 96%
4. Temperature of 135º F

1-29. Excessive tape and head wear caused by increased friction as the tape passes over the heads can happen if the relative humidity is more that what maximum percent?

1. 70%
2. 85%
3. 95%
4. 90%

1-30. Winding errors can happen when improper winding practices create an excessive or uneven force as the tape is being wound onto a tape reel.

1. True
2. False

1-31. When winding a tape onto a reel, you notice that a sudden stop causes the outer layers of the tape to continue to spin after the inner layers have stopped. What type of deformed tape pack does this cause?

1. Pack-slip
2. Cinching
3. Spoking
4. Windowing

1-32. The magnetic tape on your reel is unwinding unevenly and rubbing against the sides of the reel and the recorder's tape guides. What type of deformed tape pack could cause this condition?

1. Spoking
2. Windowing
3. Pack-slip
4. Skewing

1-33. You notice a spoked tape pack on the take-up reel of your recorder. What causes a spoked tape pack?

1. Tape is wound over a small particle on the reel hub
2. A distorted reel hub creates uneven pressures as the tape is wound onto the reel
3. Tape is wound with increasing tension toward the end of the winding
4. Each of the above

1-34. Which of the following tape pack deformities is an example of windowing?

1. The inner part of the tape pack is buckled and deformed
2. The tape pack contains steps caused by the tape shifting from side to side during winding
3. The tape pack contains voids or see-through air gaps
4. Each of the above

1-35. Which of the following materials can be used to make tape reels?

1. Plastic
2. Metal
3. Glass
4. Each of the above

1-36. The flanges of a magnetic tape reel are designed to guide the magnetic tape onto the reel.

1. True
2. False

1-37. Magnetic tape is erased by exposing it to what type of magnetic field?

1. A gradually decreasing dc field
2. A gradually increasing dc field
3. A gradually decreasing ac field
4. A gradually increasing ac field

1-38. Which of the following is a disadvantage of using a tape recorder's erase head to erase magnetic tape?

1. It causes a distorted tape pack
2. It's slow
3. It may not do a complete erasure
4. Both 2 and 3 above

1-39. Both manual and automatic tape degaussers use the same electronic principles for erasing magnetic tape.

1. True
2. False

1-40. Which of the following is NOT an appropriate place to keep a magnetic tape reel or cartridge?

1. Mounted on a magnetic tape recorder
2. Stored in a plastic bag
3. Laying on top of a magnetic tape recorder
4. Both 2 and 3 above

1-41. Which of the following is a CORRECT method for handling magnetic tape?

1. Never let any part of the tape, except the end, trail on the floor
2. Always hold a tape reel by the flanges
3. Never handle or touch a tape's working surface
4. Each of the above

1-42. Which of the following is a CORRECT method for storing magnetic tape?

1. Always store tape reels laying on their sides, never vertically
2. Store tapes away from equipment that generates stray magnetic fields
3. Keep the storage area at 40 to 80% relative humidity
4. All of the above

1-43. Which of the following is a CORRECT method for packaging magnetic tape for shipping?

1. Always use reel bands where available
2. Always package reels supported by their hubs and in a vertical position
3. Always package cartridges in their shipping cases
4. Each of the above

1-44. What parts of a magnetic tape recorder are considered the heart of magnetic tape recording?

1. Magnetic tape reel
2. Magnetic heads
3. Transport electronics
4. Operator control panel

1-45. The heads of a magnetic tape recorder perform what part of the overall tape recording process?

1. Record signal or data onto magnetic tape
2. Reproduce signal or data from magnetic tape
3. Erase signal or data from magnetic tape
4. Each of the above

1-46. All magnetic heads are made using a plastic core wrapped with a few turns of very thin wire.

1. True
2. False

1-47. What specification of a magnetic head determines the maximum frequency the head will be able to transfer onto and off of the magnetic tape?

1. Headgap
2. Size of the core
3. Number of turns of wire on the core
4. Each of the above

1-48. What is the only physical difference between a record head and a reproduce head?

1. Number of turns of wire on the core
2. Size of the core material
3. Type of core material used
4. Each of the above

1-49. A certain magnetic recorder has a maximum recording frequency response of 500 kHz. Which of the following frequencies would be a good frequency to use as an erase signal?

1. 500 kHz
2. 1200 kHz
3. 1900 kHz
4. Either 2 or 3

1-50. If you do NOT regularly clean a recorder's magnetic heads, what is the probable consequence?

1. Dirt, dust, lint, etc. will collect on the heads
2. Signal dropout errors will occur
3. Both 1 and 2 above
4. The tape pack will become skewed

1-51. What materials should you use to clean magnetic heads?

1. A bristled brush and non-detergent cleaner
2. A cotton-tipped applicator soaked in isopropyl alcohol
3. A cotton-tipped applicator soaked in a magnetic head cleaner recommended by the manufacturer
4. Either 2 or 3 above

1-52. Magnetic heads can become magnetized from many sources. Which of the following sources, if any, could magnetize a magnetic head?

1. Stray magnetic fields
2. Excessive humidity
3. Poor quality magnetic tape
4. None of the above

1-53. Magnetic head degaussers generate a strong ac magnetic field that dc-magnetizes the metal parts of a magnetic head.

1. True
2. False

1-54. Which of the following is NOT a procedure for demagnetizing magnetic heads?

1. Remove the tape reel or cartridge from the recorder
2. Touch the energized degausser to the head
3. Move the degausser back and forth across the head for 15 to 30 seconds
4. De-energize the degausser when it's an arms length away

1-55. Which of the following is a function of magnetic tape transports?

1. Moves the magnetic tape across the magnetic heads
2. Holds the moving tape
3. Protects the moving tape
4. Each of the above

IN ANSWERING QUESTIONS 1-56 THROUGH 1-59, SELECT THE DESCRIPTION IN COLUMN B THAT BEST DESCRIBES THE MAGNETIC TAPE RECORDER TRANSPORT PART LISTED IN COLUMN A.

1-56. Tape reeling system	1. Monitors and controls the movement of magnetic tape
1-57. Tape speed control system	2. Holds and protects the reels or cartridges of magnetic tape
1-58. Electronic sub-system	3. Activates the reeling device to move the magnetic tape
1-59. Basic enclosure	4. Physically moves the magnetic tape across the magnetic heads

---

1-60. What type of tape reeling system uses a "free-spooling" supply reel and a motorized take-up reel?

1. Take-up control
2. Two-motor reeling
3. Tape buffering
4. Both 2 and 3 above

1-61. What type of tape reeling system was invented to overcome the problems of uneven tape tension and stretched tape?

1. Take-up control
2. Two-motor reeling
3. Tape buffering
4. Both 2 and 3 above

1-62. Magnetic tape reeling systems that use the spring tension method of tape buffering use what type of device to sense changes in tape tension?

1. Vacuum air column
2. Electro-mechanical
3. Photo-sensitive
4. Variable-static-sensor

1-63. What are the two types of tape guides used on magnetic tape reeling systems?

1. Variable and stable
2. Round and square
3. Single and dual
4. Fixed and rotary

1-64. A co-axial tape reeling configuration places the supply and take-up reels side by side.

1. True
2. False

1-65. In which of the following types of tape transport capstan drive configurations is the tape tension and head-to-tape contact most likely to vary?

1. Dual-motor dual capstan drive
2. Peripheral drive capstan
3. Open-loop capstan drive
4. Closed-loop capstan drive

1-66. Which of the following closed-loop capstan drive tape transports will NOT work in reverse?

1. Differential velocity capstan
2. Peripheral drive capstan
3. Both 1 and 2 above
4. Dual-motors dual capstan

1-67. What type of capstan drive tape transport moves the magnetic tape by placing the capstan directly against the tape reel or tape pack?

1. Open-loop capstan drive
2. Peripheral drive capstan
3. Dual-motors dual capstan
4. Differential velocity capstan

1-68. Capstan speed control is a very important function of the magnetic tape transport system. Which of the following is NOT one of the six parts of a capstan speed control?

1. Capstan speed monitor
2. Speed select network
3. Comparison network
4. Reel motor drive circuit

1-69. What part of the capstan speed control function normally uses a photo-optical tachometer attached to the shaft of the capstan motor?

1. Precision frequency source
2. Speed select circuit
3. Capstan speed monitor
4. Comparison network

1-70. On some recorders, a servo control from tape signal is supplied to the comparison network of the capstan speed control function. What is the purpose of this signal?

1. Speeds up or slows down the capstan motor
2. Compensates for capstan speed differences when a recorded tape is played back on a different recorder
3. Monitors the true capstan motor speed
4. Provides a reference frequency that the speed select network uses to drive the capstan motor

1-71. Which of the following items can be used to clean most magnetic tape transports?

1. Isopropyl alcohol
2. Cotton swabs
3. Lint-free cloths
4. Each of the above

1-72. Which of the following is NOT a correct procedure for cleaning a magnetic tape transport?

1. When available, always use cotton swabs vice lint-free cloths
2. Apply the cleaner onto the cotton swab or lint-free cloth
3. Clean the flanged parts of the tape guides
4. While cleaning, switch swabs and cloths often

1-73. Magnetic tape transports should be demagnetized periodically. To do this, use a hand-held degausser and follow the procedures for demagnetizing magnetic heads.

1. True
2. False

ASSIGNMENT 2

Textbook assignment: Chapter 5, “Magnetic Tape Recorder Record and Reproduce Electronics,” pages 5-1 through 5-6. Chapter 6, “Magnetic Tape Recording Specifications,” pages 6-1 through 6-15. Chapter 7, “Digital Magnetic Tape Recording,” pages 7-1 through 7-9. Chapter 8 “ Magnetic Disk Recording,” pages 8-1 through 8-25.

2-1. Magnetic tape recorders use what type of electronic circuits to record and reproduce analog input signals?

1. Continuous wave
2. Frequency modulation
3. Amplitude modulation
4. Both 2 and 3 above

2-2. Direct record electronics record input signals onto magnetic tape just as they appeared at the recorder's input.

1. True
2. False

2-3. Which part of the direct record electronics component takes the input signal and the bias signal and mixes them together?

1. Input pre-amplifier circuit
2. Bias source
3. Summing network
4. Head driver circuit

2-4. Which part of the direct record electronics amplifies the signal from the summing network and sends it to the record head?

1. Bias source circuit
2. Head driver circuit
3. Input pre-amplifier circuit
4. Low-pass filter circuit

2-5. The pre-amplifier circuit of the direct reproduce electronics does which of the following functions?

1. Amplifies the reproduced signal
2. Removes the bias signal
3. Both 1 and 2 above
4. Corrects phase errors

2-6. What circuit in the direct reproduce electronics takes the pre-amplified signal and fixes frequency response problems the reproduce magnetic head may have caused?

1. Equalization and phase correction circuit
2. Output amplifier circuit
3. Head driver circuit
4. Summing network

2-7. What circuit of the direct reproduce electronics serves as an impedance matcher?

1. Pre-amplifier circuit
2. Output amplifier circuit
3. Equalization and phase correction circuit
4. Head driver circuit

2-8. How do FM record electronics process the incoming signal before sending it to the record head?

1. A high frequency, negative bias is added to the input signal
2. A summing network mixes the bias and input signal
3. Both 1 and 2 above
4. The input signal is frequency modulated onto the carrier frequency of a record oscillator

2-9. In the FM record electronics, what is the output of the record oscillator circuit?

1. The demodulated input signal
2. The frequency modulated carrier signal
3. A clean input signal with the negative bias removed
4. A combined input signal and equalization signal

THIS SPACE LEFT BLANK INTENTIONALLY.

IN ANSWERING QUESTIONS 2-10 THROUGH 2-13, SELECT THE DESCRIPTION IN COLUMN B THAT BEST DESCRIBES THE PART OF FM REPRODUCE ELECTRONICS LISTED IN COLUMN A.

2-10. Pre-amplifier circuit

2-11. Limiter/ demodulator circuit

2-12. Low-pass filter circuit

2-13. Output amplifier

1. Takes the signal from the limiter/ demodulator and cleans-up any noise or left over carrier signal
2. Takes the output from the low-pass filter and amplifies it for output
3. Takes the reproduce signal from the magnetic head and amplifies it
4. Stabilizes the amplitude level and demodulates the signal intelligence from the carrier signal

---

2-14. Which of the following generates the noise part of a recorder's SNR?

1. Magnetic heads
2. Magnetic tape
3. Both 1 and 2 above
4. Nearby equipment

2-15. The SNR can be stated in three different ways. Which of the following is NOT one of these ways?

1. Mean signal to RMS noise
2. Peak-to-peak signal to RMS noise
3. RMS signal to RMS noise
4. Peak signal-to-RMS noise

2-16. Which of the following data should be included with all SNR specifications?

1. Record level
2. Reproduce level
3. Bandwidth
4. Tape speed

2-17. What is the magnetic tape recording specification which gives a recorder's amplitude variation with frequency over a specified bandwidth?

1. Record level
2. Frequency response
3. Bandwidth
4. Both 2 and 3 above

2-18. Your LPO tells you to test the frequency response of a particular magnetic tape recorder. You use a signal generator to sweep through the frequencies as you monitor the recorder's output amplitude on a VTVM. Which of the following readings in output amplitude would indicate the upper and lower end of the recorders bandwidth?

1. +/− 2-dB
2. +/− 3-dB
3. +/− 5-dB
4. +/− 10-dB

2-19. Which of the following factors can limit or degrade the frequency response of a magnetic tape recorder?

1. The record head
2. The reproduce head
3. Magnetic head-to-tape contact
4. Each of the above

2-20. If the frequencies of the harmonic distortion are 2, 4, and 6 times the center frequency, what type of harmonic distortion is this?

1. Linear
2. Spatial
3. Even-order
4. Center frequency

2-21. Which of the following is a cause of even-order harmonics during magnetic tape recording?

1. Defective magnetic tape
2. Frequency response too low
3. Permanently magnetized heads
4. Each of the above

2-22. If you increase a magnetic tape recorder's signal bias level, what happens to the harmonic distortion?

1. Increases
2. Remains the same
3. Decreases
4. Increases odd-order harmonic distortion

2-23. When measuring the amount of harmonic distortion in a magnetic tape recorder, what electronic test equipment should you use?

1. Wave analyzer
2. VTVM
3. Spectrum analyzer
4. All of the above

2-24. When measuring harmonic distortion, you set the signal generator to input a 12-kHz test signal. At the recorder's output, what will be the frequency of the third-order harmonic?

1. 33-kHz
2. 18-kHz
3. 38-kHz
4. 36 kHz

2-25. What magnetic tape recorder specification expresses the variation of the phase shift with respect to frequency?

1. Frequency response
2. Phase response
3. Wow and Flutter
4. Each of the above

2-26. Which of the following conditions indicates that a magnetic tape recorder has a good phase response specification?

1. The SNR and frequency response are within tolerance
2. The wave analyzer shows a perfect sine wave
3. The recorder reproduces an undistorted square wave
4. Each of the above

2-27. What magnetic tape recorder specification expresses the result of non-uniform tape motion caused by variations in tape speed that produces frequency modulation of signals recorded onto magnetic tape?

1. Frequency response
2. Phase response
3. Flutter
4. Time-base error

2-28. Which of the following magnetic tape recorder transport parts can cause high frequency flutter (above 1000 Hz)?

1. Magnetic heads
2. Rotating tape guides
3. Fixed tape guides
4. Both 1 and 3 above

2-29. A magnetic tape recorder's flutter specification is usually expressed as a percent of peak or as a peak-to-peak value for what type of recorder?

1. Audio
2. Instrumentation
3. Video
4. All of the above

2-30. The time-base error (TBE) magnetic tape recorder specification is closely related to flutter. Which of the following statements best reflects this relationship?

1. TBE is an inverse measure of the effects of flutter on the stability of recorded data
2. TBE is a direct measure of the effects of flutter on the frequency response of recorded data
3. TBE is a direct measure of the effects of flutter on the stability of recorded data.
4. TBE is a direct measure of the effects of flutter on the bias level of recorded data.

2-31. The simplest way to measure a recorder's TBE is with what test equipment?

1. VTVM
2. Sweep analyzer
3. Oscilloscope
4. Ohmeter

2-32. There are two types of skew. What type does not show up when magnetic tapes are recorded and reproduced on the same magnetic tape recorder?

1. Positive
2. Dynamic
3. Negative
4. Fixed

2-33. Which of the following is NOT a cause of dynamic skew?

1. Gap scatter in the magnetic head stack
2. Sticking tape transport guides
3. Warped magnetic tape
4. Worn tape transport guides

2-34. Which of the following is NOT a format for digital magnetic tape recording?

1. Serial-parallel
2. Bi-phase
3. Serial
4. Parallel

2-35. Which of the following digital magnetic tape recording formats is normally used for instrumentation recording when the input data rate is high?

1. Serial-Parallel
2. Serial
3. Both 1 and 2 above
4. Bi-phase

2-36. The return-to-bias digital magnetic tape recording encoding method uses magnetic tape that is normally in a "neutral" condition.

1. True
2. False

2-37. Which of the following digital magnetic tape encoding methods is the most widely used?

1. RB
2. NRZ
3. E-RZ
4. RZ

2-38. Which of the four variations of NRZ encoding works best in high density magnetic tape recording and offers a bit-error rate of one error per 1 million bits?

1. E-NRZ-L
2. NRZ-L
3. NRZ-M
4. NRZ-S

2-39. Digital magnetic tape recorders are used to store and retrieve which of the following types of data?

1. Computer programs
2. Radar and other pulsed type signals
3. Special signals with a bandwidth of less than 500 kHz
4. Each of the above

2-40. Telemetry digital magnetic tape recorders are frequently called wideband recorders.

1. True
2. False

2-41. Floppy disks are made of round plastic disks coated with magnetic oxide particles and enclosed in a plastic jacket.

1. True
2. False

2-42. When discussing floppy disks, what is meant by the "density" of a floppy disk?

1. The thickness of the plastic disk
2. How much the disk can store
3. The thickness of floppy disk jacket
4. The number of sectors on the disk

IN ANSWERING QUESTIONS 2-43 THROUGH 2-46, SELECT THE STORAGE CAPACITY IN COLUMN B THAT BEST DESCRIBES THE TYPE OF FLOPPY DISK IN COLUMN A.

2-43.	5-1/4" double density	1.	1,200,000 bytes
2-44.	5-1/4" high density	2.	720,000 bytes
2-45.	3-1/2" double density	3.	360,000 bytes
2-46.	3-1/2" high density	4.	1,400,000 bytes

2-47. Data is stored on floppy disks in circular "tracks." Each track is then broken up into arcs called "cylinders."

1. True
2. False

2-48. When a floppy disk is sectored using the soft sectoring method, the computer software determines the sector size and placement. What is this process called?

1. Centering
2. Addressing
3. Formatting
4. Rastering

2-49. When you handle, store, or ship floppy disks, which of the following statements is NOT a precaution you should take?

1. Always store 8" and 5 1/4" floppy disks in their envelopes when not in use
2. Always write on a floppy disk label first, and then place it on the disk
3. Always lay floppy disks on their side when storing them
4. Always ship floppy disks in their appropriate shipping containers

2-50. Which of the following items can generate magnetic fields that can destroy data on a floppy disk?

1. Paper clip
2. Telephone
3. Printer
4. Both 2 and 3 above

2-51. How can you erase a floppy disk?

1. Record over it
2. Degauss it
3. Reformat it
4. Both 2 and 3 above

2-52. A computer places data on a hard disk by using one of what two methods?

1. Cylinder or sector
2. Cylinder or circular
3. Sector or quadrant
4. Sector or record

2-53. Using the sector method, a hard disk drive locates a place on a hard disk with only one platter by using three location numbers. Which of the following is NOT one of those location numbers?

1. Surface number
2. Track number
3. Cylinder number
4. Sector number

2-54. When you handle, store, or ship removable hard disks, which of the following statements is NOT a precaution you should take?

1. Don't touch any exposed recording surfaces
2. Keep them away from food, liquids, and cigarette smoke
3. Store them in an environment that stays between 32 to 95 degrees Fahrenheit and 40 to 85% relative humidity
4. Keep dirt, dust, etc., off of the recording surface by storing them in their case when not in use

2-55. How can you declassify a removable hard disk which contains classified information?

1. Reformat it
2. Degauss it
3. Both 1 and 2 above
4. Destroy it using the procedures in OPNAVINST 5510.1

2-56. Which of the following encoding methods is NOT used for encoding digital data onto magnetic disks?

1. Sector encoding
2. Run length limited
3. Modified frequency modulation
4. Frequency modulation

IN ANSWERING QUESTIONS 2-57 THROUGH 2-60, SELECT THE DESCRIPTION IN COLUMN B THAT DESCRIBES THE FLOPPY DISK DRIVE PART LISTED IN COLUMN A.

2-57. Head arm assembly	1. Holds and spins the floppy disk
2-58. Drive electronics circuit board	2. Holds the magnetic read/write heads
2-59. Drive motor/spindle assembly	3. Controls the electromechanical-high density parts
2-60. Actuator arm assembly	4. Positions the heads over the disks

---

2-61. What part of a hard disk drive transport uses either a dc stepper motor or a voice coil to position the heads for writing data to the correct track of the disk pack?

1. Drive motor/spindle assembly
2. Head arm assembly
3. Actuator arm assembly
4. Drive electronics circuit board

2-62. What part of a hard disk drive transport holds the four magnetic heads, and is attached to the transport's actuator arm assembly?

1. Cylinder assembly
2. Head arm assembly
3. Sectoring assembly
4. Drive motor/spindle assembly

2-63. Why do floppy disk drives require more preventive maintenance than hard disk drives?

1. They are not sealed units
2. Oxide coating from disks sticks to transport parts
3. Both 1 and 2 above
4. The drive circuit board is less protected

2-64. Which of the following is a main function of the control electronics part of a disk drive's electronics component?

1. Take incoming data from the interface electronics
2. Spin the disk at the proper speed
3. Move the heads across the recording surface
4. Both 2 and 3 above

2-65. Which of the following is a function of the interface electronics part of a disk drive's electronics component?

1. Convert data from the host computer from serial to parallel, and vice versa, as needed
2. Receive write/read control signals from the host computer
3. Receive control signals to format a disk from the host computer
4. All of the above

2-66. Which of the following is NOT one of the five most common disk drive interfaces in use today?

1. Drive motor/spindle interface
2. Naval tactical data system interface
3. ST-506/412 interface
4. Enhanced small device interface

2-67. What type of disk drive interface is often used in the hard disk drives installed in older IBM-compatible desktop computers that have a maximum capacity of 125MB?

1. Drive motor/spindle interface
2. Enhanced small device interface
3. ST-506/412 interface
4. Integrated drive electronics

2-68. What type of disk drive interface uses a high-level interface which requires only a logical sector number to locate the desired data on a disk?

1. Enhanced small device interface
2. Integrated drive electronics
3. Drive motor/spindle interface
4. Small computer systems interface

2-69. What type of disk drive interface includes all of the controller card electronics in the hard disk drive and offers a transfer rate of up to 1 MB?

1. Small computer systems interface
2. Integrated drive electronics
3. Naval tactical data system
4. Enhanced small device interface

2-70. Which of the following is NOT a benefit of the SCSI disk drive interface over previous interfaces?

1. Can handle disk drives of almost any size
2. Disconnects itself from the host computer's bus while it processes requests
3. Can transfer data up to 24 Mbits/sec
4. Can daisy-chain up to eight units off of one controller

IN ANSWERING QUESTIONS 2-71 THROUGH 2-74, SELECT THE MAGNETIC DISK RECORDING SPECIFICATION IN COLUMN B THAT MATCHES THE DEFINITION IN COLUMN A.

A.	B.
2-71. Indicates number of physical sectors that are between logical sectors on a hard disk	1. Seek time
2-72. Total time it takes a disk drive to retrieve a sector of data	2. Latency period
2-73. Time it takes for a magnetic head to position itself over a specific track	3. Access time
2-74. Time it takes a specific sector of a specific track to position itself under the magnetic head	4. Interleave factor

---

2-75. The speed at which a disk drive and a disk drive controller working together can transfer data to the host computer is what disk recording specification?

1. Seek time
2. Transfer rate
3. Access time
4. Interleave factor

Navy Electricity and Electronics Training Series

Module 24—Introduction to Fiber Optics

NAVEDTRA 14196

Notice: NETPDTC is no longer responsible for the content accuracy of the NRTCs.

For content issues, contact the servicing Center of Excellence: Center for Surface Combat System (CSCS); (540) 284-1061 or DSN: 249-1061.

Although the words "he," "him," and "his" are used sparingly in this course to enhance communication, they are not intended to be gender driven or to affront or discriminate against anyone.

PREFACE

By enrolling in this self-study course, you have demonstrated a desire to improve yourself and the Navy. Remember, however, this self-study course is only one part of the total Navy training program. Practical experience, schools, selected reading, and your desire to succeed are also necessary to successfully round out a fully meaningful training program.

COURSE OVERVIEW: To introduce the student to the subject of Fiber Optics who needs such a background in accomplishing daily work and/or in preparing for further study.

THE COURSE: This self-study course is organized into subject matter areas, each containing learning objectives to help you determine what you should learn along with text and illustrations to help you understand the information. The subject matter reflects day-to-day requirements and experiences of personnel in the rating or skill area. It also reflects guidance provided by Enlisted Community Managers (ECMs) and other senior personnel, technical references, instructions, etc., and either the occupational or naval standards, which are listed in the *Manual of Navy Enlisted Manpower Personnel Classifications and Occupational Standards,* NAVPERS 18068.

THE QUESTIONS: The questions that appear in this course are designed to help you understand the material in the text.

VALUE: In completing this course, you will improve your military and professional knowledge. Importantly, it can also help you study for the Navy-wide advancement in rate examination. If you are studying and discover a reference in the text to another publication for further information, look it up.

1998 Edition Prepared by
ETCS(SW) Donnie Jones

Sailor's Creed

"I am a United States Sailor.

I will support and defend the Constitution of the United States of America and I will obey the orders of those appointed over me.

I represent the fighting spirit of the Navy and those who have gone before me to defend freedom and democracy around the world.

I proudly serve my country's Navy combat team with honor, courage and commitment.

I am committed to excellence and the fair treatment of all."

TABLE OF CONTENTS

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current*, introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7*, Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

INSTRUCTIONS FOR TAKING THE COURSE

ASSIGNMENTS

The text pages that you are to study are listed at the beginning of each assignment. Study these pages carefully before attempting to answer the questions. Pay close attention to tables and illustrations and read the learning objectives. The learning objectives state what you should be able to do after studying the material. Answering the questions correctly helps you accomplish the objectives.

SELECTING YOUR ANSWERS

Read each question carefully, then select the BEST answer. You may refer freely to the text. The answers must be the result of your own work and decisions. You are prohibited from referring to or copying the answers of others and from giving answers to anyone else taking the course.

SUBMITTING YOUR ASSIGNMENTS

To have your assignments graded, you must be enrolled in the course with the Nonresident Training Course Administration Branch at the Naval Education and Training Professional Development and Technology Center (NETPDTC). Following enrollment, there are two ways of having your assignments graded: (1) use the Internet to submit your assignments as you complete them, or (2) send all the assignments at one time by mail to NETPDTC.

Grading on the Internet: Advantages to Internet grading are:

- you may submit your answers as soon as you complete an assignment, and
- you get your results faster; usually by the next working day (approximately 24 hours).

In addition to receiving grade results for each assignment, you will receive course completion confirmation once you have completed all the assignments. To submit your assignment answers via the Internet, go to:

https://courses.cnet.navy.mil

COMPLETION TIME

Courses must be completed within 12 months from the date of enrollment. This includes time required to resubmit failed assignments.

PASS/FAIL ASSIGNMENT PROCEDURES

If your overall course score is 3.2 or higher, you will pass the course and will not be required to resubmit assignments. Once your assignments have been graded you will receive course completion confirmation.

If you receive less than a 3.2 on any assignment and your overall course score is below 3.2, you will be given the opportunity to resubmit failed assignments. **You may resubmit failed assignments only once.** Internet students will receive notification when they have failed an assignment—they may then resubmit failed assignments on the web site. Internet students may view and print results for failed assignments from the web site. Students who submit by mail will receive a failing result letter and a new answer sheet for resubmission of each failed assignment.

COMPLETION CONFIRMATION

After successfully completing this course, you will receive a letter of completion.

STUDENT FEEDBACK QUESTIONS

We value your suggestions, questions, and criticisms on our courses. If you would like to communicate with us regarding this course, we encourage you, if possible, to use e-mail.

NAVAL RESERVE RETIREMENT CREDIT

If you are a member of the Naval Reserve, you may earn retirement points for successfully completing this course, if authorized under current directives governing retirement of Naval Reserve personnel. For Naval Reserve retirement, this course is evaluated at 6 points. (Refer to *Administrative Procedures for Naval Reservists on Inactive Duty,* BUPERSINST 1001.39, for more information about retirement points.)

Student Comments

Course Title: *NEETS Module 24*
Introduction to Fiber Optics

NAVEDTRA: 14196 **Date**: ______

We need some information about you:

Rate/Rank and Name: ______ SSN: ______ Command/Unit ______

NETPDTC 1550/41 (Rev 4-00)

CHAPTER 1

BACKGROUND ON FIBER OPTICS

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions are based on the objectives. By successfully completing the NRTC, you indicate that you have met the objectives and have learned the information. The learning objectives are listed below.

Upon completing this chapter, you should be able to do the following:

1. Describe the term *fiber optics*.
2. List the parts of a fiber optic data link.
3. Understand the function of each fiber optic data link part.
4. Outline the progress made in the history of fiber optic technology.
5. Describe the trade-offs in fiber properties and component selection in the design of fiber optic systems.
6. List the advantages and the disadvantages of fiber optic systems compared to electrical communications systems.

DEFINITION OF FIBER OPTICS

In the other Navy Electricity and Electronics Training Series (*NEETS*) modules, you learn the basic concepts used in electrical systems. Electrical systems include telephone, radio, cable television (CATV), radar, and satellite links. In the past 30 years, researchers have developed a new technology that offers greater data rates over longer distances at costs lower than copper wire systems. This new technology is **fiber optics**.

Fiber optics uses light to send information (data). More formally, **fiber optics** is the branch of optical technology concerned with the transmission of radiant power (light energy) through fibers.

Q1. Define fiber optics.

FIBER OPTIC DATA LINKS

A fiber optic data link sends input data through fiber optic components and provides this data as output information. It has the following three **basic functions**:

- To convert an electrical input signal to an optical signal
- To send the optical signal over an optical fiber

- To convert the optical signal back to an electrical signal

A fiber optic data link consists of three parts—**transmitter**, **optical fiber**, and **receiver**. Figure 1-1 is an illustration of a fiber optic data-link connection. The transmitter, optical fiber, and receiver perform the basic functions of the fiber optic data link. Each part of the data link is responsible for the successful transfer of the data signal. A fiber optic data link needs a transmitter that can effectively convert an electrical input signal to an optical signal and launch the data-containing light down the optical fiber. A fiber optic data link also needs a receiver that can effectively transform this optical signal back into its original form. This means that the electrical signal provided as data output should exactly match the electrical signal provided as data input.

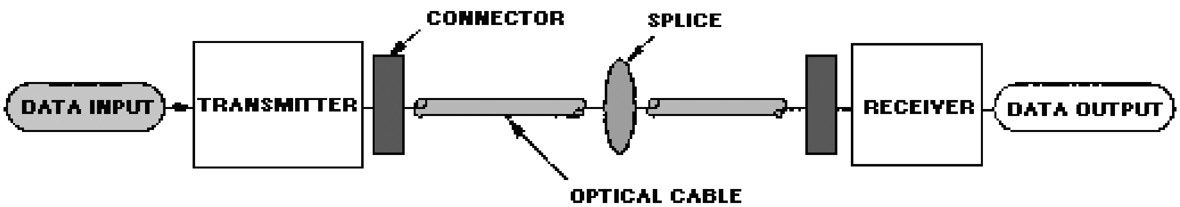

Figure 1-1.—Parts of a fiber optic data link.

The transmitter converts the input signal to an optical signal suitable for transmission. The transmitter consists of two parts, an interface circuit and a source drive circuit. The transmitter's drive circuit converts the electrical signals to an optical signal. It does this by varying the current flow through the light source. The two types of optical sources are light-emitting diodes (LEDs) and laser diodes.

The optical source launches the optical signal into the fiber. The optical signal will become progressively weakened and distorted because of scattering, absorption, and dispersion mechanisms in the fiber waveguides. Chapter 2 discusses the fiber mechanisms of scattering, absorption, and dispersion. Chapter 3 discusses the types of optical fibers and cables.

The receiver converts the optical signal exiting the fiber back into an electrical signal. The receiver consists of two parts, the optical detector and the signal-conditioning circuits. An optical detector detects the optical signal. The signal-conditioning circuit conditions the detector output so that the receiver output matches the original input to the transmitter. The receiver should amplify and process the optical signal without introducing noise or signal distortion. Noise is any disturbance that obscures or reduces the quality of the signal. Noise effects and limitations of the signal-conditioning circuits cause the distortion of the receiver's electrical output signal.

An optical detector can be either a semiconductor positive-intrinsic-negative (*PIN*) diode or an avalanche photodiode (APD). A *PIN* diode changes its electrical conductivity according to the intensity and wavelength of light. The *PIN* diode consists of an intrinsic region between p-type and n-type semiconductor material. Chapter 6 provides further explanation of optical sources. Chapter 7 provides further explanation of optical detectors.

A fiber optic data link also includes passive components other than an optical fiber. Figure 1-1 does not show the optical connections used to complete the construction of the fiber optic data link. Passive components used to make fiber connections affect the performance of the data link. These components can also prevent the link from operating. Fiber optic components used to make the optical connections include optical splices, connectors, and couplers. Chapter 4 outlines the types of optical splices, connectors, and couplers and their connection properties that affect system performance.

Proof of link performance is an integral part of the design, fabrication, and installation of any fiber optic system. Various measurement techniques are used to test individual parts of a data link. Each data link part is tested to be sure the link is operating properly. Chapter 5 discusses the laboratory and field measurements used to measure link performance.

Q2. Describe the basic functions of a fiber optic data link.

Q3. List the three parts of a fiber optic data link.

Q4. What mechanisms in the fiber waveguides weaken and distort the optical signal?

Q5. What effect does noise have on the fiber optic signal?

HISTORY OF FIBER OPTIC TECHNOLOGY

People have used light to transmit information for hundreds of years. However, it was not until the 1960s, with the invention of the laser, that widespread interest in optical (light) systems for data communications began. The invention of the laser prompted researchers to study the potential of fiber optics for data communications, sensing, and other applications. Laser systems could send a much larger amount of data than telephone, microwave, and other electrical systems. The first experiment with the laser involved letting the laser beam transmit freely through the air. Researchers also conducted experiments letting the laser beam transmit through different types of waveguides. Glass fibers, gas-filled pipes, and tubes with focusing lenses are examples of optical waveguides.

Glass fibers soon became the preferred medium for fiber optic research. Initially, the very large losses in the optical fibers prevented coaxial cables from being replaced. **Loss** is the decrease in the amount of light reaching the end of the fiber. Early fibers had losses around 1,000 dB/km making them impractical for communications use. In 1969, several scientists concluded that impurities in the fiber material caused the signal loss in optical fibers. The basic fiber material did not prevent the light signal from reaching the end of the fiber. These researchers believed it was possible to reduce the losses in optical fibers by removing the impurities. By removing the impurities, construction of low-loss optical fibers was possible.

There are two basic types of optical fibers, multimode fibers and single mode fibers. Chapter 2 discusses the differences between the fiber types. In 1970, Corning Glass Works made a multimode fiber with losses under 20 dB/km. This same company, in 1972, made a high silica-core multimode optical fiber with 4dB/km minimum attenuation (loss). Currently, multimode fibers can have losses as low as 0.5 dB/km at wavelengths around 1300 nm. Single mode fibers are available with losses lower than 0.25 dB/km at wavelengths around 1500 nm.

Developments in semiconductor technology, which provided the necessary light sources and detectors, furthered the development of fiber optics. Conventional light sources, such as lamps or lasers, were not easily used in fiber optic systems. These light sources tended to be too large and required lens systems to launch light into the fiber. In 1971, Bell Laboratories developed a small area light-emitting diode (LED). This light source was suitable for low-loss coupling to optical fibers. Researchers could then perform source-to-fiber jointing easily and repeatedly. Early semiconductor sources had operating lifetimes of only a few hours. However, by 1973, projected lifetimes of lasers advanced from a few hours to greater than 1,000 hours. By 1977, projected lifetimes of lasers advanced to greater than 7,000 hours. By 1979, these devices were available with projected lifetimes of more than 100,000 hours.

In addition, researchers also continued to develop new fiber optic parts. The types of new parts developed included low-loss fibers and fiber cables, splices, and connectors. These parts permitted demonstration and research on complete fiber optic systems.

Advances in fiber optics have permitted the introduction of fiber optics into present applications. These applications are mostly in the telephone long-haul systems, but are growing to include cable television, computer networks, video systems, and data links. Research should increase system performance and provide solutions to existing problems in conventional applications. The impressive results from early research show there are many advantages offered by fiber optic systems.

Q6. Define loss.

Q7. In 1969, what did several scientists conclude about optical fiber loss?

Q8. How can loss be reduced during construction (or fabrication) of optical fibers?

Q9. What are the two basic types of optical fibers?

FIBER OPTIC SYSTEMS

System design has centered on long-haul communications and the subscriber-loop plant. The subscriber-loop plant is the part of a system that connects a subscriber to the nearest switching center. Cable television is an example. Limited work has also been done on short-distance applications and some military systems. Initially, central office trunking required multimode optical fibers with moderate to good performance. Fiber performance depends on the amount of loss and signal distortion introduced by the fiber when it is operating at a specific wavelength. Long-haul systems require single mode optical fibers with very high performance. Single mode fibers tend to have lower loss and produce less signal distortion.

In contrast, short-distance and military systems tend to use only multimode technology. Examples of short-distance systems include process control and local area networks (LANs). Short-distance and military systems have many connections. The larger fiber core and higher fiber numerical aperture (NA) of multimode fibers reduce losses at these connections. Chapter 4 explains fiber connection properties in more detail. Chapter 2 provides more detail on multimode and single mode fibers.

In military and subscriber-loop applications, system design and parts selection are related. Designers consider **trade-offs** in the following areas:

- Fiber properties
- Types of connections
- Optical sources
- Detector types

Designers develop systems to meet stringent working requirements, while trying to maintain economic performance. It is quite difficult to identify a standard system design approach. This module identifies the types of components chosen by the Navy for shipboard applications.

Future system design improvements depend on continued research. Researchers expect fiber optic product improvements to upgrade performance and lower costs for short-distance applications. Future systems center on broadband services that will allow transmission of voice, video, and data. Services will include television, data retrieval, video word processing, electronic mail, banking, and shopping.

Q10. Which type of optical fiber (multimode or single mode) tends to have lower loss and produces less signal distortion?

Q11. What optical fiber properties reduce connection loss in short-distance systems?

Q12. In fiber optic systems, designers consider what trade-offs?

ADVANTAGES AND DISADVANTAGES OF FIBER OPTICS

Fiber optic systems have many attractive features that are superior to electrical systems. These include improved system performance, immunity to electrical noise, signal security, and improved safety and electrical isolation. Other advantages include reduced size and weight, environmental protection, and overall system economy. Table 1-1 details the main advantages of fiber optic systems.

Table 1-1.— Advantages of Fiber Optics

System Performance	• Greatly increased bandwidth and capacity • Lower signal attenuation (loss)
Immunity to Electrical Noise	• Immune to noise (electromagnetic interference [EMI] and radio-frequency interference [RFI] • No crosstalk • Lower bit error rates
Signal Security	• Difficult to tap • Nonconductive (does not radiate signals)
Electrical Isolation	• No common ground required • Freedom from short circuit and sparks
Size and Weight	• Reduced size and weight cables
Environmental Protection	• Resistant to radiation and corrosion • Resistant to temperature variations • Improved ruggedness and flexibility • Less restrictive in harsh environments
Overall System Economy	• Low per-channel cost • Lower installation cost • Silica is the principle, abundant, and inexpensive material (source is sand)

Despite the many advantages of fiber optic systems, there are some disadvantages. Because of the relative newness of the technology, fiber optic components are expensive. Fiber optic transmitters and receivers are still relatively expensive compared to electrical interfaces. The lack of standardization in the industry has also limited the acceptance of fiber optics. Many industries are more comfortable with the use of electrical systems and are reluctant to switch to fiber optics. However, industry researchers are eliminating these disadvantages.

Standards committees are addressing fiber optic part and test standardization. The cost to install fiber optic systems is falling because of an increase in the use of fiber optic technology. Published articles, conferences, and lectures on fiber optics have begun to educate managers and technicians. As the technology matures, the use of fiber optics will increase because of its many advantages over electrical systems.

Q13. List seven advantages of fiber optics over electrical systems.

SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas you have learned. You should have a thorough understanding of these principles before advancing to chapter 2.

FIBER OPTICS is the branch of optical technology concerned with the transmission of radiant power (light energy) through fibers.

A **FIBER OPTIC DATA LINK** has three basic functions: to convert an electrical input signal to an optical signal, to send the optical signal over an optical fiber, and to convert the optical signal back to an electrical signal. It consists of three parts: transmitter, optical fiber, and receiver.

The **TRANSMITTER** consists of two parts, an interface circuit and a source drive circuit. The transmitter converts the electrical input signal to an optical signal by varying the current flow through the light source.

The **RECEIVER** consists of two parts, the optical detector and signal conditioning circuits. The receiver converts the optical signal exiting the fiber back into the original form of the electrical input signal.

SCATTERING, ABSORPTION, and **DISPERSION MECHANISMS** in the fiber waveguides cause the optical signal launched into the fiber to become weakened and distorted.

NOISE is any disturbance that obscures or reduces the quality of the signal.

SIGNAL LOSS is the decrease in the amount of light reaching the end of the fiber. Impurities in the fiber material cause the signal loss in optical fibers. By removing these impurities, construction of low-loss optical fibers was possible.

The **TWO BASIC TYPES OF OPTICAL FIBERS** are multimode fibers and single mode fibers.

A **LOW-LOSS MULTIMODE OPTICAL FIBER** was developed in 1970.

A **SMALL AREA LIGHT-EMITTING DIODE (LED)** was developed in 1971. This light source was suitable for low-loss coupling to optical fibers.

FIBER OPTIC SYSTEM DESIGN has centered on long-haul communications and the subscriber-loop plant. Limited work has also been done on short-distance applications and some military systems.

FIBER PERFORMANCE depends on the amount of loss and signal distortion introduced by the fiber when it is operating at a specific wavelength. Single mode fibers tend to have lower loss and produce less distortion than multimode fibers.

The **LARGER FIBER CORE** and the **HIGHER NUMERICAL APERTURE (NA)** of multimode fibers reduce the amount of loss at fiber connections.

In **MILITARY** and **SUBSCRIBER-LOOP APPLICATIONS**, system designers consider trade-offs in the following areas: fiber properties, types of connections, optical sources, and detector types.

The **ADVANTAGES** of fiber optic systems include improved system performance, immunity to electrical noise, signal security, and electrical isolation. Advantages also include reduced size and weight, environmental protection, and overall system economy.

The **DISADVANTAGES** of fiber optic systems include problems with the relative newness of the technology, the relatively expensive cost, and the lack of component and system standardization. However, these disadvantages are already being eliminated because of increased use and acceptance of fiber optic technology.

ANSWERS TO QUESTIONS Q1. THROUGH Q13.

A1. Fiber optics is the branch of optical technology concerned with the transmission of radiant power (light energy) through fibers.

A2. The basic functions of a fiber optic data link are to convert an electrical input signal to an optical signal, send the optical signal over an optical fiber, and convert the optical signal back to an electrical signal.

A3. Transmitter, optical fiber, and receiver.

A4. Scattering, absorption, and dispersion.

A5. Noise obscures or reduces the quality of the signal.

A6. Loss is the decrease in the amount of light reaching the end of the fiber.

A7. Impurities in the fiber material caused the signal loss in optical fibers. The basic fiber material did not prevent the light signal from reaching the end of the fiber.

A8. By removing the impurities from optical fiber.

A9. Multimode and single mode fibers.

A10. Single mode fiber.

A11. Larger fiber core and higher fiber numerical aperture (NA).

A12. Trade-offs in fiber properties, types of connections, optical sources, and detector types in military and subscriber-loop applications.

A13. Advantages of fiber optics are improved system performance, immunity to electrical noise, signal security, electrical isolation, reduced size and weight, environmental protection, and overall system economy.

CHAPTER 2

FIBER OPTIC CONCEPTS

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to do the following:

1. Understand the nature of light propagation.
2. Discuss the electromagnetic theory of light.
3. Describe the properties of light reflection, refraction, diffusion, and absorption.
4. Explain how optical fibers transmit light.
5. Identify the basic optical fiber material properties.
6. Describe the ray and mode theories of light propagation along an optical fiber.
7. State the difference between multimode and single mode optical fibers.
8. Explain how optical fibers attenuate and distort light signals as they travel along the optical fiber.
9. Understand the processes of light attenuation and dispersion.

FIBER OPTIC LIGHT TRANSMISSION

Fiber optics deals with the transmission of light energy through transparent fibers. How an optical fiber guides light depends on the nature of the light and the structure of the optical fiber. A light wave is a form of energy that is moved by wave motion. Wave motion can be defined as a recurring disturbance advancing through space with or without the use of a physical medium. In fiber optics, wave motion is the movement of light energy through an optical fiber. To fully understand the concept of wave motion, refer to *NEETS* Module 10—*Introduction to Wave Propagation, Transmission Lines, and Antennas*. Before we introduce the subject of light transmission through optical fibers, you must first understand the nature of light and the properties of light waves.

PROPAGATION OF LIGHT

The exact nature of light is not fully understood, although people have been studying the subject for many centuries. In the 1700s and before, experiments seemed to indicate that light was composed of particles. In the early 1800s, a physicist Thomas Young showed that light exhibited wave characteristics. Further experiments by other physicists culminated in James Clerk (pronounced Clark) Maxwell collecting the four fundamental equations that completely describe the behavior of the electromagnetic fields. James Maxwell deduced that light was simply a component of the electromagnetic spectrum. This seems to firmly establish that light is a wave. Yet, in the early 1900s, the interaction of light with semiconductor materials, called the photoelectric effect, could not be explained with electromagnetic-wave theory. The advent of quantum physics successfully explained the photoelectric effect in terms of fundamental particles of energy called **quanta**. Quanta are known as **photons** when referring to light energy.

Today, when studying light that consists of many photons, as in propagation, that light behaves as a continuum—an electromagnetic wave. On the other hand, when studying the interaction of light with semiconductors, as in sources and detectors, the quantum physics approach is taken. The wave versus particle dilemma can be addressed in a more formal way, but that is beyond the scope of this text. It suffices to say that much has been reconciled between the two using quantum physics. In this manual, we use both the electromagnetic wave and photon concepts, each in the places where it best matches the phenomenon we are studying.

The electromagnetic energy of light is a form of electromagnetic radiation. Light and similar forms of radiation are made up of moving electric and magnetic forces. A simple example of motion similar to these radiation waves can be made by dropping a pebble into a pool of water. In this example, the water is not actually being moved by the outward motion of the wave, but rather by the up-and-down motion of the water. The up-and-down motion is transverse, or at right angles, to the outward motion of the waves. This type of wave motion is called **transverse-wave motion**. The transverse waves spread out in expanding circles until they reach the edge of the pool, in much the same manner as the transverse waves of light spread from the sun. However, the waves in the pool are very slow and clumsy in comparison with light, which travels approximately 186,000 miles per second.

Light radiates from its source in all directions until it is absorbed or diverted by some substance (fig. 2-1). The lines drawn from the light source (a light bulb in this instance) to any point on one of the transverse waves indicate the direction that the wavefronts are moving. These lines, are called **light rays**.

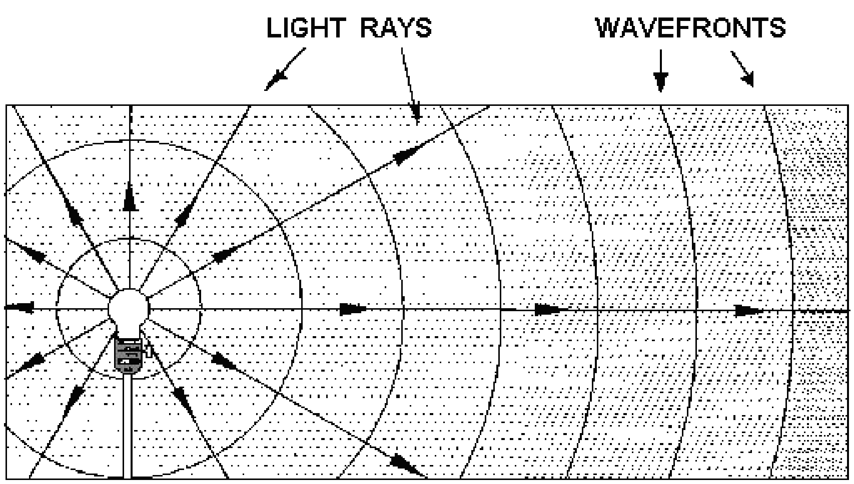

Figure 2-1.—Light rays and wavefronts from a nearby light source.

Although single rays of light typically do not exist, light rays shown in illustrations are a convenient method used to show the direction in which light is traveling at any point. A ray of light can be illustrated as a straight line.

Q1. Quantum physics successfully explained the photoelectric effect in terms of fundamental particles of energy called quanta. What are the fundamental particles of energy (quanta) known as when referring to light energy?

Q2. What type of wave motion is represented by the motion of water?

PROPERTIES OF LIGHT

When light waves, which travel in straight lines, encounter any substance, they are either reflected, absorbed, transmitted, or refracted. This is illustrated in figure 2-2. Those substances that transmit almost all the light waves falling upon them are said to be **transparent**. A transparent substance is one through which you can see clearly. Clear glass is transparent because it transmits light rays without diffusing them (view A of figure 2-3). There is no substance known that is perfectly transparent, but many substances are nearly so. Substances through which some light rays can pass, but through which objects cannot be seen clearly because the rays are diffused, are called **translucent** (view B of figure 2-3). The frosted glass of a light bulb and a piece of oiled paper are examples of translucent materials. Those substances that are unable to transmit any light rays are called **opaque** (view C of figure 2-3). Opaque substances either reflect or absorb all the light rays that fall upon them.

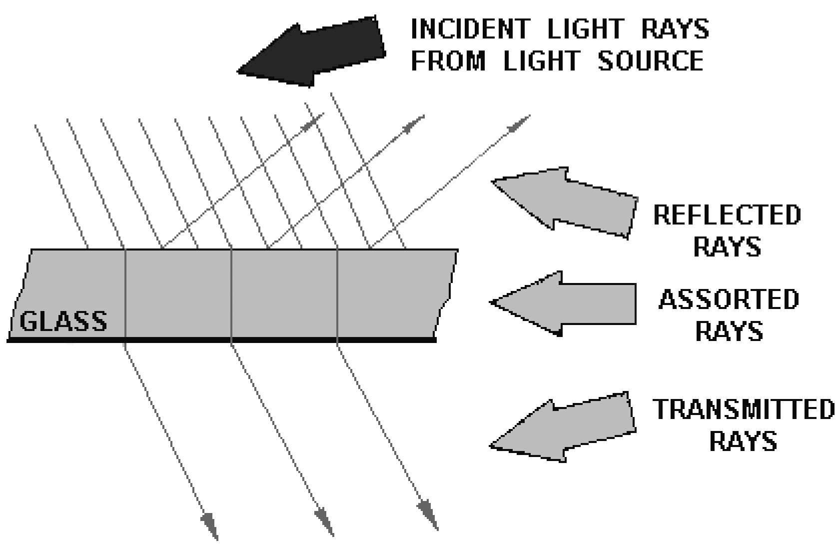

Figure 2-2.—Light waves reflected, absorbed, and transmitted.

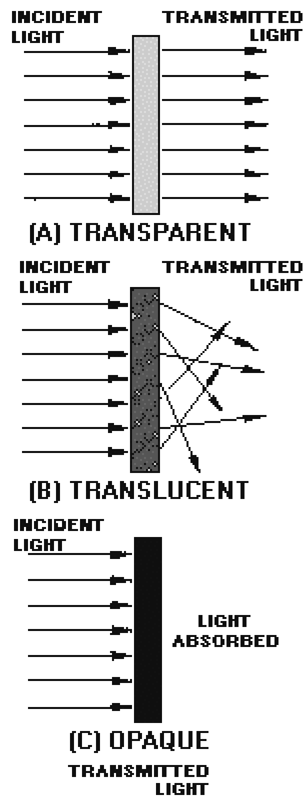

Figure 2-3.—Substances: A. Transparent; B. Translucent; and C. Opaque.

All substances that are not light sources are visible only because they reflect all or some part of the light reaching them from some luminous source. Examples of luminous sources include the sun, a gas flame, and an electric light filament, because they are sources of light energy. If light is neither transmitted nor reflected, it is absorbed or taken up by the medium. When light strikes a substance, some absorption and some reflection always take place. No substance completely transmits, reflects, or absorbs all the light rays that reach its surface.

Q3. When light waves encounter any substance, what four things can happen?

Q4. A substance that transmits almost all of the light waves falling upon it is known as what type of substance?

Q5. A substance that is unable to transmit any light waves is known as what type of substance?

REFLECTION OF LIGHT

Reflected waves are simply those waves that are neither transmitted nor absorbed, but are reflected from the surface of the medium they encounter. When a wave approaches a reflecting surface, such as a mirror, the wave that strikes the surface is called the **incident** wave, and the one that bounces back is called the **reflected** wave (refer to figure 2-4). An imaginary line perpendicular to the point at which the incident wave strikes the reflecting surface is called the **normal**, or the perpendicular. The angle between the incident wave and the normal is called the **angle of incidence**. The angle between the reflected wave and the normal is called the **angle of reflection**.

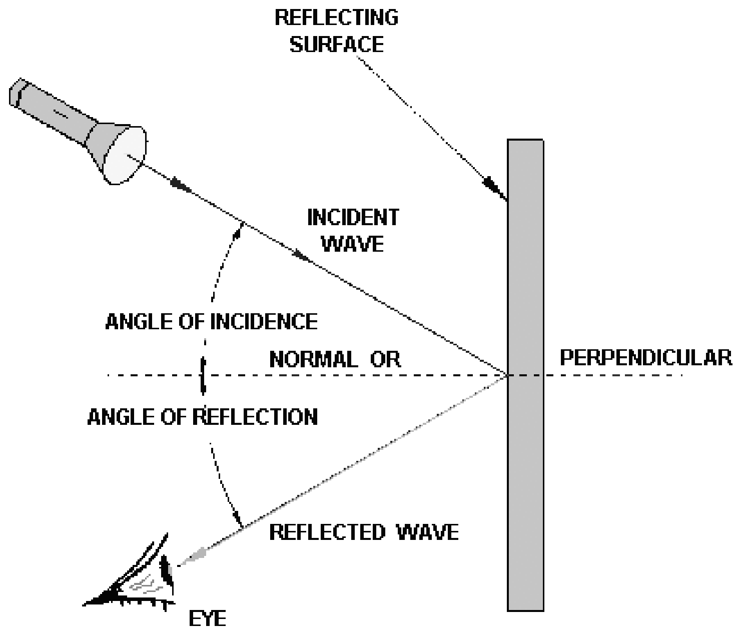

Figure 2-4.—Reflection of a wave.

If the surface of the medium contacted by the incident wave is smooth and polished, each reflected wave will be reflected back at the same angle as the incident wave. The path of the wave reflected from the surface forms an angle equal to the one formed by its path in reaching the medium. This conforms to the **law of reflection** which states: <u>The angle of incidence is equal to the angle of reflection</u>.

The amount of incident-wave energy that is reflected from a surface depends on the nature of the surface and the angle at which the wave strikes the surface. The amount of wave energy reflected increases as the angle of incidence increases. The reflection of energy is the greatest when the wave is nearly parallel to the reflecting surface. When the incidence wave is perpendicular to the surface, more of the energy is transmitted into the substance and reflection of energy is at its least. At any incident angle, a mirror reflects almost all of the wave energy, while a dull, black surface reflects very little.

Light waves obey the law of reflection. Light travels in a straight line through a substance of uniform density. For example, you can see the straight path of light rays admitted through a narrow slit into a darkened room. The straight path of the beam is made visible by illuminated dust particles suspended in the air. If the light is made to fall onto the surface of a mirror or other reflecting surface, however, the direction of the beam changes sharply. The light can be reflected in almost any direction, depending on the angle with which the mirror is held.

Q6. What is the law of reflection?

Q7. When a wave is reflected from a surface, energy is reflected. When is the reflection of energy the greatest?

Q8. When is the reflection energy the least?

Q9. Light waves obey what law?

REFRACTION OF LIGHT

When a light wave passes from one medium into a medium having a different velocity of propagation (the speed waves can travel through a medium), a change in the direction of the wave will occur. This change of direction as the wave enters the second medium is called refraction. As in the discussion of reflection, the wave striking the boundary (surface) is called the incident wave, and the imaginary line perpendicular to the boundary is called the normal. The angle between the incident wave and the normal is called the angle of incidence. As the wave passes through the boundary, it is bent either toward or away from the normal. The angle between the normal and the path of the wave through the second medium is the angle of refraction.

A light wave passing through a block of glass is shown in figure 2-5. The wave moves from point A to point B at a constant speed. This is the incident wave. As the wave penetrates the glass boundary at point B, the velocity of the wave is slowed down. This causes the wave to bend toward the normal. The wave then takes the path from point B to point C through the glass and becomes both the refracted wave from the top surface and the incident wave to the lower surface. As the wave passes from the glass to the air (the second boundary), it is again refracted, this time away from the normal, and takes the path from point C to point D. After passing through the last boundary, the velocity increases to the original velocity of the wave. As illustrated, refracted waves can bend toward or away from the normal. This bending depends on the velocity of the wave through different mediums. The broken line between points B and E is the path that the wave would travel if the two mediums (air and glass) had the same density.

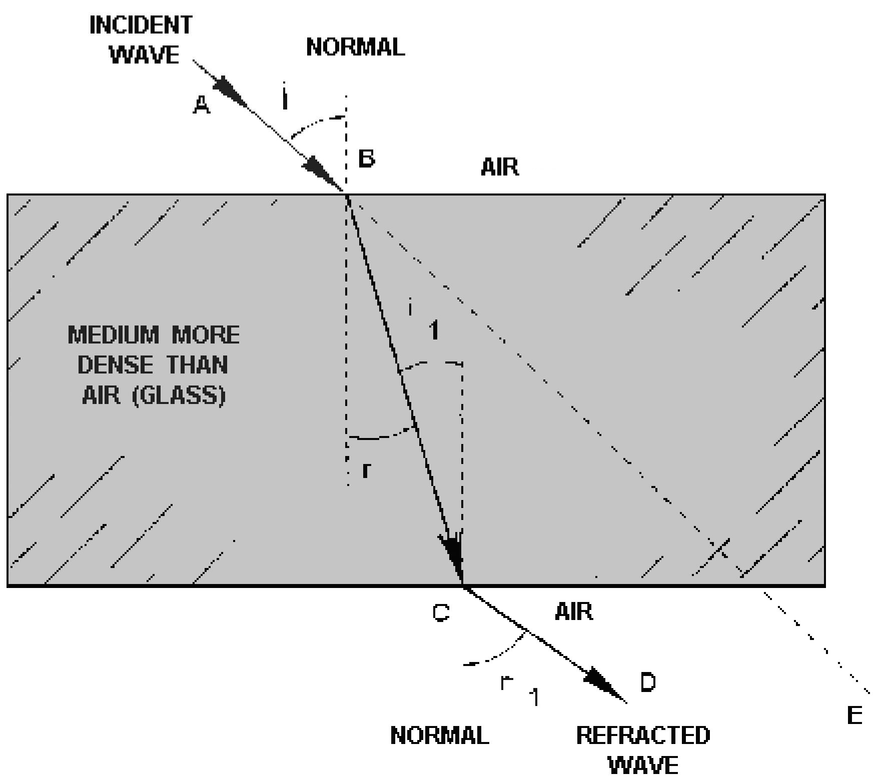

Figure 2-5.—Refraction of a wave.

Another interesting condition can be shown using figure 2-5. If the wave passes from a less dense to a more dense medium, it is bent toward the normal, and the angle of refraction (r) is less than the angle of incidence (i). Likewise, if the wave passes from a more dense to a less dense medium, it is bent away from the normal, and the angle of refraction (r_1) is greater than the angle of incidence (i_1).

An example of refraction is the apparent bending of a spoon when it is immersed in a cup of water. The bending seems to take place at the surface of the water, or exactly at the point where there is a change of density. Obviously, the spoon does not bend from the pressure of the water. The light forming the image of the spoon is bent as it passes from the water (a medium of high density) to the air (a medium of comparatively low density).

Without refraction, light waves would pass in straight lines through transparent substances without any change of direction. Figure 2-5 shows that rays striking the glass at any angle other than perpendicular are refracted. However, perpendicular rays, which enter the glass normal to the surface, continue through the glass and into the air in a straight line—no refraction takes place.

Q10. A refracted wave occurs when a wave passes from one medium into another medium. What determines the angle of refraction?

Q11. A light wave enters a sheet of glass at a perfect right angle to the surface. Is the majority of the wave reflected, refracted, transmitted, or absorbed?

DIFFUSION OF LIGHT

When light is reflected from a mirror, the angle of reflection equals the angle of incidence. When light is reflected from a piece of plain white paper; however, the reflected beam is scattered, or diffused, as shown in figure 2-6. Because the surface of the paper is not smooth, the reflected light is broken up into many light beams that are reflected in all directions.

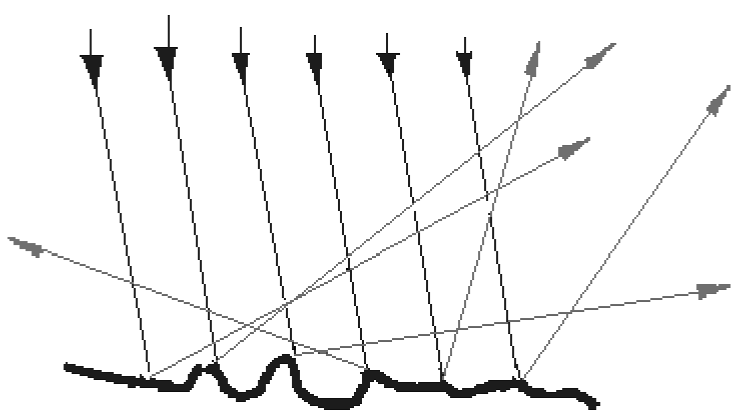

Figure 2-6.—Diffusion of light.

Q12. When light strikes a piece of white paper, the light is reflected in all directions. What do we call this scattering of light?

ABSORPTION OF LIGHT

You have just seen that a light beam is reflected and diffused when it falls onto a piece of white paper. If the light beam falls onto a piece of black paper, the black paper absorbs most of the light rays and very little light is reflected from the paper. If the surface upon which the light beam falls is perfectly black, there is no reflection; that is, the light is totally absorbed. No matter what kind of surface light falls upon, some of the light is absorbed.

TRANSMISSION OF LIGHT THROUGH OPTICAL FIBERS

The transmission of light along optical fibers depends not only on the nature of light, but also on the structure of the optical fiber. Two methods are used to describe how light is transmitted along the optical fiber. The first method, ray theory, uses the concepts of light reflection and refraction. The second method, mode theory, treats light as electromagnetic waves. You must first understand the basic optical properties of the materials used to make optical fibers. These properties affect how light is transmitted through the fiber.

Q13. Two methods describe how light propagates along an optical fiber. These methods define two theories of light propagation. What do we call these two theories?

BASIC OPTICAL-MATERIAL PROPERTIES

The basic optical property of a material, relevant to optical fibers, is the index of refraction. The index of refraction (n) measures the speed of light in an optical medium. The index of refraction of a material is the ratio of the speed of light in a vacuum to the speed of light in the material itself. The speed of light (c) in free space (vacuum) is 3×10^8 meters per second (m/s). The speed of light is the frequency (f) of light multiplied by the wavelength of light (λ). When light enters the fiber material (an optically dense medium), the light travels slower at a speed (v). Light will always travel slower in the fiber material than in air. The index of refraction is given by:

$$n = \frac{c}{v}$$

A light ray is reflected and refracted when it encounters the boundary between two different transparent mediums. For example, figure 2-7 shows what happens to the light ray when it encounters the interface between glass and air. The index of refraction for glass (n_1) is 1.50. The index of refraction for air (n_2) is 1.00.

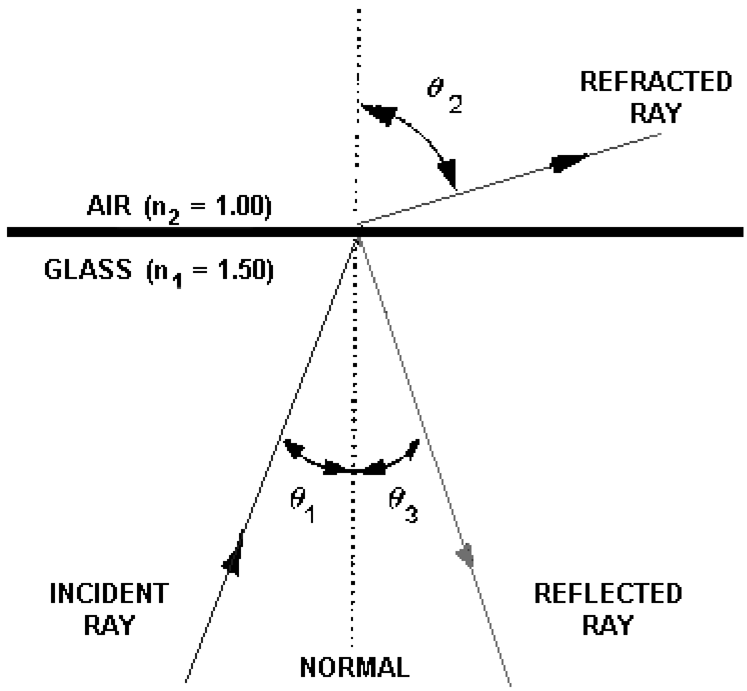

Figure 2-7.—Light reflection and refraction at a glass-air boundary.

Let's assume the light ray or incident ray is traveling through the glass. When the light ray encounters the glass-air boundary, there are two results. The first result is that part of the ray is reflected back into the glass. The second result is that part of the ray is refracted (bent) as it enters the air. The bending of the light at the glass-air interface is the result of the difference between the index of refractions. Since n_1 is greater than n_2, the angle of refraction (¯ $_2$) will be greater than the angle of incidence (¯ $_1$). Snell's law of refraction is used to describe the relationship between the incident and the refracted rays at the boundary. Snell's Law is given by:

$$n_1 \times \sin\Theta_1 = n_2 \times \sin\Theta_2$$

As the angle of incidence (¯ $_1$) becomes larger, the angle of refraction (¯ $_2$) approaches 90 degrees. At this point, no refraction is possible. The light ray is totally reflected back into the glass medium. No light escapes into the air. This condition is called total internal reflection. The angle at which total internal reflection occurs is called the critical angle of incidence. The critical angle of incidence (¯) is shown in figure 2-8. At any angle of incidence (¯ $_1$) greater than the critical angle, light is totally reflected back into the glass medium. The critical angle of incidence is determined by using Snell's Law. The critical angle is given by:

$$\sin\Theta_c = \frac{n_2}{n_1}$$

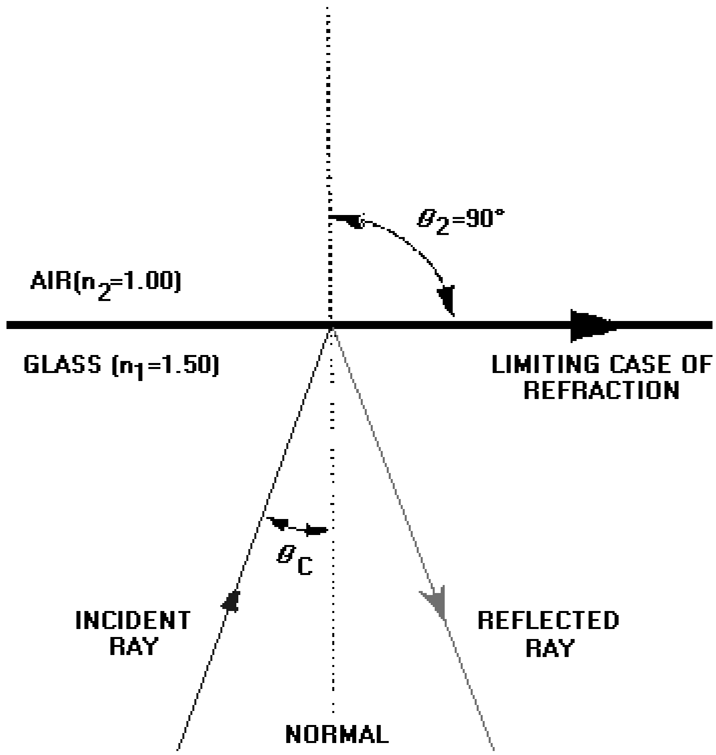

Figure 2-8.—Critical angle of incidence.

The condition of total internal reflection is an ideal situation. However, in reality, there is always some light energy that penetrates the boundary. This situation is explained by the mode theory, or the electromagnetic wave theory, of light.

Q14. What is the basic optical-material property relevant to optical fiber light transmission?

Q15. The index of refraction measures the speed of light in an optical fiber. Will light travel faster in an optically dense material or in one that is less dense?

Q16. Assume light is traveling through glass, what happens when this light strikes the glass-air boundary?

Q17. What condition causes a light ray to be totally reflected back into its medium of propagation?

Q18. What name is given to the angle where total internal reflection occurs?

BASIC STRUCTURE OF AN OPTICAL FIBER

The basic structure of an optical fiber consists of three parts; the core, the cladding, and the coating or buffer. The basic structure of an optical fiber is shown in figure 2-9. The core is a cylindrical rod of dielectric material. Dielectric material conducts no electricity. Light propagates mainly along the core of the fiber. The core is generally made of glass. The core is described as having a radius of (a) and an index of refraction n_1. The core is surrounded by a layer of material called the cladding. Even though light will propagate along the fiber core without the layer of cladding material, the cladding does perform some necessary functions.

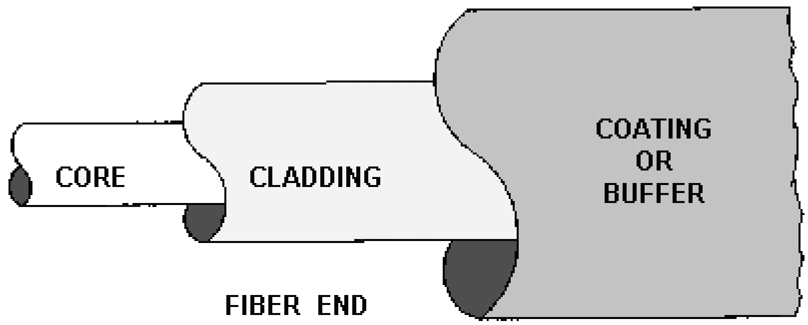

Figure 2-9.—Basic structure of an optical fiber.

The cladding layer is made of a dielectric material with an index of refraction n_2. The index of refraction of the cladding material is less than that of the core material. The cladding is generally made of glass or plastic. The cladding performs the following functions:

- Reduces loss of light from the core into the surrounding air
- Reduces scattering loss at the surface of the core
- Protects the fiber from absorbing surface contaminants
- Adds mechanical strength

For extra protection, the cladding is enclosed in an additional layer called the coating or buffer.

The coating or buffer is a layer of material used to protect an optical fiber from physical damage. The material used for a buffer is a type of plastic. The buffer is elastic in nature and prevents abrasions. The buffer also prevents the optical fiber from scattering losses caused by microbends. Microbends occur when an optical fiber is placed on a rough and distorted surface. Microbends are discussed later in this chapter.

Q19. List the three parts of an optical fiber.

Q20. Which fiber material, core or cladding, has a higher index of refraction?

PROPAGATION OF LIGHT ALONG A FIBER

The concept of light propagation, the transmission of light along an optical fiber, can be described by two theories. According to the first theory, light is described as a simple ray. This theory is the ray theory, or geometrical optics, approach. The advantage of the ray approach is that you get a clearer picture of the propagation of light along a fiber. The ray theory is used to approximate the light acceptance and guiding properties of optical fibers. According to the second theory, light is described as an electromagnetic wave. This theory is the mode theory, or wave representation, approach. The mode theory describes the behavior of light within an optical fiber. The mode theory is useful in describing the optical fiber properties of absorption, attenuation, and dispersion. These fiber properties are discussed later in this chapter.

Q21. Light transmission along an optical fiber is described by two theories. Which theory is used to approximate the light acceptance and guiding properties of an optical fiber?

Ray Theory

Two types of rays can propagate along an optical fiber. The first type is called meridional rays. Meridional rays are rays that pass through the axis of the optical fiber. Meridional rays are used to illustrate the basic transmission properties of optical fibers. The second type is called skew rays. Skew rays are rays that travel through an optical fiber without passing through its axis.

MERIDIONAL RAYS.—Meridional rays can be classified as bound or unbound rays. Bound rays remain in the core and propagate along the axis of the fiber. Bound rays propagate through the fiber by total internal reflection. Unbound rays are refracted out of the fiber core. Figure 2-10 shows a possible path taken by bound and unbound rays in a step-index fiber. The core of the step-index fiber has an index of refraction n_1. The cladding of a step-index has an index of refraction n_2, that is lower than n_1. Figure 2-10 assumes the core-cladding interface is perfect. However, imperfections at the core-cladding interface will cause part of the bound rays to be refracted out of the core into the cladding. The light rays refracted into the cladding will eventually escape from the fiber. In general, meridional rays follow the laws of reflection and refraction.

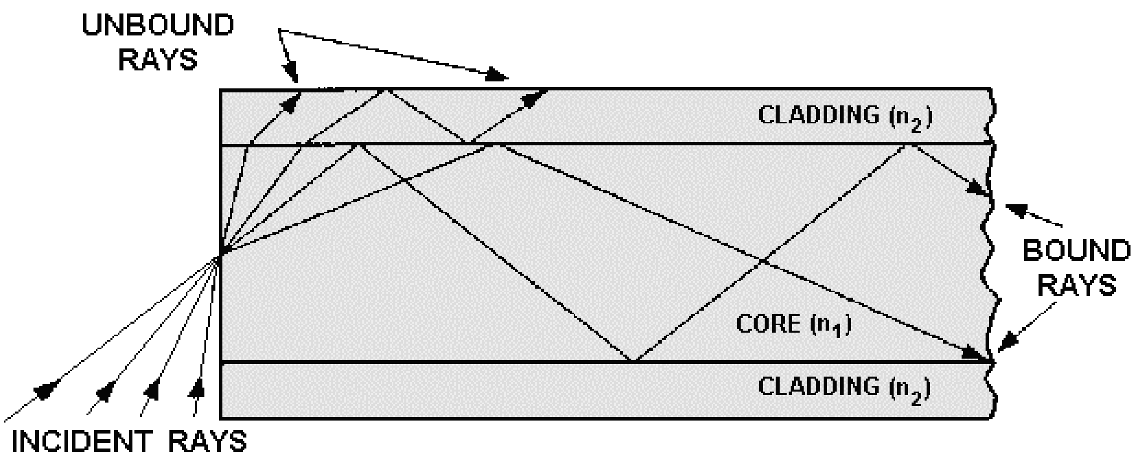

Figure 2-10.—Bound and unbound rays in a step-index fiber.

It is known that bound rays propagate in fibers due to total internal reflection, but how do these light rays enter the fiber? Rays that enter the fiber must intersect the core-cladding interface at an angle greater than the critical angle (θ_c). Only those rays that enter the fiber and strike the interface at these angles will propagate along the fiber.

How a light ray is launched into a fiber is shown in figure 2-11. The incident ray I_1 enters the fiber at the angle θ_a. I_1 is refracted upon entering the fiber and is transmitted to the core-cladding interface. The ray then strikes the core-cladding interface at the critical angle (θ_c). I_1 is totally reflected back into the core and continues to propagate along the fiber. The incident ray I_2 enters the fiber at an angle greater than θ_a. Again, I_2 is refracted upon entering the fiber and is transmitted to the core-cladding interface. I_2 strikes the core-cladding interface at an angle less than the critical angle (θ_c). I_2 is refracted into the cladding and is eventually lost. The light ray incident on the fiber core must be within the acceptance cone defined by the angle θ_a shown in figure 2-12. Angle θ_a is defined as the acceptance angle. The acceptance angle (θ_a) is the maximum angle to the axis of the fiber that light entering the fiber is propagated. The value of the angle of acceptance (¯ $_a$) depends on fiber properties and transmission conditions.

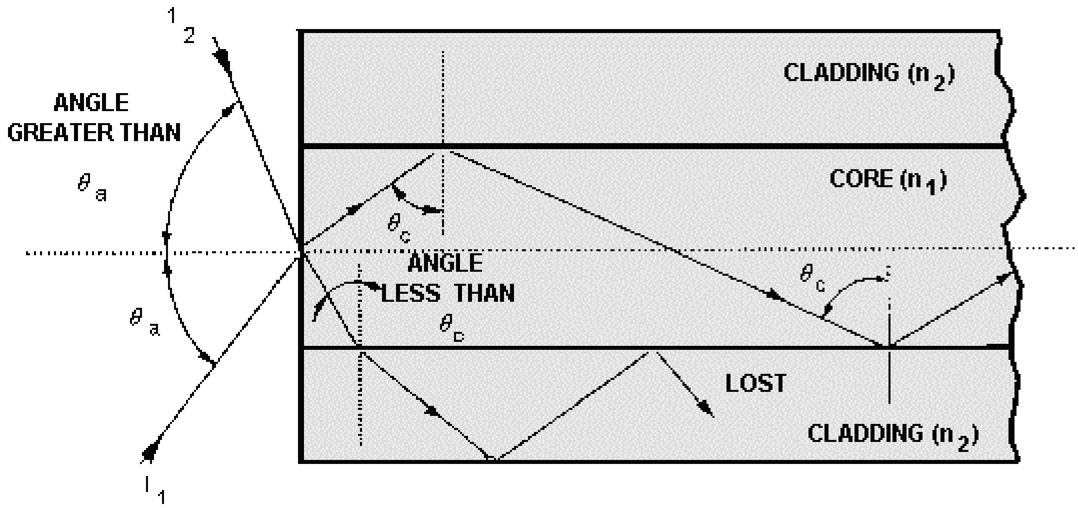

Figure 2-11.—How a light ray enters an optical fiber.

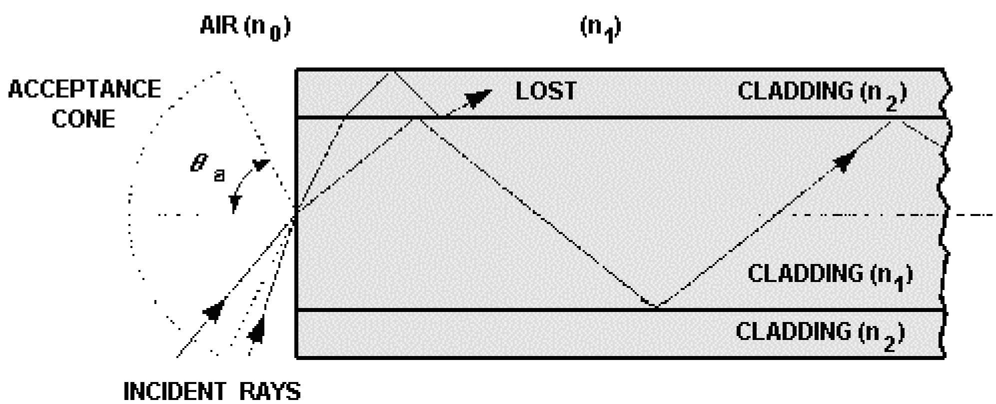

Figure 2-12.—Fiber acceptance angle.

The acceptance angle is related to the refractive indices of the core, cladding, and medium surrounding the fiber. This relationship is called the numerical aperture of the fiber. The numerical aperture (NA) is a measurement of the ability of an optical fiber to capture light. The NA is also used to define the acceptance cone of an optical fiber.

Figure 2-12 illustrates the relationship between the acceptance angle and the refractive indices. The index of refraction of the fiber core is n_1. The index of refraction of the fiber cladding is n_2. The index of refraction of the surrounding medium is n_0. By using Snell's law and basic trigonometric relationships, the NA of the fiber is given by:

$$NA = n_0 \times \sin\Theta_a = (n_1^2 - n_2^2)^{\frac{1}{2}}$$

Since the medium next to the fiber at the launching point is normally air, n_0 is equal to 1.00. The NA is then simply equal to sin ¯ $_a$.

The NA is a convenient way to measure the light-gathering ability of an optical fiber. It is used to measure source-to-fiber power-coupling efficiencies. A high NA indicates a high source-to-fiber coupling efficiency. Source-to-fiber coupling efficiency is described in chapter 6. Typical values of NA range from 0.20 to 0.29 for glass fibers. Plastic fibers generally have a higher NA. An NA for plastic fibers can be higher than 0.50.

In addition, the NA is commonly used to specify multimode fibers. However, for small core diameters, such as in single mode fibers, the ray theory breaks down. Ray theory describes only the direction a plane wave takes in a fiber. Ray theory eliminates any properties of the plane wave that interfere with the transmission of light along a fiber. In reality, plane waves interfere with each other. Therefore, only certain types of rays are able to propagate in an optical fiber. Optical fibers can support only a specific number of guided modes. In small core fibers, the number of modes supported is one or only a few modes. Mode theory is used to describe the types of plane waves able to propagate along an optical fiber.

SKEW RAYS.—A possible path of propagation of skew rays is shown in figure 2-13. Figure 2-13, view A, provides an angled view and view B provides a front view. Skew rays propagate without passing through the center axis of the fiber. The acceptance angle for skew rays is larger than the acceptance angle of meridional rays. This condition explains why skew rays outnumber meridional rays. Skew rays are often used in the calculation of light acceptance in an optical fiber. The addition of skew rays increases the amount of light capacity of a fiber. In large NA fibers, the increase may be significant.

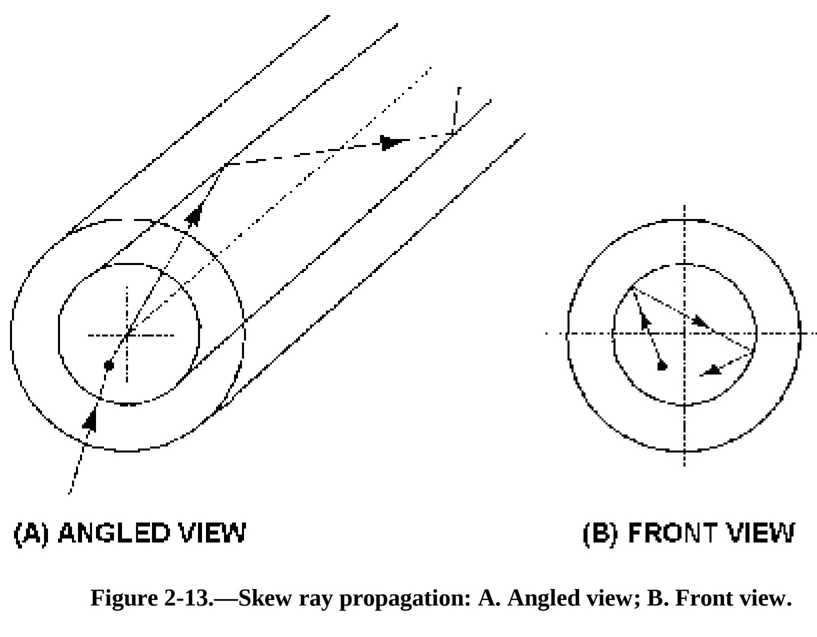

Figure 2-13.—Skew ray propagation: A. Angled view; B. Front view.

The addition of skew rays also increases the amount of loss in a fiber. Skew rays tend to propagate near the edge of the fiber core. A large portion of the number of skew rays that are trapped in the fiber core are considered to be leaky rays. Leaky rays are predicted to be totally reflected at the core-cladding boundary. However, these rays are partially refracted because of the curved nature of the fiber boundary. Mode theory is also used to describe this type of leaky ray loss.

Q22. Meridional rays are classified as either bound or unbound rays. Bound rays propagate through the fiber according to what property?

Q23. A light ray incident on the optical fiber core is propagated along the fiber. Is the angle of incidence of the light ray entering the fiber larger or smaller than the acceptance angle (Θ_a)

Q24. What fiber property does numerical aperture (NA) measure?

Q25. Skew rays and meridional rays define different acceptance angles. Which acceptance angle is larger, the skew ray angle or the meridional ray angle?

Mode Theory

The mode theory, along with the ray theory, is used to describe the propagation of light along an optical fiber. The mode theory is used to describe the properties of light that ray theory is unable to explain. The mode theory uses electromagnetic wave behavior to describe the propagation of light along a fiber. A set of guided electromagnetic waves is called the modes of the fiber.

Q26. The mode theory uses electromagnetic wave behavior to describe the propagation of the light along the fiber. What is a set of guided electromagnetic waves called?

PLANE WAVES.—The mode theory suggests that a light wave can be represented as a plane wave. A plane wave is described by its direction, amplitude, and wavelength of propagation. A plane wave is a wave whose surfaces of constant phase are infinite parallel planes normal to the direction of propagation. The planes having the same phase are called the wavefronts. The wavelength (λ) of the plane wave is given by:

$$\text{wavelength } (\lambda) = \frac{c}{fn}$$

where *c* is the speed of light in a vacuum, *f* is the frequency of the light, and n is the index of refraction of the plane-wave medium.

Figure 2-14 shows the direction and wavefronts of plane-wave propagation. Plane waves, or wavefronts, propagate along the fiber similar to light rays. However, not all wavefronts incident on the fiber at angles less than or equal to the critical angle of light acceptance propagate along the fiber. Wavefronts may undergo a change in phase that prevents the successful transfer of light along the fiber.

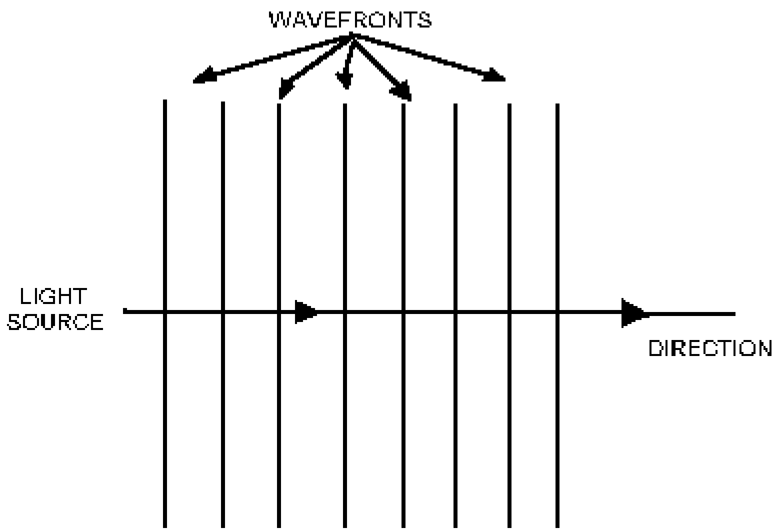

Figure 2-14.—Plane-wave propagation.

Wavefronts are required to remain in phase for light to be transmitted along the fiber. Consider the wavefront incident on the core of an optical fiber as shown in figure 2-15. Only those wavefronts incident on the fiber at angles less than or equal to the critical angle may propagate along the fiber. The wavefront undergoes a gradual phase change as it travels down the fiber. Phase changes also occur when the wavefront is reflected. The wavefront must remain in phase after the wavefront transverses the fiber twice and is reflected twice. The distance transversed is shown between point A and point B on figure 2-15. The reflected waves at point A and point B are in phase if the total amount of phase collected is an integer multiple of 2π radian. If propagating wavefronts are not in phase, they eventually disappear. Wavefronts disappear because of destructive interference. The wavefronts that are in phase interfere with the wavefronts that are out of phase. This interference is the reason why only a finite number of modes can propagate along the fiber.

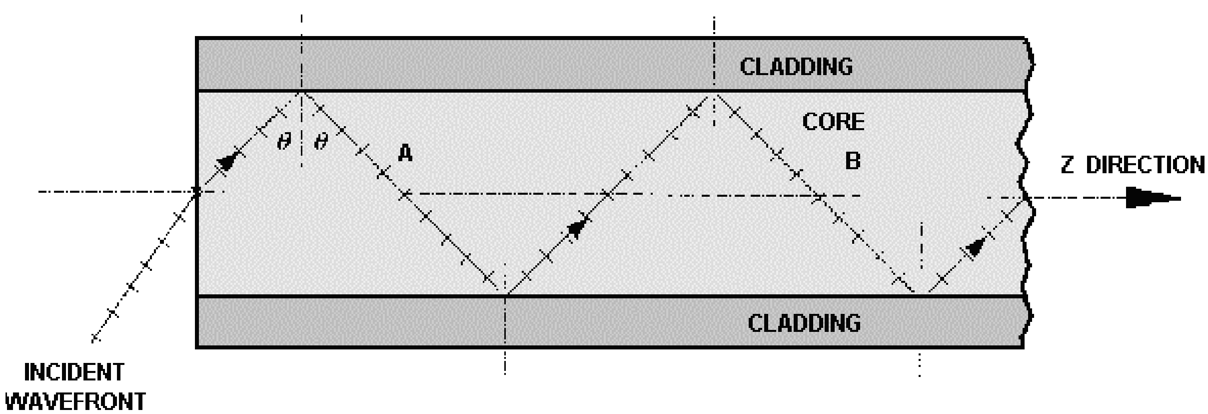

Figure 2-15.—Wavefront propagation along an optical fiber.

The plane waves repeat as they travel along the fiber axis. The direction the plane waves travel is assumed to be the z direction as shown in figure 2-15. The plane waves repeat at a distance equal to λ/sin¯ . Plane waves also repeat at a periodic frequency $\beta = 2\pi$ sin ¯ /λ. The quantity β is defined as the propagation constant along the fiber axis. As the wavelength (λ) changes, the value of the propagation constant must also change. For a given mode, a change in wavelength can prevent the mode from propagating along the fiber. The mode is no longer bound to the fiber. The mode is said to be cut off. Modes that are bound at one wavelength may not exist at longer wavelengths. The wavelength at which a mode ceases to be bound is called the cutoff wavelength for that mode. However, an optical fiber is always able to propagate at least one mode. This mode is referred to as the fundamental mode of the fiber. The fundamental mode can never be cut off. The wavelength that prevents the next higher mode from propagating is called the cutoff wavelength of the fiber. An optical fiber that operates above the cutoff wavelength (at a longer wavelength) is called a single mode fiber. An optical fiber that operates below the cutoff wavelength is called a multimode fiber. Single mode and multimode optical fibers are discussed later in this chapter.

In a fiber, the propagation constant of a plane wave is a function of the wave's wavelength and mode. The change in the propagation constant for different waves is called dispersion. The change in the propagation constant for different wavelengths is called chromatic dispersion. The change in propagation constant for different modes is called modal dispersion. These dispersions cause the light pulse to spread as it goes down the fiber (fig. 2-16). Some dispersion occurs in all types of fibers. Dispersion is discussed later in this chapter.

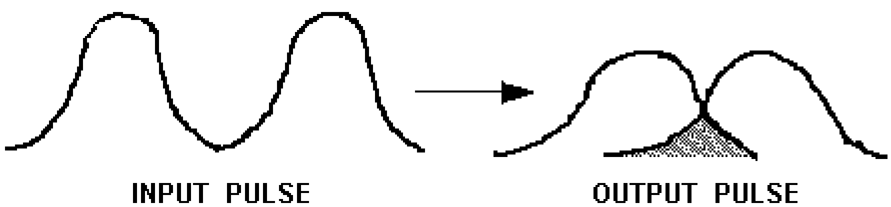

Figure 2-16.—The spreading of a light pulse.

MODES.—A set of guided electromagnetic waves is called the modes of an optical fiber. Maxwell's equations describe electromagnetic waves or modes as having two components. The two components are the electric field, E(x, y, z), and the magnetic field, H(x, y, z). The electric field, E, and the magnetic field, H, are at right angles to each other. Modes traveling in an optical fiber are said to be transverse. The transverse modes, shown in figure 2-17, propagate along the axis of the fiber. The mode field patterns shown in figure 2-17 are said to be transverse electric (TE). In TE modes, the electric field is perpendicular to the direction of propagation. The magnetic field is in the direction of propagation. Another type of transverse mode is the transverse magnetic (TM) mode. TM modes are opposite to TE modes. In TM modes, the magnetic field is perpendicular to the direction of propagation. The electric field is in the direction of propagation. Figure 2-17 shows only TE modes.

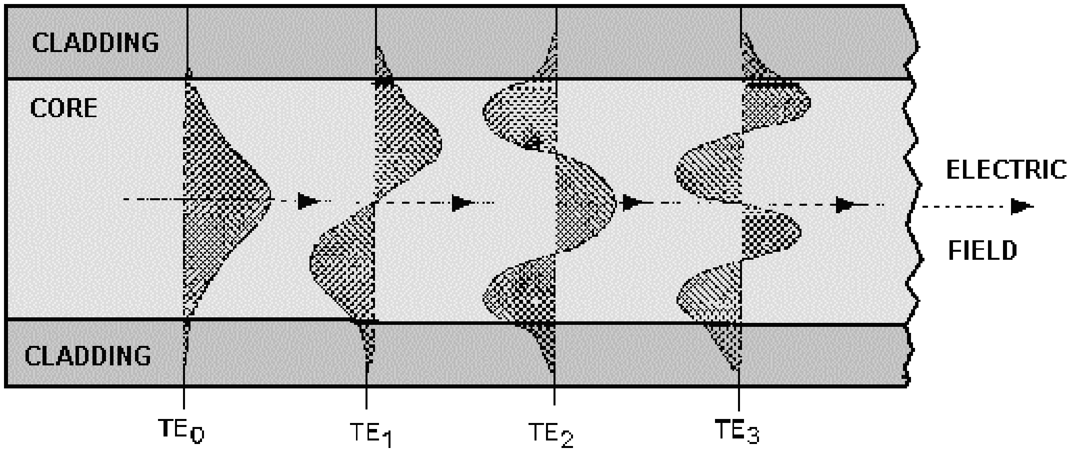

Figure 2-17.—Transverse electric (TE) mode field patterns.

The TE mode field patterns shown in figure 2-17 indicate the order of each mode. The order of each mode is indicated by the number of field maxima within the core of the fiber. For example, TE_0 has one field maxima. The electric field is a maximum at the center of the waveguide and decays toward the core-cladding boundary. TE_0 is considered the fundamental mode or the lowest order standing wave. As the number of field maxima increases, the order of the mode is higher. Generally, modes with more than a few (5-10) field maxima are referred to as high-order modes.

The order of the mode is also determined by the angle the wavefront makes with the axis of the fiber. Figure 2-18 illustrates light rays as they travel down the fiber. These light rays indicate the direction of the wavefronts. High-order modes cross the axis of the fiber at steeper angles. Low-order and high-order modes are shown in figure 2-18.

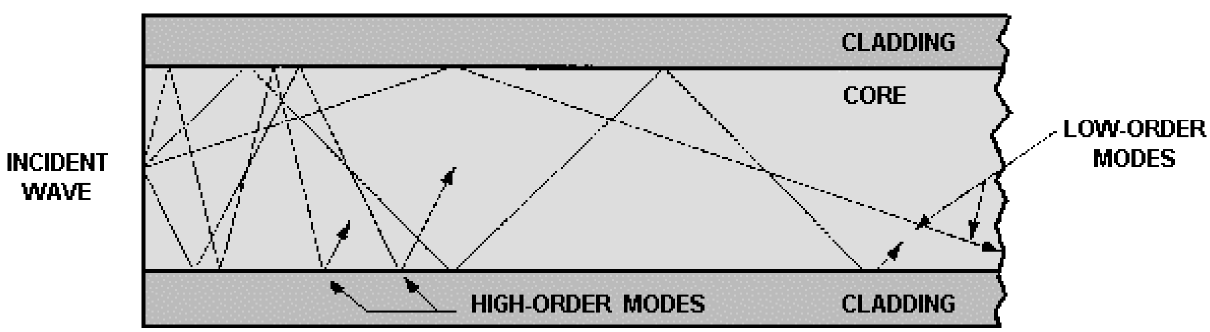

Figure 2-18.—Low-order and high-order modes.

Before we progress, let us refer back to figure 2-17. Notice that the modes are not confined to the core of the fiber. The modes extend partially into the cladding material. Low-order modes penetrate the cladding only slightly. In low-order modes, the electric and magnetic fields are concentrated near the center of the fiber. However, high-order modes penetrate further into the cladding material. In high-order modes, the electrical and magnetic fields are distributed more toward the outer edges of the fiber.

This penetration of low-order and high-order modes into the cladding region indicates that some portion is refracted out of the core. The refracted modes may become trapped in the cladding due to the dimension of the cladding region. The modes trapped in the cladding region are called cladding modes. As the core and the cladding modes travel along the fiber, mode coupling occurs. Mode coupling is the exchange of power between two modes. Mode coupling to the cladding results in the loss of power from the core modes.

In addition to bound and refracted modes, there are leaky modes. Leaky modes are similar to leaky rays. Leaky modes lose power as they propagate along the fiber. For a mode to remain within the core, the mode must meet certain boundary conditions. A mode remains bound if the propagation constant β meets the following boundary condition:

$$\frac{2\pi n_2}{\lambda} < \beta < \frac{2\pi n_1}{\lambda}$$

where n_1 and n_2 are the index of refraction for the core and the cladding, respectively. When the propagation constant becomes smaller than $2\pi n_2/\lambda$, power leaks out of the core and into the cladding. Generally, modes leaked into the cladding are lost in a few centimeters. However, leaky modes can carry a large amount of power in short fibers.

NORMALIZED FREQUENCY.—Electromagnetic waves bound to an optical fiber are described by the fiber's normalized frequency. The normalized frequency determines how many modes a fiber can support. Normalized frequency is a dimensionless quantity. Normalized frequency is also related to the fiber's cutoff wavelength. Normalized frequency (V) is defined as:

$$V = \frac{2\pi a}{\lambda}(n_1^2 - n_2^2)^{\frac{1}{2}}$$

where n_1 is the core index of refraction, n_2 is the cladding index of refraction, *a* is the core diameter, and λ is the wavelength of light in air.

The number of modes that can exist in a fiber is a function of V. As the value of V increases, the number of modes supported by the fiber increases. Optical fibers, single mode and multimode, can support a different number of modes. The number of modes supported by single mode and multimode fiber types is discussed later in this chapter.

Q27. A light wave can be represented as a plane wave. What three properties of light propagation describe a plane wave?

Q28. A wavefront undergoes a phase change as it travels along the fiber. If the wavefront transverses the fiber twice and is reflected twice and the total phase change is equal to 1/2π, will the wavefront disappear? If yes, why?

Q29. Modes that are bound at one wavelength may not exist at longer wavelengths. What is the wavelength at which a mode ceases to be bound called?

Q30. What type of optical fiber operates below the cutoff wavelength?

Q31. Low-order and high-order modes propagate along an optical fiber. How are modes determined to be low-order or high-order modes?

Q32. As the core and cladding modes travel along the fiber, mode coupling occurs. What is mode coupling?

Q33. The fiber's normalized frequency (V) determines how many modes a fiber can support. As the value of V increases, will the number of modes supported by the fiber increase or decrease?

OPTICAL FIBER TYPES

Optical fibers are characterized by their structure and by their properties of transmission. Basically, optical fibers are classified into two types. The first type is single mode fibers. The second type is multimode fibers. As each name implies, optical fibers are classified by the number of modes that propagate along the fiber. As previously explained, the structure of the fiber can permit or restrict modes from propagating in a fiber. The basic structural difference is the core size. Single mode fibers are manufactured with the same materials as multimode fibers. Single mode fibers are also manufactured by following the same fabrication process as multimode fibers.

Single Mode Fibers

The core size of single mode fibers is small. The core size (diameter) is typically around 8 to 10 micrometers (¯m). A fiber core of this size allows only the fundamental or lowest order mode to propagate around a 1300 nanometer (nm) wavelength. Single mode fibers propagate only one mode, because the core size approaches the operational wavelength (λ). The value of the normalized frequency parameter (V) relates core size with mode propagation. In single mode fibers, V is less than or equal to 2.405. When V ¯ 2.405, single mode fibers propagate the fundamental mode down the fiber core, while high-order modes are lost in the cladding. For low V values (¯1.0), most of the power is propagated in the cladding material. Power transmitted by the cladding is easily lost at fiber bends. The value of V should remain near the 2.405 level.

Single mode fibers have a lower signal loss and a higher information capacity (bandwidth) than multimode fibers. Single mode fibers are capable of transferring higher amounts of data due to low fiber dispersion. Basically, dispersion is the spreading of light as light propagates along a fiber. Dispersion mechanisms in single mode fibers are discussed in more detail later in this chapter. Signal loss depends on the operational wavelength (λ). In single mode fibers, the wavelength can increase or decrease the losses caused by fiber bending. Single mode fibers operating at wavelengths larger than the cutoff wavelength lose more power at fiber bends. They lose power because light radiates into the cladding, which is lost at fiber bends. In general, single mode fibers are considered to be low-loss fibers, which increase system bandwidth and length.

Q34. The value of the normalized frequency parameter (V) relates the core size with mode propagation. When single mode fibers propagate only the fundamental mode, what is the value of V?

Multimode Fibers

As their name implies, multimode fibers propagate more than one mode. Multimode fibers can propagate over 100 modes. The number of modes propagated depends on the core size and numerical aperture (NA). As the core size and NA increase, the number of modes increases. Typical values of fiber core size and NA are 50 to 100 ¯m and 0.20 to 0.29, respectively.

A large core size and a higher NA have several advantages. Light is launched into a multimode fiber with more ease. The higher NA and the larger core size make it easier to make fiber connections. During fiber splicing, core-to-core alignment becomes less critical. Another advantage is that multimode fibers permit the use of light-emitting diodes (LEDs). Single mode fibers typically must use laser diodes. LEDs are cheaper, less complex, and last longer. LEDs are preferred for most applications.

Multimode fibers also have some disadvantages. As the number of modes increases, the effect of modal dispersion increases. Modal dispersion (intermodal dispersion) means that modes arrive at the fiber end at slightly different times. This time difference causes the light pulse to spread. Modal dispersion affects system bandwidth. Fiber manufacturers adjust the core diameter, NA, and index profile properties of multimode fibers to maximize system bandwidth.

Q35. The number of modes propagated in a multimode fiber depends on core size and numerical aperture (NA). If the core size and the NA decrease, will the number of modes propagated increase or decrease?

Q36. Modal dispersion affects the bandwidth of multimode systems. It is essential to adjust what three fiber properties to maximize system bandwidth?

PROPERTIES OF OPTICAL FIBER TRANSMISSION

The principles behind the transfer of light along an optical fiber were discussed earlier in this chapter. You learned that propagation of light depended on the nature of light and the structure of the optical fiber. However, our discussion did not describe how optical fibers affect system performance. In this case, system performance deals with signal loss and bandwidth.

Signal loss and system bandwidth describe the amount of data transmitted over a specified length of fiber. Many optical fiber properties increase signal loss and reduce system bandwidth. The most important properties that affect system performance are fiber attenuation and dispersion.

Attenuation reduces the amount of optical power transmitted by the fiber. Attenuation controls the distance an optical signal (pulse) can travel as shown in figure 2-19. Once the power of an optical pulse is reduced to a point where the receiver is unable to detect the pulse, an error occurs. Attenuation is mainly a result of **light absorption, scattering**, and **bending losses**. Dispersion spreads the optical pulse as it travels along the fiber. This spreading of the signal pulse reduces the system bandwidth or the information-carrying capacity of the fiber. Dispersion limits how fast information is transferred as shown in figure 2-19. An error occurs when the receiver is unable to distinguish between input pulses caused by the spreading of each pulse. The effects of attenuation and dispersion increase as the pulse travels the length of the fiber as shown in figure 2-20.

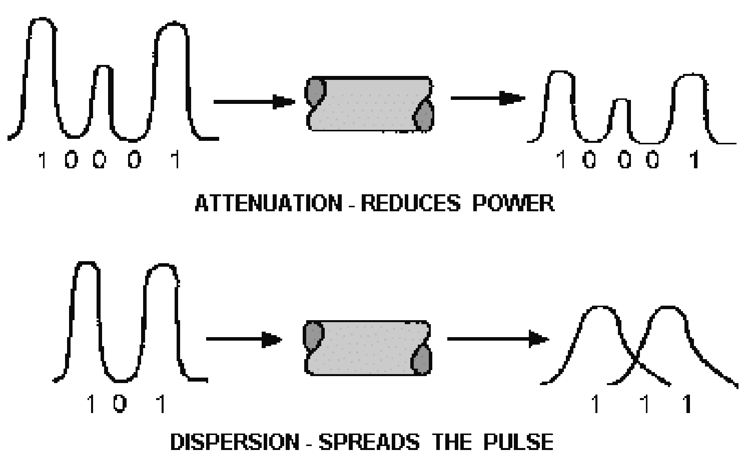

Figure 2-19.—Fiber transmission properties.

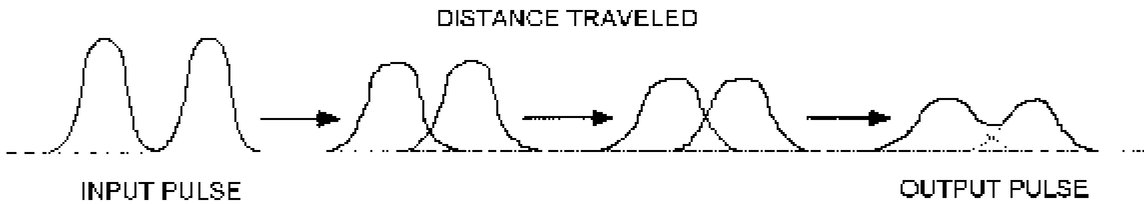

Figure 2-20.—Pulse spreading and power loss along an optical fiber.

In addition to fiber attenuation and dispersion, other optical fiber properties affect system performance. Fiber properties, such as modal noise, pulse broadening, and polarization, can reduce system performance. Modal noise, pulse broadening, and polarization are too complex to discuss as introductory level material. However, you should be aware that attenuation and dispersion are not the only fiber properties that affect performance.

Q37. Attenuation is mainly a result of what three properties?

Attenuation

Attenuation in an optical fiber is caused by absorption, scattering, and bending losses. **Attenuation** is the loss of optical power as light travels along the fiber. Signal attenuation is defined as the ratio of optical input power (P_i) to the optical output power (P_o). Optical input power is the power injected into the fiber from an optical source. Optical output power is the power received at the fiber end or optical detector. The following equation defines signal attenuation as a unit of length:

$$\text{attenuation} = \left(\frac{10}{L}\right)\log_{10}\left(\frac{P_i}{P_o}\right)$$

Signal attenuation is a log relationship. Length (L) is expressed in kilometers. Therefore, the unit of attenuation is decibels/kilometer (dB/km).

As previously stated, attenuation is caused by absorption, scattering, and bending losses. Each mechanism of loss is influenced by fiber-material properties and fiber structure. However, loss is also present at fiber connections. Fiber connector, splice, and coupler losses are discussed in chapter 4. The present discussion remains relative to optical fiber attenuation properties.

Q38. Define attenuation.

ABSORPTION.—Absorption is a major cause of signal loss in an optical fiber. **Absorption** is defined as the portion of attenuation resulting from the conversion of optical power into another energy form, such as heat. Absorption in optical fibers is explained by three factors:

- Imperfections in the atomic structure of the fiber material
- The intrinsic or basic fiber-material properties
- The extrinsic (presence of impurities) fiber-material properties

Imperfections in the atomic structure induce absorption by the presence of missing molecules or oxygen defects. Absorption is also induced by the diffusion of hydrogen molecules into the glass fiber. Since intrinsic and extrinsic material properties are the main cause of absorption, they are discussed further.

Intrinsic Absorption.—Intrinsic absorption is caused by basic fiber-material properties. If an optical fiber were absolutely pure, with no imperfections or impurities, then all absorption would be intrinsic. Intrinsic absorption sets the minimal level of absorption. In fiber optics, silica (pure glass) fibers are used predominately. Silica fibers are used because of their low intrinsic material absorption at the wavelengths of operation.

In silica glass, the wavelengths of operation range from 700 nanometers (nm) to 1600 nm. Figure 2-21 shows the level of attenuation at the wavelengths of operation. This wavelength of operation is between two intrinsic absorption regions. The first region is the ultraviolet region (below 400-nm wavelength). The second region is the infrared region (above 2000-nm wavelength).

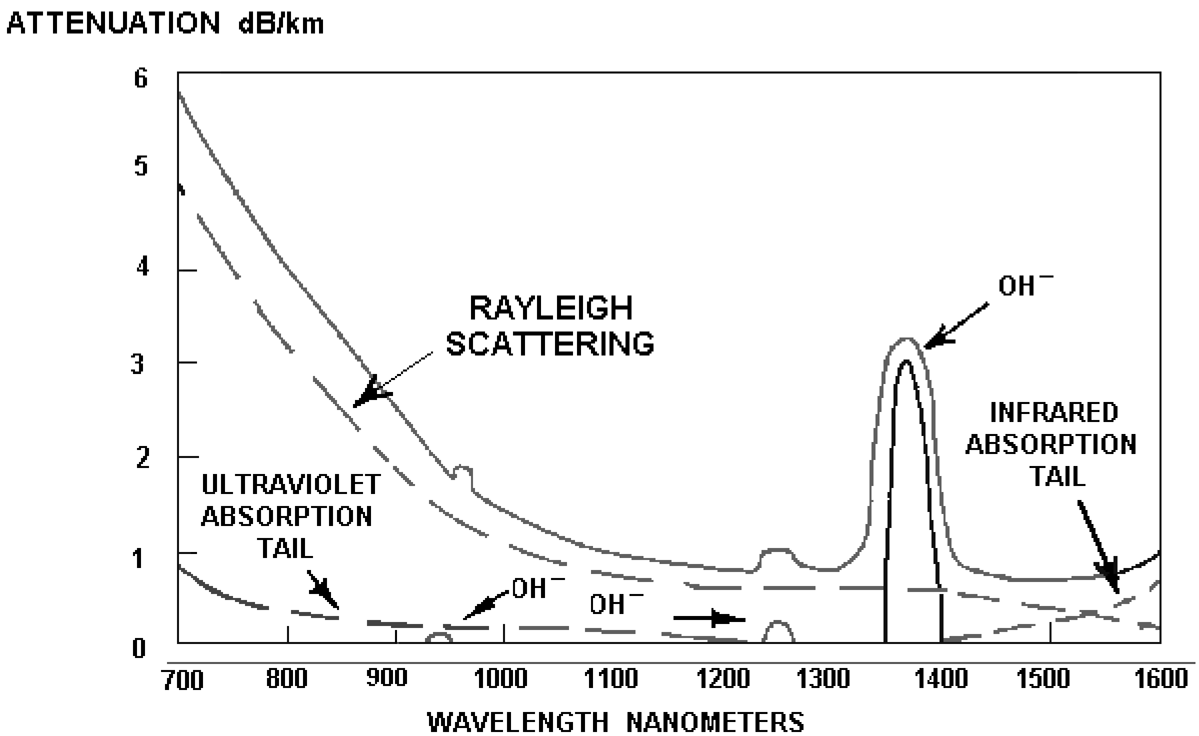

Figure 2-21.—Fiber losses.

Intrinsic absorption in the ultraviolet region is caused by electronic absorption bands. Basically, absorption occurs when a light particle (photon) interacts with an electron and excites it to a higher energy level. The tail of the ultraviolet absorption band is shown in figure 2-21.

The main cause of intrinsic absorption in the infrared region is the characteristic vibration frequency of atomic bonds. In silica glass, absorption is caused by the vibration of silicon-oxygen (Si-O) bonds. The interaction between the vibrating bond and the electromagnetic field of the optical signal causes intrinsic absorption. Light energy is transferred from the electromagnetic field to the bond. The tail of the infrared absorption band is shown in figure 2-21.

Extrinsic Absorption.—Extrinsic absorption is caused by impurities introduced into the fiber material. Trace metal impurities, such as iron, nickel, and chromium, are introduced into the fiber during fabrication. **Extrinsic absorption** is caused by the electronic transition of these metal ions from one energy level to another.

Extrinsic absorption also occurs when hydroxyl ions (OH^-) are introduced into the fiber. Water in silica glass forms a silicon-hydroxyl (Si-OH) bond. This bond has a fundamental absorption at 2700 nm. However, the harmonics or overtones of the fundamental absorption occur in the region of operation. These harmonics increase extrinsic absorption at 1383 nm, 1250 nm, and 950 nm. Figure 2-21 shows the presence of the three OH^- harmonics. The level of the OH^- harmonic absorption is also indicated.

These absorption peaks define three regions or windows of preferred operation. The first window is centered at 850 nm. The second window is centered at 1300 nm. The third window is centered at 1550 nm. Fiber optic systems operate at wavelengths defined by one of these windows.

The amount of water (OH^-) impurities present in a fiber should be less than a few parts per billion. Fiber attenuation caused by extrinsic absorption is affected by the level of impurities (OH^-) present in the fiber. If the amount of impurities in a fiber is reduced, then fiber attenuation is reduced.

Q39. What are the main causes of absorption in optical fiber?

Q40. Silica (pure glass) fibers are used because of their low intrinsic material absorption at the wavelengths of operation. This wavelength of operation is between two intrinsic absorption regions. What are these two regions called? What are the wavelengths of operation for these two regions?

Q41. Extrinsic (OH^-) absorption peaks define three regions or windows of preferred operation. List the three windows of operation.

SCATTERING.—Basically, scattering losses are caused by the interaction of light with density fluctuations within a fiber. Density changes are produced when optical fibers are manufactured. During manufacturing, regions of higher and lower molecular density areas, relative to the average density of the fiber, are created. Light traveling through the fiber interacts with the density areas as shown in figure 2-22. Light is then partially scattered in all directions.

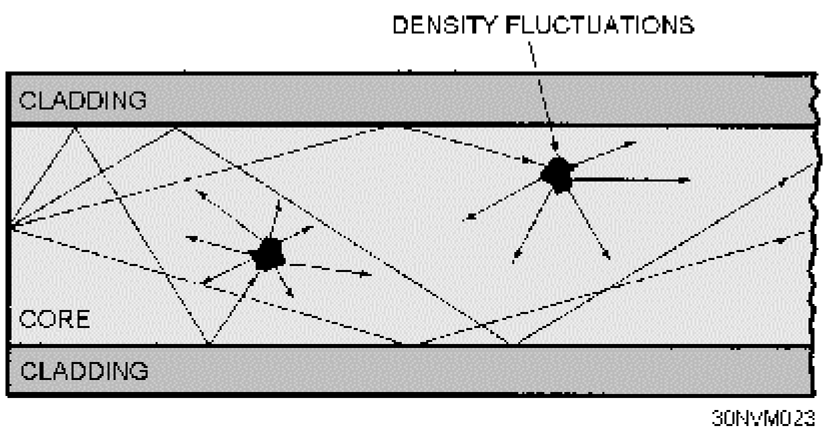

Figure 2-22.—Light scattering.

In commercial fibers operating between 700-nm and 1600-nm wavelength, the main source of loss is called Rayleigh scattering. Rayleigh scattering is the main loss mechanism between the ultraviolet and infrared regions as shown in figure 2-21. Rayleigh scattering occurs when the size of the density fluctuation (fiber defect) is less than one-tenth of the operating wavelength of light. Loss caused by Rayleigh scattering is proportional to the fourth power of the wavelength ($1/\lambda^4$). As the wavelength increases, the loss caused by Rayleigh scattering decreases.

If the size of the defect is greater than one-tenth of the wavelength of light, the scattering mechanism is called Mie scattering. Mie scattering, caused by these large defects in the fiber core, scatters light out of the fiber core. However, in commercial fibers, the effects of Mie scattering are insignificant. Optical fibers are manufactured with very few large defects.

Q42. What is the main loss mechanism between the ultraviolet and infrared absorption regions?

Q43. Scattering losses are caused by the interaction of light with density fluctuations within a fiber. What are the two scattering mechanisms called when the size of the density fluctuations is (a) greater than and (b) less than one-tenth of the operating wavelength?

BENDING LOSS.—Bending the fiber also causes attenuation. Bending loss is classified according to the bend radius of curvature: microbend loss or macrobend loss. Microbends are small microscopic bends of the fiber axis that occur mainly when a fiber is cabled. Macrobends are bends having a large radius of curvature relative to the fiber diameter. Microbend and macrobend losses are very important loss mechanisms. Fiber loss caused by microbending can still occur even if the fiber is cabled correctly. During installation, if fibers are bent too sharply, macrobend losses will occur.

Microbend losses are caused by small discontinuities or imperfections in the fiber. Uneven coating applications and improper cabling procedures increase microbend loss. External forces are also a source of microbends. An external force deforms the cabled jacket surrounding the fiber but causes only a small bend in the fiber. Microbends change the path that propagating modes take, as shown in figure 2-23. Microbend loss increases attenuation because low-order modes become coupled with high-order modes that are naturally lossy.

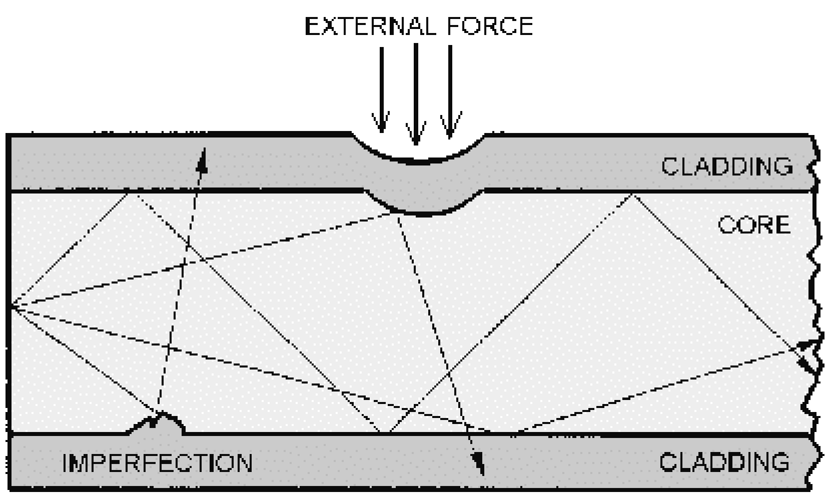

Figure 2-23.—Microbend loss.

Macrobend losses are observed when a fiber bend's radius of curvature is large compared to the fiber diameter. These bends become a great source of loss when the radius of curvature is less than several centimeters. Light propagating at the inner side of the bend travels a shorter distance than that on the outer side. To maintain the phase of the light wave, the mode phase velocity must increase. When the fiber bend is less than some critical radius, the mode phase velocity must increase to a speed greater than the speed of light. However, it is impossible to exceed the speed of light. This condition causes some of the light within the fiber to be converted to high-order modes. These high-order modes are then lost or radiated out of the fiber.

Fiber sensitivity to bending losses can be reduced. If the refractive index of the core is increased, then fiber sensitivity decreases. Sensitivity also decreases as the diameter of the overall fiber increases. However, increases in the fiber core diameter increase fiber sensitivity. Fibers with larger core size propagate more modes. These additional modes tend to be more lossy.

Q44. Microbend loss is caused by microscopic bends of the fiber axis. List three sources of microbend loss.

Q45. How is fiber sensitivity to bending losses reduced?

DISPERSION

There are two different types of dispersion in optical fibers. The types are intramodal and intermodal dispersion. Intramodal, or chromatic, dispersion occurs in all types of fibers. Intermodal, or modal, dispersion occurs only in multimode fibers. Each type of dispersion mechanism leads to pulse spreading. As a pulse spreads, energy is overlapped. This condition is shown in figure 2-24. The spreading of the optical pulse as it travels along the fiber limits the information capacity of the fiber.

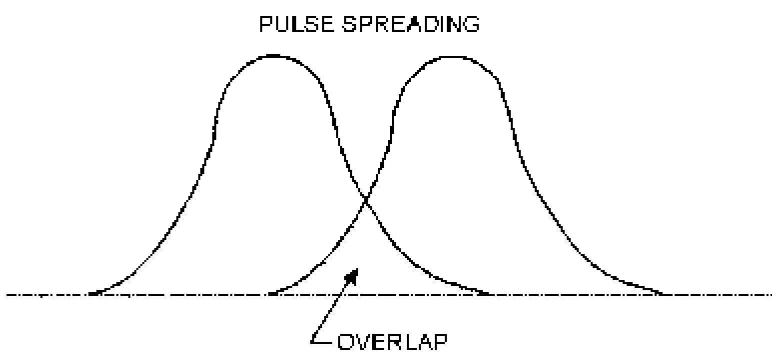

Figure 2-24.—Pulse overlap.

Intramodal Dispersion

Intramodal, or chromatic, dispersion depends primarily on fiber materials. There are two types of intramodal dispersion. The first type is material dispersion. The second type is waveguide dispersion. Intramodal dispersion occurs because different colors of light travel through different materials and different waveguide structures at different speeds.

Material dispersion occurs because the spreading of a light pulse is dependent on the wavelengths' interaction with the refractive index of the fiber core. Different wavelengths travel at different speeds in the fiber material. Different wavelengths of a light pulse that enter a fiber at one time exit the fiber at different times. Material dispersion is a function of the source spectral width. The spectral width specifies the range of wavelengths that can propagate in the fiber. Material dispersion is less at longer wavelengths.

Waveguide dispersion occurs because the mode propagation constant (β) is a function of the size of the fiber's core relative to the wavelength of operation. Waveguide dispersion also occurs because light propagates differently in the core than in the cladding.

In multimode fibers, waveguide dispersion and material dispersion are basically separate properties. Multimode waveguide dispersion is generally small compared to material dispersion. Waveguide dispersion is usually neglected. However, in single mode fibers, material and waveguide dispersion are interrelated. The total dispersion present in single mode fibers may be minimized by trading material and waveguide properties depending on the wavelength of operation.

Q46. Name the two types of intramodal, or chromatic, dispersion.

Q47. Which dispersion mechanism (material or waveguide) is a function of the size of the fiber's core relative to the wavelength of operation?

Intermodal Dispersion

Intermodal or modal dispersion causes the input light pulse to spread. The input light pulse is made up of a group of modes. As the modes propagate along the fiber, light energy distributed among the modes is delayed by different amounts. The pulse spreads because each mode propagates along the fiber at different speeds. Since modes travel in different directions, some modes travel longer distances. Modal dispersion occurs because each mode travels a different distance over the same time span, as shown in figure 2-25. The modes of a light pulse that enter the fiber at one time exit the fiber a different times. This condition causes the light pulse to spread. As the length of the fiber increases, modal dispersion increases.

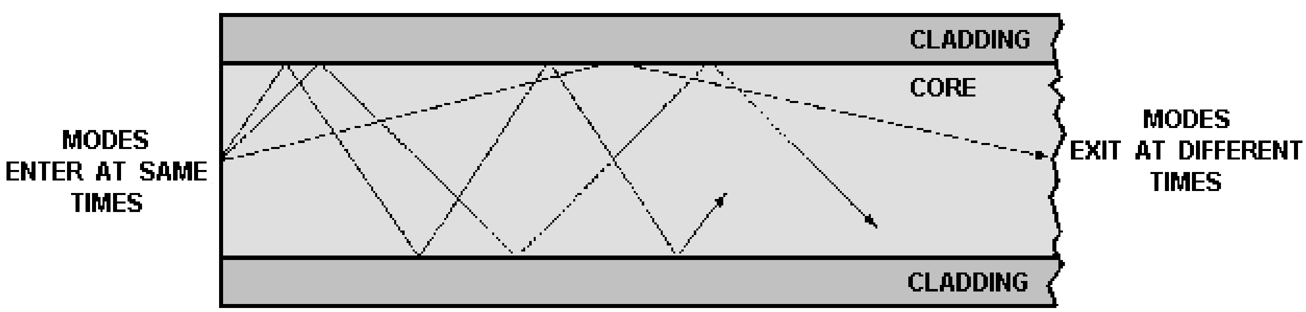

Figure 2-25.—Distance traveled by each mode over the same time span.

Modal dispersion is the dominant source of dispersion in multimode fibers. Modal dispersion does not exist in single mode fibers. Single mode fibers propagate only the fundamental mode. Therefore, single mode fibers exhibit the lowest amount of total dispersion. Single mode fibers also exhibit the highest possible bandwidth.

Q48. Modes of a light pulse that enter the fiber at one time exit the fiber at different times. This condition causes the light pulse to spread. What is this condition called?

SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas that you have learned. You should have a thorough understanding of these principles before moving on to chapter 3.

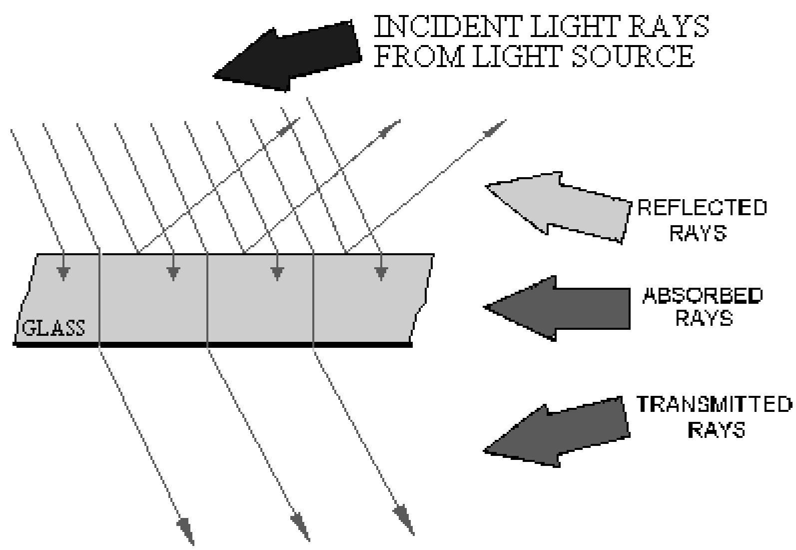
A **LIGHT WAVE** is a form of energy that is moved by wave motion.

WAVE MOTION is defined as a recurring disturbance advancing through space with or without the use of a physical medium.

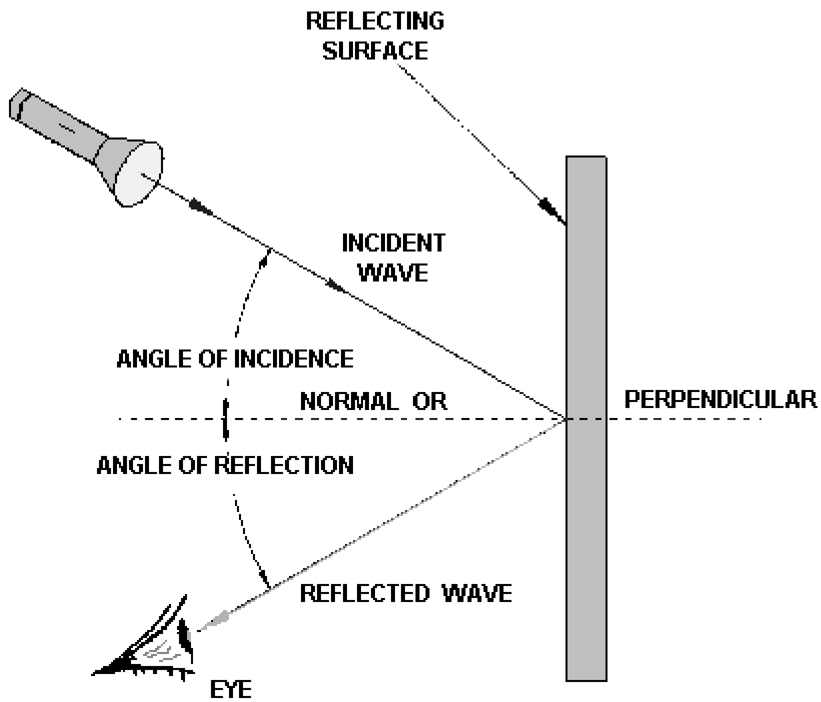
SCIENTIFIC EXPERIMENTS seem to show that light is composed of tiny particles, while other experiments indicate that light is made up of waves. Today, physicists have come to accept a theory concerning light that is a combination of particle (ray) theory and wave (mode) theory.

TRANSVERSE WAVE MOTION describes the up and down wave motion that is at right angle (transverse) to the outward motion of the waves.

LIGHT RAYS, when they encounter any substance, are either transmitted, refracted, reflected, or absorbed.

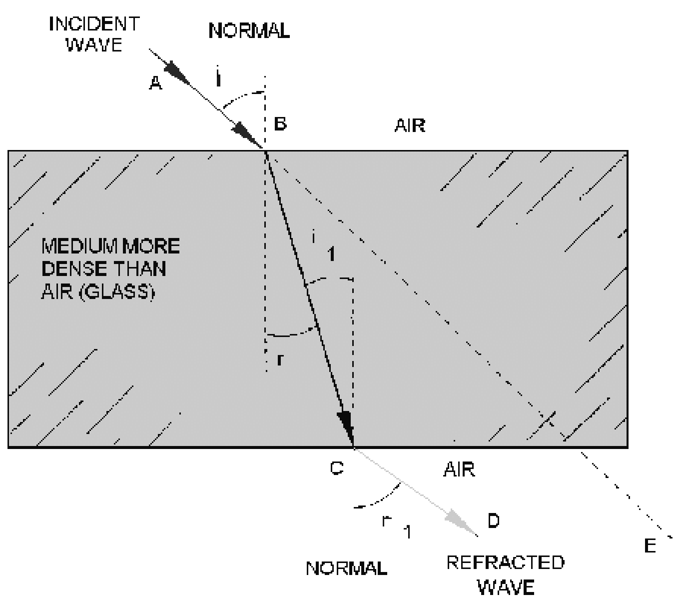


REFLECTION occurs when a wave strikes an object and bounces back (toward the source). The wave that moves from the source to the object is called the **incident wave**, and the wave that moves away from the object is called the **reflected wave**.



The **LAW OF REFLECTION** states that the angle of incidence is equal to the angle of reflection.

REFRACTION occurs when a wave traveling through two different mediums passes through the **boundary** of the mediums and bends toward or away from the **normal**.



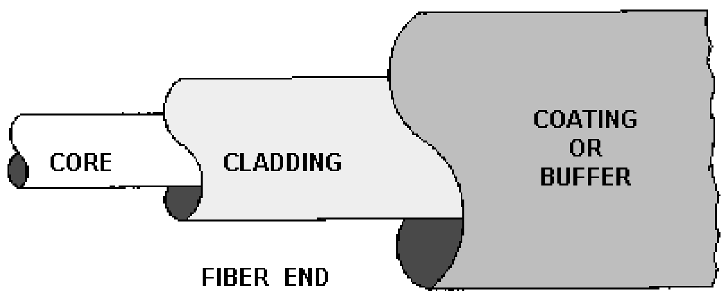
The **RAY THEORY** and the **MODE THEORY** describe how light energy is transmitted along an optical fiber.

The **INDEX OF REFRACTION** is the basic optical material property that measures the speed of light in an optical medium.

SNELL'S LAW OF REFRACTION describes the relationship between the incident and the refracted rays when light rays encounter the boundary between two different transparent materials.

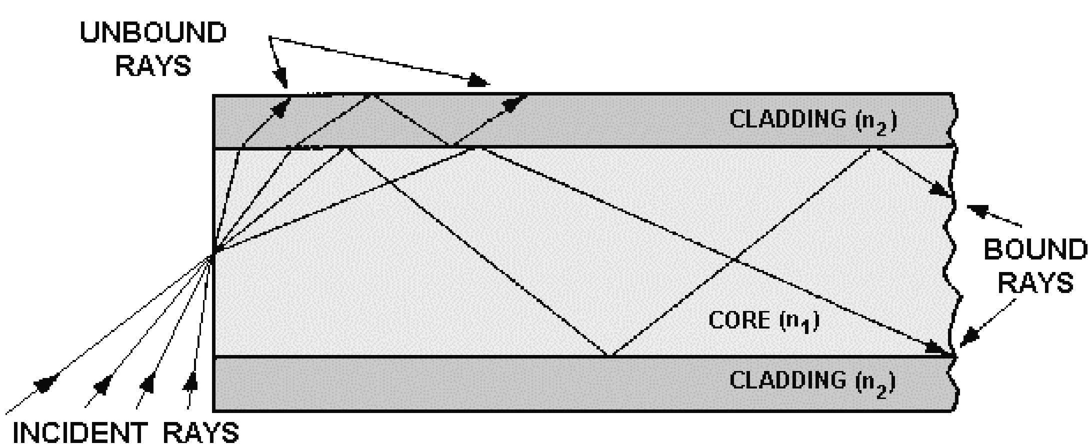
TOTAL INTERNAL REFLECTION occurs when light rays are totally reflected at the boundary between two different transparent materials. The angle at which total internal reflection occurs is called the **critical angle of incidence**.

The **CORE, CLADDING**, and **COATING** or **BUFFER** are the three basic parts of an optical fiber.

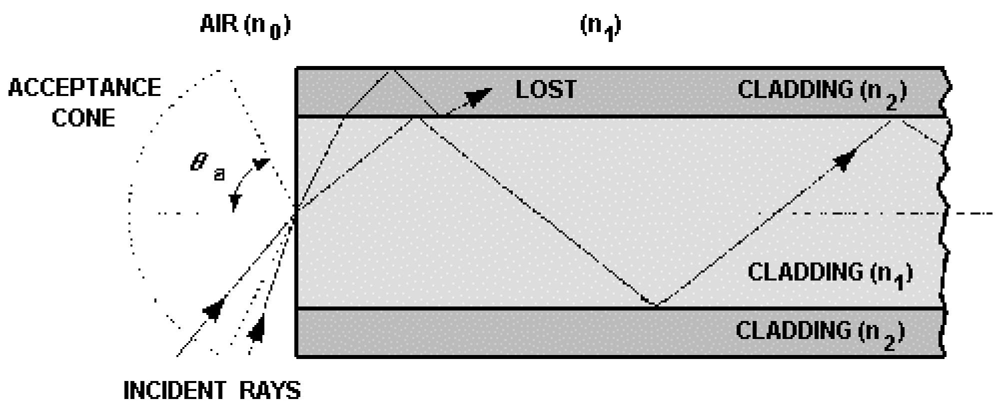


The **RAY THEORY** describes how light rays propagate along an optical fiber. **MERIDIONAL RAYS** pass through the axis of the optical fiber. **SKEW RAYS** propagate through an optical fiber without passing through its axis.

BOUND RAYS propagate through an optical fiber core by total internal reflection. **UNBOUND RAYS** refract out of the fiber core into the cladding and are eventually lost.



The **ACCEPTANCE ANGLE** is the maximum angle to the axis of the fiber that light entering the fiber is bound or propagated. The light ray incident on the fiber core must be within the acceptance cone defined by the acceptance angle to be propagated along an optical fiber.



NUMERICAL APERTURE (NA) is a measurement of the ability of an optical fiber to capture light.

The **MODE THEORY** uses electromagnetic wave behavior to describe the propagation of light along an optical fiber. A set of guided electromagnetic waves are called the **modes** of the fiber.

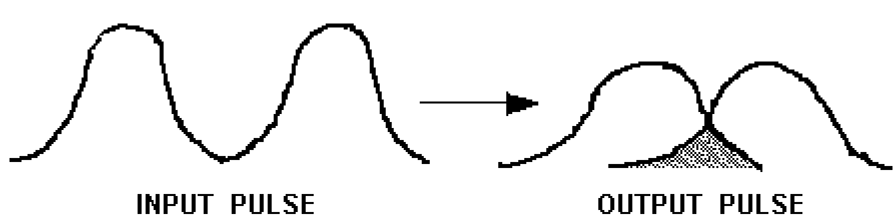
MODES traveling in an optical fiber are said to be transverse. Modes are described by their electric, E(x,y,z), and magnetic, H(x,y,z), fields. The electric field and magnetic field are at right angles to each other.

NORMALIZED FREQUENCY determines how many modes a fiber can support. The number of modes is represented by the normalized frequency constant.

SINGLE MODE and **MULTIMODE FIBERS** are classified by the number of modes that propagate along the optical fiber. Single mode fibers propagate only one mode because the core size approaches the operational wavelength. Multimode fibers can propagate over 100 modes depending on the core size and numerical aperture.

ATTENUATION is the loss of optical power as light travels along an optical fiber. Attenuation in an optical fiber is caused by absorption, scattering, and bending losses.

DISPERSION spreads the optical pulse as it travels along the fiber. Dispersion limits how fast information is transferred.

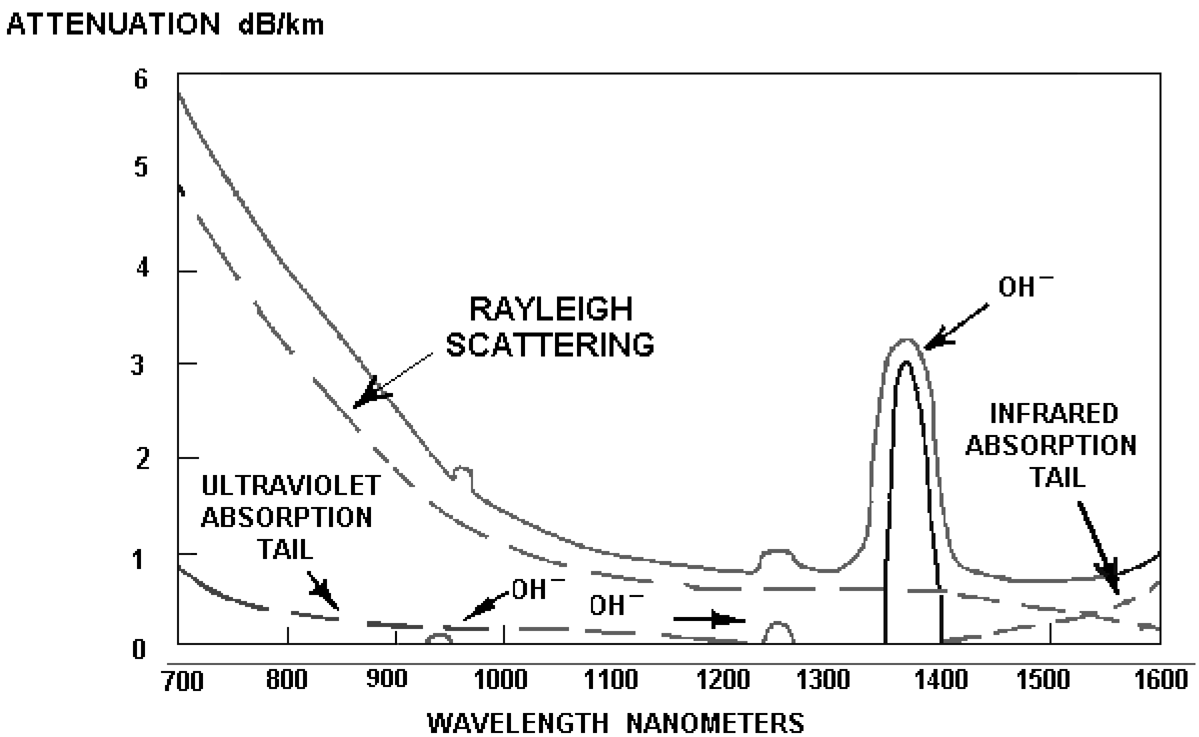


ABSORPTION is the conversion of optical power into another energy form, such as heat. **INTRINSIC ABSORPTION** is caused by basic fiber-material properties. **EXTRINSIC ABSORPTION** is caused by impurities introduced into the fiber material.

SILICA FIBERS are predominately used in fiber optic communications. They have low intrinsic material absorption at the wavelengths of operation.

The **WAVELENGTH OF OPERATION** in fiber optics is between 700 nm and 1600 nm. The wavelength of operation is between the ultraviolet (below 400 nm) and infrared (above 2000 nm) intrinsic absorption regions.

EXTRINSIC ABSORPTION occurs when impurities, such as hydroxyl ions (OH^-), are introduced into the fiber. OH^- absorption peaks define three regions or windows of preferred operation. The first window is centered at 850 nm. The second window is centered at 1300 nm. The third window is centered at 1550 nm.

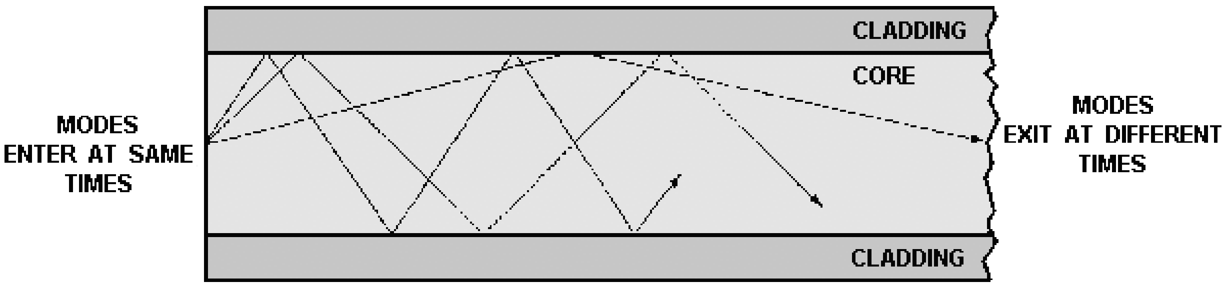


SCATTERING losses are caused by the interaction of light with density fluctuations within a fiber. **Rayleigh scattering** is the main source of loss in commercial fibers operating between 700 nm and 1600 nm.

MICROBENDS are small microscopic bends of the fiber axis that occur mainly when a fiber is cabled. **MACROBENDS** are bends having a large radius of curvature relative to the fiber diameter.

INTRAMODAL, or **CHROMATIC**, **DISPERSION** occurs because light travels through different materials and different waveguide structures at different speeds. **MATERIAL DISPERSION** is dependent on the light wavelengths interaction with the refractive index of the core. **WAVEGUIDE DISPERSION** is a function of the size of the fiber's core relative to the wavelength of operation.

INTERMODAL, or **MODAL**, **DISPERSION** occurs because each mode travels a different distance over the same time span.



ANSWERS TO QUESTIONS Q1. THROUGH Q48.

A1. Photons.

A2. Transverse-wave motion.

A3. Light waves are either transmitted, refracted, reflected, or absorbed.

A4. Transparent.

A5. Opaque.

A6. The law of reflection states that the angle of incidence is equal to the angle of reflection.

A7. When the wave is nearly parallel to the reflecting surface.

A8. When the wave is perpendicular to the reflecting surface.

A9. The law of reflection.

A10. Depends on the bending caused by the velocity difference of the wave traveling through different mediums.

A11. Transmitted.

A12. Diffusion.

A13. The ray theory and the mode theory.

A14. The index of refraction.

A15. Light will travel faster in an optical material that is less dense.

A16. Part of the light ray is reflected back into the glass and part of the light ray is refracted (bent) as it enters the air.

A17. Total internal reflection occurs when the angle of refraction approaches 90 degrees. This condition occurs when the angle of incidence increases to the point where no refraction is possible.

A18. Critical angle of incidence.

A19. Core, cladding, and coating or buffer.

A20. Core.

A21. The ray theory.

A22. Total internal reflection.

A23. Smaller.

A24. NA measures the light-gathering ability of an optical fiber.

A25. Skew ray angle.

A26. Modes of the fiber.

A27. Direction, amplitude, and wavelength of propagation.

A28. Yes, the wavefront will disappear because the total amount of phase collected must be an integer multiple of 2π*. (If the propagating wavefronts are out of phase, they will disappear. The wavefronts that are in phase interfere with the wavefronts out of phase. This type of interference is called destructive interference.)*

A29. Cutoff wavelength.

A30. Multimode fiber.

A31. The order of a mode is indicated by the number of field maxima within the core of the fiber. The order of a mode is also determined by the angle that the wavefront makes with the axis of the fiber.

A32. Mode coupling is the exchange of power between two modes.

A33. Increase.

A34. $V \leq 2.405$*.*

A35. Decrease.

A36. Core diameter, NA, and index profile properties.

A37. Light absorption, scattering, and bending losses.

A38. Attenuation is the loss of optical power as light travels along the fiber.

A39. Intrinsic and extrinsic material properties.

A40. Ultraviolet absorption region (below 400 nm) and infrared absorption region (above 2000 nm).

A41. The first, second, and third windows of operation are 850 nm, 1300 nm, and 1550 nm, respectively.

A42. Rayleigh scattering.

A43. (a) Mie scattering; (b) Rayleigh scattering.

A44. Uneven coating applications, improper cabling procedures, and external force.

A45. Fiber sensitivity to bending losses can be reduced if the refractive index of the core is increased and/or if the overall diameter of the fiber increases.

A46. Material dispersion and waveguide dispersion.

A47. Waveguide dispersion.

A48. Modal dispersion.

CHAPTER 3

OPTICAL FIBERS AND CABLES

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to do the following:

1. Describe multimode and single mode step-index and graded-index fibers.
2. Explain the terms refractive index profile, relative refractive index difference, and profile parameter.
3. List the performance advantages of 62.5/125 μm multimode graded-index fibers.
4. Identify the two basic types of single mode step-index fibers.
5. Describe the vapor phase oxidation and direct-melt optical fiber fabrication procedures.
6. Describe the fiber drawing process.
7. List the benefits of cabled optical fibers over bare fibers.
8. Identify the basic cable components, such as buffers, strength members, and jacket materials.
9. Describe the material and design requirements imposed on military fiber optic cable designs.
10. Describe the advantages and disadvantages of OFCC cable, stranded cable, and ribbon cable designs.

OPTICAL FIBER AND CABLE DESIGN

Optical fibers are thin cylindrical dielectric (non-conductive) waveguides used to send light energy for communication. Optical fibers consist of three parts: the core, the cladding, and the coating or buffer. The choice of optical fiber materials and fiber design depends on operating conditions and intended application. Optical fibers are protected from the environment by incorporating the fiber into some type of cable structure. Cable strength members and outer jackets protect the fiber. Optical cable structure and material composition depend on the conditions of operation and the intended application.

OPTICAL FIBERS

Chapter 2 classified optical fibers as either single mode or multimode fibers. Fibers are classified according to the number of modes that they can propagate. Single mode fibers can propagate only the fundamental mode. Multimode fibers can propagate hundreds of modes. However, the classification of an optical fiber depends on more than the number of modes that a fiber can propagate.

An optical fiber's refractive index profile and core size further distinguish single mode and multimode fibers. The **refractive index profile** describes the value of refractive index as a function of radial distance at any fiber diameter. Fiber refractive index profiles classify single mode and multimode fibers as follows:

- Multimode step-index fibers
- Multimode graded-index fibers
- Single mode step-index fibers
- Single mode graded-index fibers

In a **step-index** fiber, the refractive index of the core is uniform and undergoes an abrupt change at the core-cladding boundary. Step-index fibers obtain their name from this abrupt change called the step change in refractive index. In **graded-index** fibers, the refractive index of the core varies gradually as a function of radial distance from the fiber center.

Single mode and multimode fibers can have a step-index or graded-index refractive index profile. The performance of multimode graded-index fibers is usually superior to multimode step-index fibers. However, each type of multimode fiber can improve system design and operation depending on the intended application. Performance advantages for single mode graded-index fibers compared to single mode step-index fibers are relatively small. Therefore, single mode fiber production is almost exclusively step-index. Figure 3-1 shows the refractive index profile for a multimode step-index fiber and a multimode graded-index fiber. Figure 3-1 also shows the refractive index profile for a single mode step-index fiber. Since light propagates differently in each fiber type, figure 3-1 shows the propagation of light along each fiber.

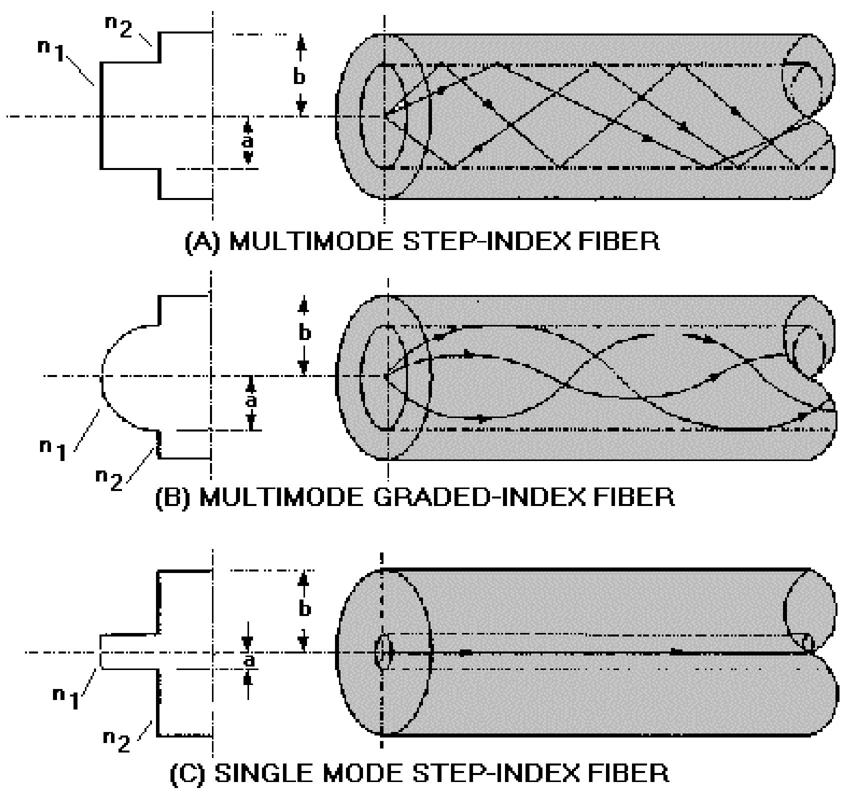


Figure 3-1.—The refractive index profiles and light propagation in multimode step-index, multimode graded-index, and single mode step-index fibers.

In chapter 2, you learned that fiber core size and material composition can affect system performance. A small change in core size and material composition affects fiber transmission properties, such as attenuation and dispersion. When selecting an optical fiber, the system designer decides which fiber core size and material composition is appropriate.

Standard core sizes for multimode step-index fibers are 50 μm and 100 μm. Standard core sizes for multimode graded-index fibers are 50 μm, 62.5 μm, 85 μm, and 100 μm. Standard core sizes for single mode fibers are between 8 μm and 10 μm. In most cases, the material used in the preparation of optical fibers is high-quality glass (SiO_2). This glass contains very low amounts of impurities, such as water or elements other than silica and oxygen. Using high-quality glass produces fibers with low losses. Small amounts of some elements other than silica and oxygen are added to the glass material to change its index of refraction. These elements are called material dopants. Silica doped with various materials forms the refractive index profile of the fiber core and material dopants are discussed in more detail later in this chapter. Glass is not the only material used in fabrication of optical fibers. Plastics are also used for core and cladding materials in some applications.

A particular optical fiber design can improve fiber optic system performance. Each single mode or multimode, step-index or graded-index, glass or plastic, or large or small core fiber has an intended application. The system designer must choose an appropriate fiber design that optimizes system performance in his application.

Q1. Describe the term "refractive index profile."

Q2. The refractive index of a fiber core is uniform and undergoes an abrupt change at the core-cladding boundary. Is this fiber a step-index or graded-index fiber?

Q3. Multimode optical fibers can have a step-index or graded-index refractive index profile. Which fiber, multimode step-index or multimode graded-index fiber, usually performs better?

Q4. List the standard core sizes for multimode step-index, multimode graded-index, and single mode fibers.

MULTIMODE STEP-INDEX FIBERS

A multimode step-index fiber has a core of radius (a) and a constant refractive index n_1. A cladding of slightly lower refractive index n_2 surrounds the core. Figure 3-2 shows the refractive index profile n(r) for this type of fiber. n(r) is equal to n_1 at radial distances $r < a$ (core). n(r) is equal to n_2 at radial distances $r \geq a$ (cladding). Notice the step decrease in the value of refractive index at the core-cladding interface. This step decrease occurs at a radius equal to distance (a). The difference in the core and cladding refractive index is the parameter Δ:

$$\Delta = \frac{n_1^2 - n_2^2}{2n_1^2}$$

Δ is the **relative refractive index difference.**

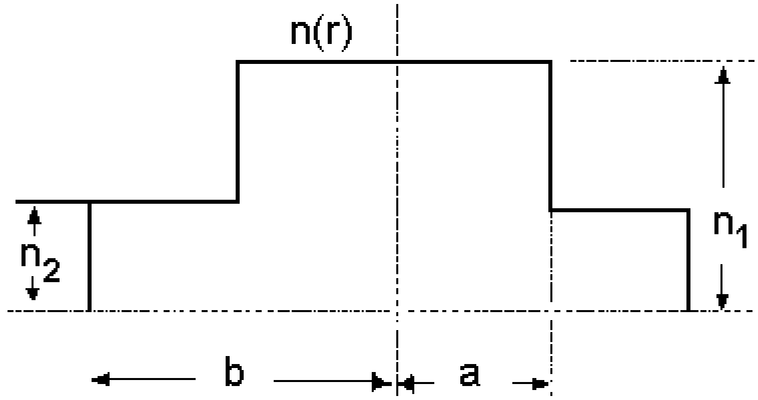

Figure 3-2.—The refractive index profile for multimode step-index fibers.

The ability of the fiber to accept optical energy from a light source is related to Δ. Δ also relates to the numerical aperture by

$$NA \simeq n_1\sqrt{2\Delta}.$$

The number of modes that multimode step-index fibers propagate depends on Δ and core radius (a) of the fiber. The number of propagating modes also depends on the wavelength (λ) of the transmitted light. In a typical multimode step-index fiber, there are hundreds of propagating modes.

Most modes in multimode step-index fibers propagate far from cutoff. Modes that are cut off cease to be bound to the core of the fiber. Modes that are farther away from the cutoff wavelength concentrate most of their light energy into the fiber core. Modes that propagate close to cutoff have a greater percentage of their light energy propagate in the cladding. Since most modes propagate far from cutoff, the majority of light propagates in the fiber core. Therefore, in multimode step-index fibers, cladding properties, such as cladding diameter, have limited affect on mode (light) propagation.

Multimode step-index fibers have relatively large core diameters and large numerical apertures. A large core size and a large numerical aperture make it easier to couple light from a light-emitting diode (LED) into the fiber. Multimode step-index fiber core size is typically 50 µm or 100 µm. Unfortunately, multimode step-index fibers have limited bandwidth capabilities. Dispersion, mainly modal dispersion, limits the bandwidth or information-carrying capacity of the fiber. System designers consider each factor when selecting an appropriate fiber for each particular application.

Multimode step-index fiber selection depends on system application and design. Short-haul, limited bandwidth, low-cost applications typically use multimode step-index fibers.

Q5. Multimode step-index fibers have a core and cladding of constant refractive index n_1 and n_2, respectively. Which refractive index, the core or cladding, is lower?

Q6. In multimode step-index fibers, the majority of light propagates in the fiber core for what reason?

Q7. Multimode step-index fibers have relatively large core diameters and large numerical apertures. These provide what benefit?

MULTIMODE GRADED-INDEX FIBERS

A multimode graded-index fiber has a core of radius (a). Unlike step-index fibers, the value of the refractive index of the core (n_1) varies according to the radial distance (r). The value of n_1 decreases as the distance (r) from the center of the fiber increases. The value of n_1 decreases until it approaches the value of the refractive index of the cladding (n_2). The value of n_1 must be higher than the value of n_2 to allow for proper mode propagation. Like the step-index fiber, the value of n_2 is constant and has a slightly lower value than the maximum value of n_1. The relative refractive index difference (Δ) is determined using the maximum value of n_1 and the value of n_2.

Figure 3-3 shows a possible refractive index profile n(r) for a multimode graded-index fiber. Notice the parabolic refractive index profile of the core. The **profile parameter** (α) determines the shape of the core's profile. As the value of α increases, the shape of the core's profile changes from a triangular shape to step as shown in figure 3-4. Most multimode graded-index fibers have a parabolic refractive index profile. Multimode fibers with near parabolic graded-index profiles provide the best performance. Unless otherwise specified, when discussing multimode graded-index fibers, assume that the core's refractive index profile is parabolic (α=2).

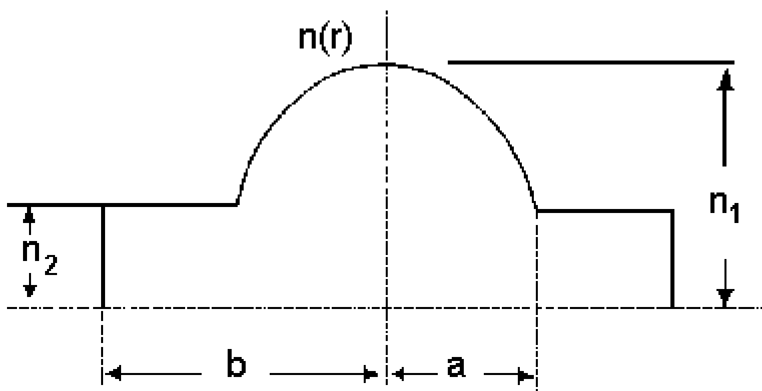

Figure 3-3.—The refractive index profile for multimode graded-index fibers.

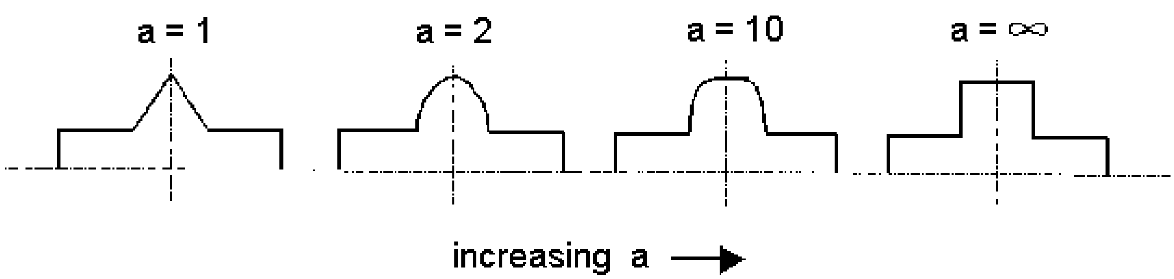

Figure 3-4.—The refractive index profiles for different values of α.

Light propagates in multimode graded-index fibers according to refraction and total internal reflection. The gradual decrease in the core's refractive index from the center of the fiber causes the light rays to be refracted many times. The light rays become refracted or curved, which increases the angle of incidence at the next point of refraction. Total internal reflection occurs when the angle of incidence becomes larger than the critical angle of incidence. Figure 3-5 shows the process of refraction and total internal reflection of light in multimode graded-index fibers. Figure 3-5 also illustrates the boundaries of different values of core refractive index by dotted lines. Light rays may be reflected to the axis of the fiber before reaching the core-cladding interface.

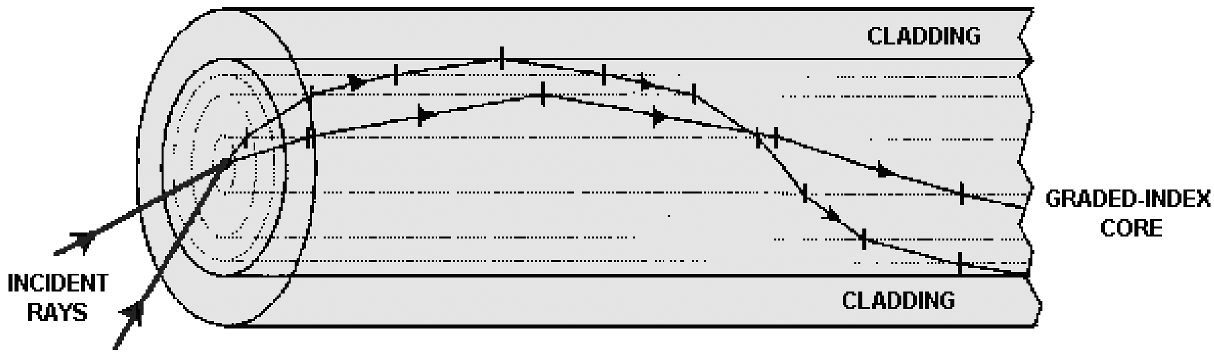

Figure 3-5.—Refractive index grading and light propagation in multimode graded-index fibers.

The NA of a multimode graded-index fiber is at its maximum value at the fiber axis. This NA is the **axial numerical aperture [NA(0)]**. NA(0) is approximately equal to

$$n_1\sqrt{2\Delta}.$$

However, the NA for graded-index fibers varies as a function of the radial distance (r). NA varies because of the refractive index grading in the fiber's core. The NA decreases from the maximum, NA(0), to zero at distances greater than the core-cladding boundary distance (r>a). The NA, relative refractive index difference (Δ), profile parameter (α), and normalized frequency (V) determine the number of propagating modes in multimode graded-index fibers. A multimode graded-index fiber with the same normalized frequency as a multimode step-index fiber will have approximately one-half as many propagating modes. However, multimode graded-index fibers typically have over one-hundred propagating modes.

Multimode graded-index fibers accept less light than multimode step-index fibers with the same core Δ. However, graded-index fibers usually outperform the step-index fibers. The core's parabolic refractive index profile causes multimode graded-index fibers to have less modal dispersion.

Figure 3-5 shows possible paths that light may take when propagating in multimode graded-index fibers. Light rays that travel farther from the fiber's axis travel a longer distance. Light rays that travel farther from the center travel in core material with an average lower refractive index.

In chapter 2, you learned that light travels faster in a material with a lower refractive index. Therefore, those light rays that travel the longer distance in the lower refractive index parts of the core travel at a greater average velocity. This means that the rays that travel farther from the fiber's axis will arrive at each point along the fiber at nearly the same time as the rays that travel close to the fiber's axis. The decrease in time difference between light rays reduces modal dispersion and increases multimode graded-index fiber bandwidth. The increased bandwidth allows the use of multimode graded-index fibers in most applications.

Most present day applications that use multimode fiber use graded-index fibers. The basic design parameters are the fiber's core and cladding size and Δ. Standard multimode graded-index fiber core and cladding sizes are 50/125 μm, 62.5/125 μm, 85/125 μm, and 100/140 μm. Each fiber design has a specific

Δ that improves fiber performance. Typical values of Δ are around 0.01 to 0.02. Although no single multimode graded-index fiber design is appropriate for all applications, the 62.5/125 μm fiber with a Δ of 0.02 offers the best overall performance.

A multimode graded-index fiber's source-to-fiber coupling efficiency and insensitivity to microbending and macrobending losses are its most distinguishing characteristics. The fiber core size and Δ affect the amount of power coupled into the core and loss caused by microbending and macrobending. Coupled power increases with both core diameter and Δ, while bending losses increase directly with core diameter and inversely with Δ. However, while these values favor high Δs, a smaller Δ improves fiber bandwidth. In most applications, a multimode graded-index fiber with a core and cladding size of 62.5/125 μm offers the best combination of the following properties:

- Relatively high source-to-fiber coupling efficiency
- Low loss
- Low sensitivity to microbending and macrobending
- High bandwidth
- Expansion capability

For example, local area network (LAN) and shipboard applications use multimode graded-index fibers with a core and cladding size of 62.5/125 μm. In LAN-type environments, macrobend and microbend losses are hard to predict. Cable tension, bends, and local tie-downs increase macrobend and microbend losses. In shipboard applications, a ship's cable-way may place physical restrictions, such as tight bends, on the fiber during cable plant installation. The good microbend and macrobend performance of 62.5/125 μm fiber permits installation of a rugged and robust cable plant. 62.5/125 μm multimode graded-index fibers allow for uncomplicated growth because of high fiber bandwidth capabilities for the expected short cable runs on board ships.

Q8. The profile parameter (α) determines the shape of the multimode graded-index core's refractive index profile. As the value of the α increases, how does the core's profile change?

Q9. Light propagates in multimode graded-index fibers according to refraction and total internal reflection. When does total internal reflection occur?

Q10. What four fiber properties determine the number of modes propagating in a multimode graded-index fiber?

Q11. Light travels faster in a material with a lower refractive index. Therefore, light rays that travel a longer distance in a lower refractive index travel at a greater average velocity. What effect does this have on multimode graded-index fiber modal dispersion and bandwidth?

Q12. What multimode graded-index fiber offers the best overall performance for most applications?

Q13. What are the most distinguishing characteristics of a multimode graded-index fiber?

Q14. How are source-to-fiber coupling and microbending and macrobending losses affected by changes in core diameter and Δ?

Q15. While coupled power and bending loss favor a high Δ, which Δ value, smaller or larger, improves fiber bandwidth?

SINGLE MODE STEP-INDEX FIBERS

There are two basic types of single mode step-index fibers: matched clad and depressed clad. **Matched cladding** means that the fiber cladding consists of a single homogeneous layer of dielectric material. **Depressed cladding** means that the fiber cladding consists of two regions: the inner and outer cladding regions. Matched-clad and depressed-clad single mode step-index fibers have unique refractive index profiles.

A matched-clad single mode step-index fiber has a core of radius (a) and a constant refractive index n_1. A cladding of slightly lower refractive index surrounds the core. The cladding has a refractive index n_2. Figure 3-6 shows the refractive index profile n(r) for the matched-clad single mode fiber.

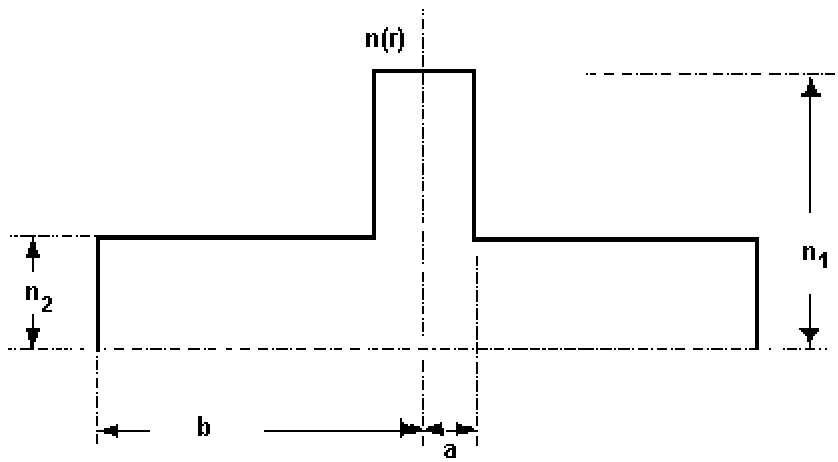

Figure 3-6.—Matched-clad refractive index profile.

Figure 3-7 shows the refractive index profile n(r) for the depressed-clad single mode fiber. A depressed-clad single mode step-index fiber has a core of radius (a) with a constant refractive index n_1. A cladding, made of two regions, surrounds the core. An inner cladding region surrounds the core of the fiber and has a refractive index of n_2. The inner cladding refractive index n_2 is lower than the core's refractive index n_1. An outer cladding region surrounds the inner cladding region and has a higher refractive index n_3 than the inner cladding region. However, the outer cladding refractive index n_3 is lower than the core's refractive index n_1.

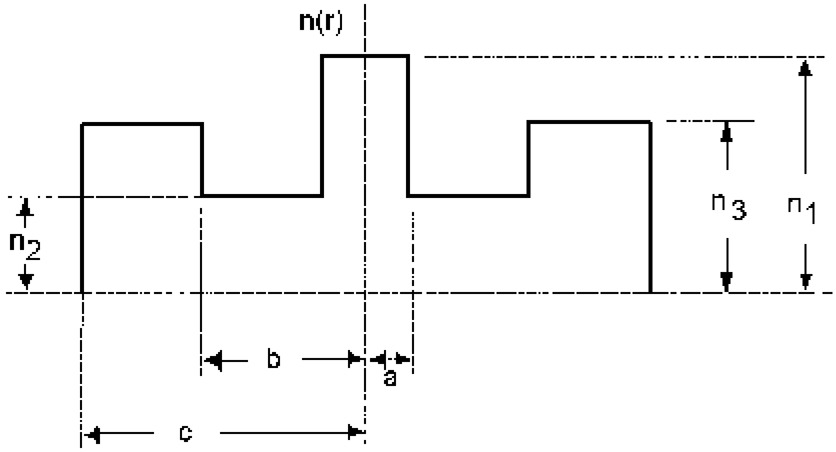

Figure 3-7.—Depressed-clad refractive index profile.

Single mode step-index fibers propagate only one mode, called the fundamental mode. Single mode operation occurs when the value of the fiber's normalized frequency is between 0 and 2.405 ($0 \leq V < 2.405$). The value of V should remain near the 2.405 level. When the value of V is less than 1, single mode fibers carry a majority of the light power in the cladding material. The portion of light transmitted by the cladding material easily radiates out of the fiber. For example, light radiates out of the cladding material at fiber bends and splices.

Single mode fiber cutoff wavelength is the smallest operating wavelength when single mode fibers propagate only the fundamental mode. At this wavelength, the 2nd-order mode becomes lossy and radiates out of the fiber core. As the operating wavelength becomes longer than the cutoff wavelength, the fundamental mode becomes increasingly lossy. The higher the operating wavelength is above the cutoff wavelength, the more power is transmitted through the fiber cladding. As the fundamental mode extends into the cladding material, it becomes increasingly sensitive to bending loss. Single mode fiber designs include claddings of sufficient thickness with low absorption and scattering properties to reduce attenuation of the fundamental mode. To increase performance and reduce losses caused by fiber bending and splicing, fiber manufacturers adjust the value of V. To adjust the value of V, they vary the core and cladding sizes and relative refractive index difference (Δ).

A single mode step-index fiber has low attenuation and high bandwidth properties. Present applications for single mode fibers include long-haul, high-speed telecommunication systems. Future applications include single mode fibers for sensor systems. However, the current state of single mode technology makes installation of single mode systems expensive and difficult. Short cable runs, low to moderate bandwidth requirements, and high component cost make installation of single mode fiber shipboard systems impractical at this time.

Q16. What are the two basic types of single mode step-index fibers?

Q17. Which fiber cladding, matched or depressed, consists of two regions?

Q18. In single mode operation, the value of the normalized frequency (V) should remain near the 2.405 level. If the value of V is less than 1, do single mode fibers carry a majority of the power in the core or cladding material?

Q19. What happens to the fundamental mode as the operating wavelength becomes longer than the single mode cutoff wavelength?

Q20. Give two reasons why the value of the normalized frequency (V) is varied in single mode step-index fibers?

SINGLE MODE GRADED-INDEX FIBERS

There are several types of single mode graded-index fibers. These fibers are not standard fibers and are typically only used in specialty applications. Information on single mode graded-index fibers can be found in the references in appendix 2.

FIBER ALTERNATIVES

In most applications, the standard multimode and step-index single mode optical fibers mentioned before have significant performance advantages over conventional copper-based systems. However, performance requirements and cost restraints may prohibit the use of these fibers in certain applications. Fiber manufacturers modify standard multimode and single mode fiber material composition and structural design to meet these additional requirements. Optical fiber design can depart from a traditional circular core and cladding, low-loss glass design. The intent of each change is to increase performance and reduce cost.

Optical fibers composed of plastic have been in use longer than glass fibers. Types of standard fibers using plastics include multimode step-index and graded-index fibers. Multimode step-index and graded-index **plastic clad silica** (PCS) fibers exist. PCS fibers have a silica glass core and a plastic cladding. Normally, PCS fibers are cheaper than all-glass fibers but have limited performance characteristics. PCS fibers lose more light through a plastic cladding than a glass cladding.

Multimode step-index fibers may also have a plastic core and cladding. All-plastic fibers have a higher NA, a larger core size, and cost less to manufacture. However, all-plastic fibers exhibit high loss in the thousands of decibels per kilometer. This high loss is caused by impurities and intrinsic absorption. PCS and all-plastic fibers are used in applications typically characterized by one or all of the following:

- High NA
- Low bandwidth
- Tight bend radius
- Short length (less than 10m to 20m)
- Low cost

Improved fabrication techniques provide the opportunity to experiment with material composition in both multimode and single mode fibers. Fiber manufacturers fabricate optical fibers using glass material whose characteristics improve system performance in the far infrared region. Fiber manufacturers add dopant material to reduce fiber loss and limit material and structural imperfections. Fiber material used in fabrication of low-loss, long wavelength optical fibers include the following:

- Heavy-metal fluorides (such as zirconium and beryllium fluoride)
- Chalcogenide glasses (such as arsenic/sulfur)
- Crystalline materials (such as silver bromide and silver chloride)

In shipboard applications, stringent environmental requirements dictate the design of special optical fibers. In some cases, manufacturers hermetically coat optical fibers to increase survivability and reliability in high-moisture and high-strain environments. Manufacturers also design radiation-hard fibers for nuclear power, space, and military systems. Radiation resistant fibers operate after exposure to nuclear radiation. Shipboard system performance requirements determine whether the use of hermetic and radiation resistant fibers or less costly commercial optical fibers is necessary.

Q21. Give two reasons why optical fiber manufacturers depart from the traditional circular core and cladding, low-loss glass fiber design?

Q22. What five characteristics do applications using plastic clad silica (PCS) and all-plastic fibers typically have?

Q23. List the types of materials used in fabricating low-loss, long wavelength optical fibers.

FABRICATION OF OPTICAL FIBERS

Basically, fiber manufacturers use two methods to fabricate multimode and single mode glass fibers. One method is vapor phase oxidation, and the other method is direct-melt process. In **vapor phase oxidation**, gaseous metal halide compounds, dopant material, and oxygen are oxidized (burned) to form a white silica powder (SiO_2). Manufacturers call SiO_2 the **soot**. Manufacturers deposit the soot on the surface of a glass substrate (mandrel) or inside a hollow tube by one of the following three methods:

- Outside Vapor Phase Oxidation (OVPO).
- Inside Vapor Phase Oxidation (IVPO).
- Vapor Phase Axial Deposition (VAD).

The soot forms the core and cladding material of the preform. The refractive index of each layer of soot is changed by varying the amount of dopant material being oxidized. Figures 3-8, 3-9, and 3-10 illustrate the different vapor phase oxidation preform preparation methods.

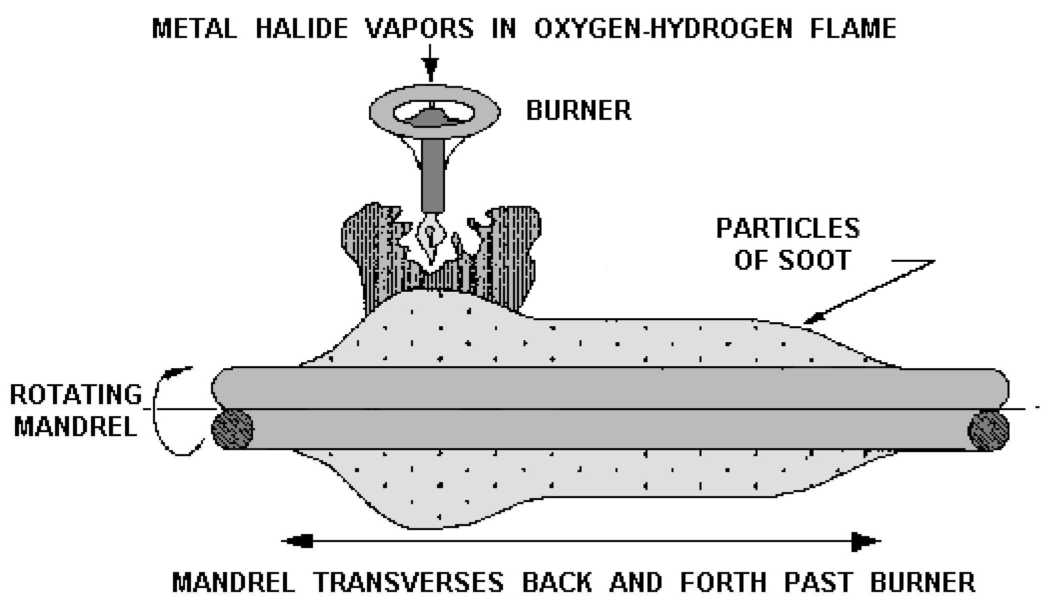

Figure 3-8.—OVPO preform preparation.

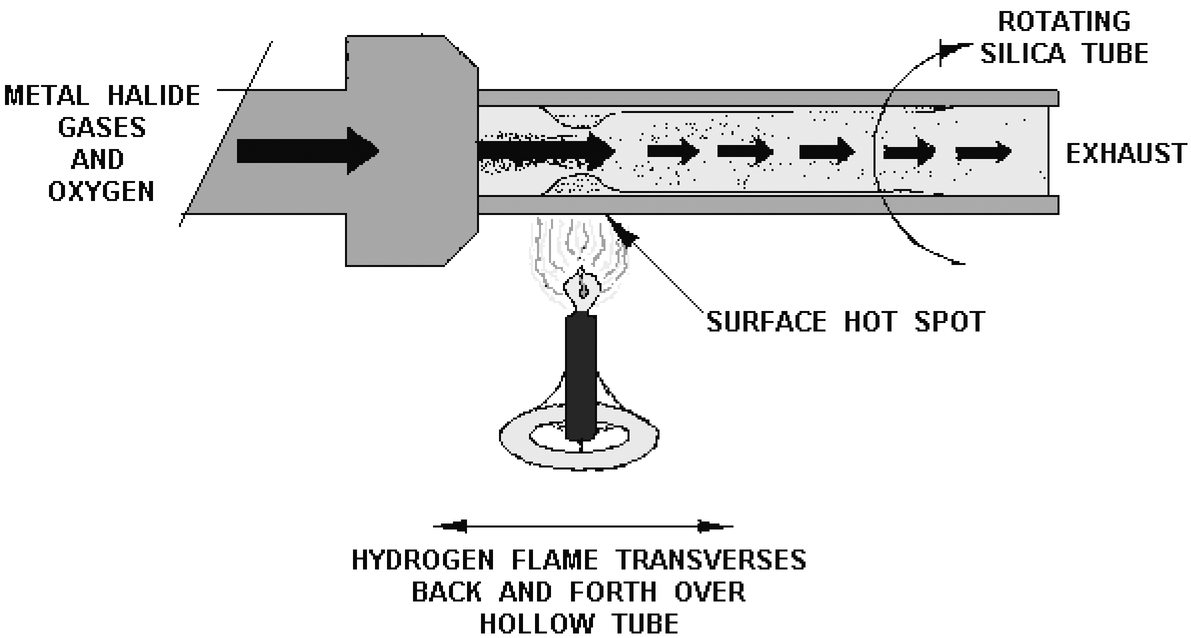

Figure 3-9.—IVPO preform preparation.

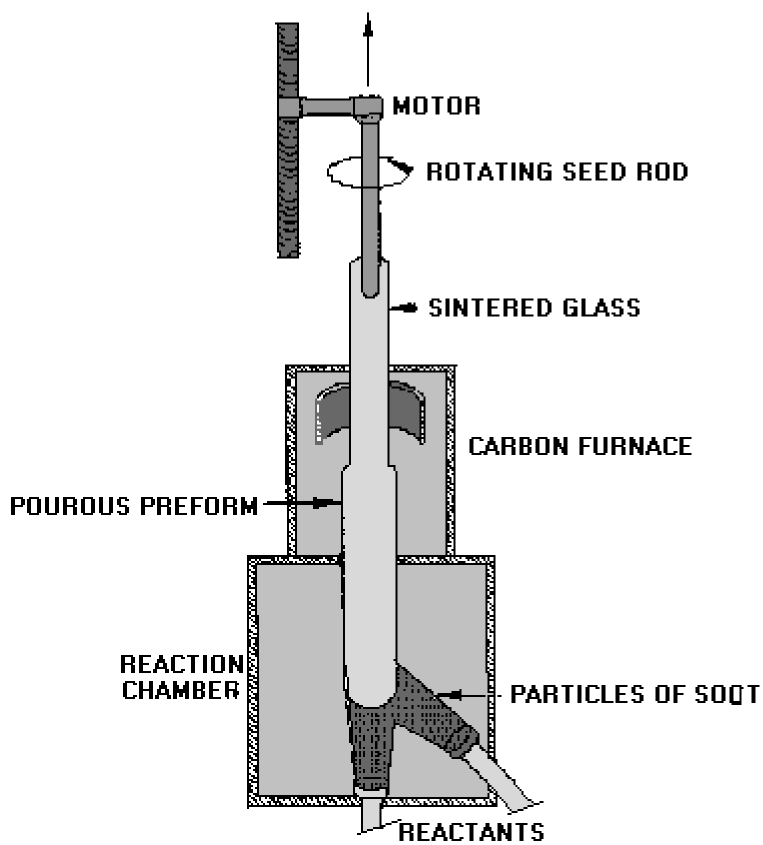

Figure 3-10.—VAD preform preparation.

During vapor phase oxidation, the mandrel or tube continuously moves from side to side and rotates while soot particles are deposited on the surface. This process forms cylindrical layers of soot on the surface of the mandrel or inside the hollow tube. This deposited material is transformed into a solid glass preform by heating the porous material (without melting). The solid preform is then drawn or pulled into an optical fiber by a process called fiber drawing.

The fiber drawing process begins by feeding the glass preform into the drawing furnace. The drawing furnace softens the end of the preform to the melting point. Manufacturers then pull the softened preform into a thin glass filament (glass fiber). To protect the bare fiber from contaminants, manufacturers add an acrylate coating in the draw process. The coating protects the bare fiber from contaminants such as atmospheric dust and water vapor. Figure 3-11 illustrates the process of drawing an optical fiber from the preform.

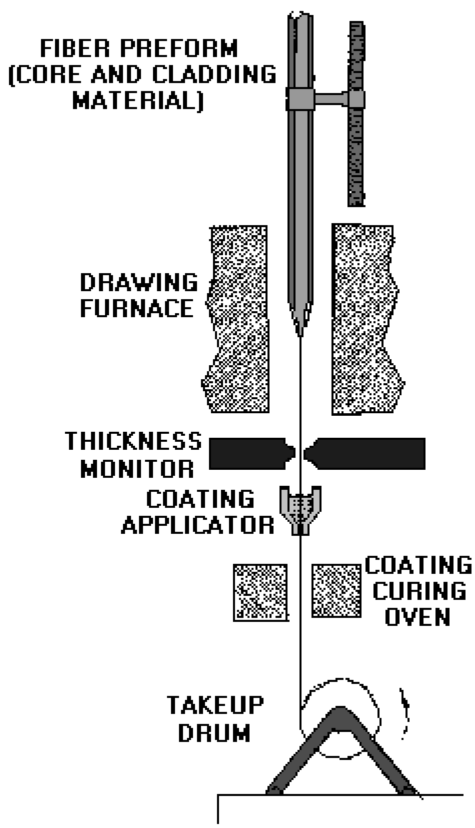

Figure 3-11.—Fiber drawing process.

In the **direct-melt process**, multicomponent glass rods form the fiber structure. Rods of multicomponent glass combine in a molten state to form the fiber core and cladding. The double-crucible method is the most common direct-melt process. The double-crucible method combines the molten rods into a single preform using two concentric crucibles. Optical fibers are drawn from this molten glass using a similar fiber drawing process as in vapor phase oxidation. Figure 3-12 illustrates the double-crucible drawing process.

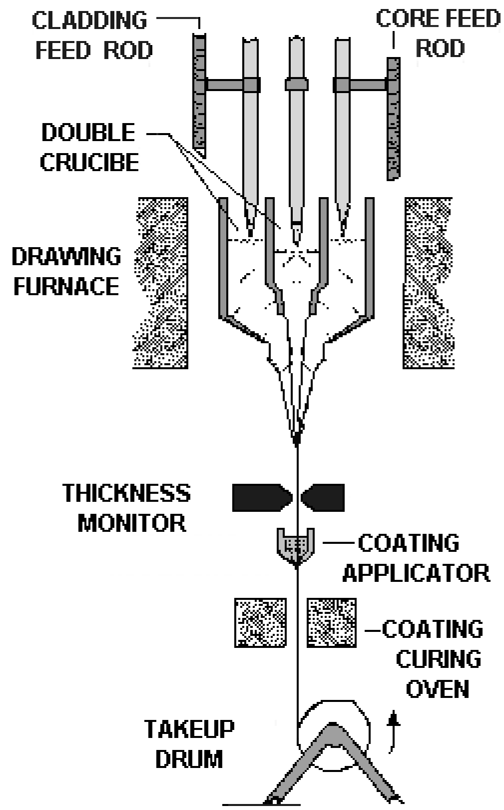

Figure 3-12.—Double-crucible fiber drawing process.

Q24. What are the two methods used by fiber manufacturers to fabricate multimode and single mode glass fibers?

Q25. Which method, vapor phase oxidation or direct-melt process, transforms deposited material into a solid glass preform by heating the porous material without melting?

OPTICAL CABLES

Optical fibers have small cross sectional areas. Without protection, optical fibers are fragile and can be broken. The optical cable structure protects optical fibers from environmental damage. Cable structure includes buffers, strength members, and jackets. Many factors influence the design of fiber optic cables. The cable design relates to the cable's intended application. Properly designed optical cables perform the following functions:

- Protect optical fibers from damage and breakage during installation and over the fiber's lifetime.
- Provide stable fiber transmission characteristics compared with uncabled fibers. Stable transmission includes stable operation in extreme climate conditions.
- Maintain the physical integrity of the optical fiber by reducing the mechanical stresses placed on the fiber during installation and use. Static fatigue caused by tension, torsion, compression, and bending can reduce the lifetime of an optical fiber.

Navy applications require that fiber optic cables meet stringent design specifications. Fiber optic cables must be rugged to meet the optical, environmental, and mechanical performance requirements imposed by Navy systems. Critical system downtime caused by cable failure cannot be tolerated. However, in commercial applications, the requirements imposed on cable designs are not as stringent. Each additional requirement imposed on the fiber optic cable design adds to its cost. Cost is always a main consideration of cable designers in commercial applications. Cost is also considered in Navy applications, but system reliability is the main goal.

Q26. List three benefits that properly cabled optical fibers provide.

FIBER BUFFERS

Coatings and buffers protect the optical fiber from breakage and loss caused by microbends. During the fiber drawing process, the addition of a primary coating protects the bare glass from abrasions and other surface contaminants. For additional protection, manufacturers add a layer of buffer material. The buffer material provides additional mechanical protection for the fiber and helps preserve the fiber's inherent strength.

Manufacturers use a variety of techniques to buffer optical fibers. The types of fiber buffers include tight-buffered, loose-tube, and gel-filled loose-tube. Figure 3-13 shows each type of fiber buffer. The choice of buffering techniques depends on the intended application. In large fiber count commercial applications, manufacturers use the loose-tube buffers. In commercial building and Navy applications, manufacturers use tight buffers.

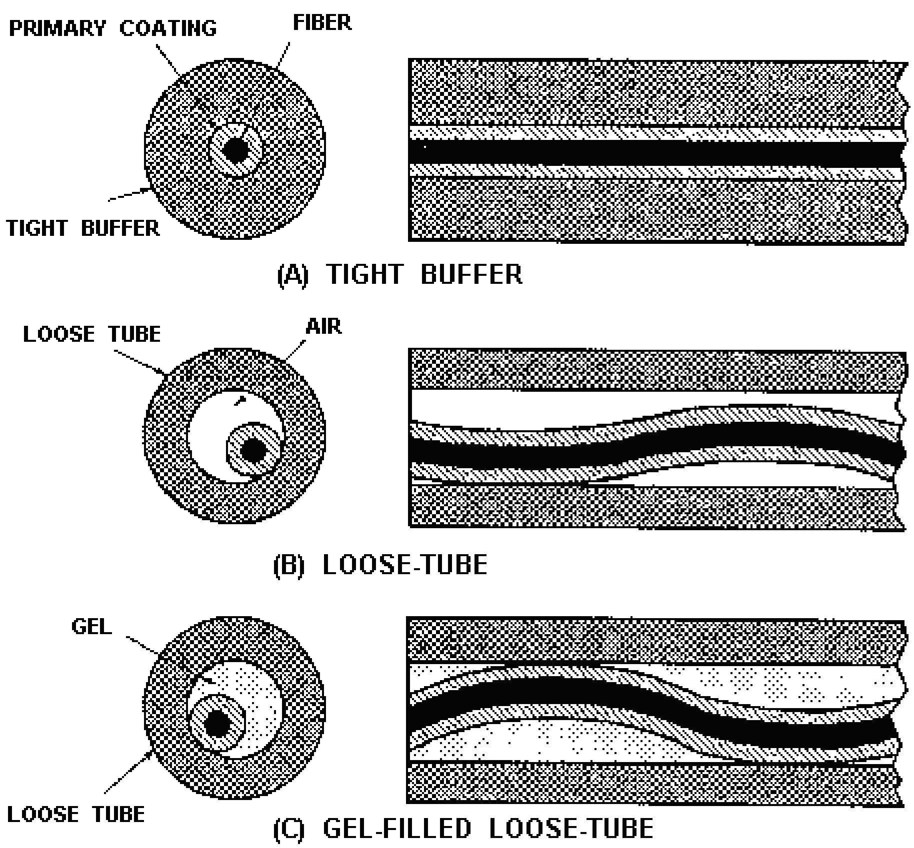

Figure 3-13.—Tight-buffered, loose-tube, and gel-filled loose-tube buffer techniques.

Q27. In addition to a primary coating, manufacturers add a layer of buffer material for what reasons?

Q28. List the three techniques used by manufacturers to buffer optical fibers.

CABLE STRENGTH AND SUPPORT MEMBERS

Fiber optic cables use strength members to increase the cables' strength and protect the fiber from strain. Fiber optic cables may use central support members in cable construction. The central support members generally have buffered fibers or single fiber sub-cables stranded over their surface in a structured, helical manner. The central members may support the optical fibers as cable strength members or may only serve as fillers. Strength and support members must be light and flexible. In commercial applications, the materials used for strength and support include steel wire and textile fibers (such as nylon and arimid yarn). They also include carbon fibers, glass fibers, and glass reinforced plastics. For Navy applications, only non-metallic strength and support members are allowed.

CABLE JACKET, OR SHEATH, MATERIAL

The jacket, or sheath, material provides extra environmental and mechanical protection. Jacket materials for Navy cables have the following properties:

- Low smoke generation
- Low toxicity
- Low halogen content
- Flame retardance
- Fluid resistance
- High abrasion resistance
- Stable performance over temperature

It is difficult to produce a material compound that satisfies every requirement without being too costly. Originally, the production of fire retardant cables included the use of halogenated polymers and additives. These fire retardant cables were also highly toxic. Commercial jacket materials currently used include polyethylene, polyvinyl chloride (PVC), polyurethane, and polyester elastomers. Most commercial jacket materials are unsuitable for use in Navy applications. Researchers have developed jacket materials that are suitable for Navy use.

Q29. List seven properties cable jackets should have.

CABLE DESIGNS

Manufacturers design fiber optic cables for specific applications. Is the cable buried underground or hung from telephone poles? Is the cable snaked through cableways, submerged in water, or just laid on the ground? Is the cable used in industrial, telecommunication, utility, or military applications? Each different application may require a slightly different cable design.

Agreement on standard cable designs is difficult. Cable design choices include jacket materials, water blocking techniques, and the number of fibers to place within the cable. The cable design chosen depends on the cable's intended application. There are presently many types of fiber optic cables. Some fiber optic cables are used in commercial applications, while others are used in military applications.

Standard commercial cable designs will develop over time as fiber optic technology becomes more established. However, this chapter provides only a short discussion on cable designs considered for Navy applications.

Navy systems require that fiber optic cables meet stringent environmental conditions. The types of cable designs considered by the Navy include the optical fiber cable component (OFCC), stranded, and ribbon cable designs. The cable must meet minimal levels of performance in safety (low smoke, low toxicity, low halogen content, etc.), durability (able to withstand shock, vibration, fluids, etc.), and optical performance. The cable must also be easy to install and repair. These factors greatly influence the design of the cables.

Optical Fiber Cable Component (OFCC) Cable

An OFCC cable consists of individual single fiber cables, called **optical fiber cable components (OFCCs)**. OFCCs are a tight-buffered fiber surrounded by arimid yarn and a low-halogen outer jacket. The OFCC outer diameter is typically 2 millimeters (mm). The fiber is typically buffered with a polyester elastomer to a total diameter of 900 μm. Figure 3-14 illustrates the design of the OFCCs. The size of the OFCCs limits the amount of fibers contained within an OFCC cable. An OFCC cable generally contains less than 36 fibers (OFCCs). An OFCC cable of 0.5-inch cable outer diameter can accommodate about 12 fibers.

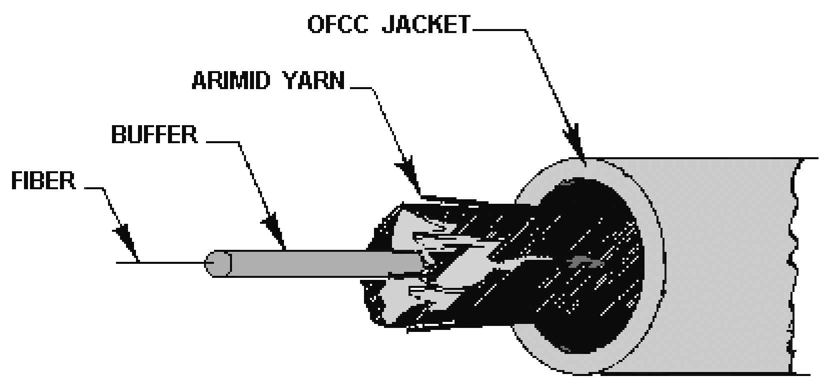

Figure 3-14.—The design of optical fiber cable components (OFCCs).

Figure 3-15 shows an isometric view of a four-fiber shipboard OFCC cable. In this multifiber cable design, the OFCCs surround a flexible central member in a helical manner. The central member may add to cable strength or only support the OFCCs. For additional protection, two layers of arimid yarn strength members encase the OFCC units. These strength members are stranded in opposing lays to minimize microbending of the fibers. The arimid yarn strength members may be treated with polymers that are water absorbing, blocking, and sealing. This treatment eliminates the need for additional water blocking protection. Finally, a low-halogen, flame-resistant outer jacket is extruded over the strength members.

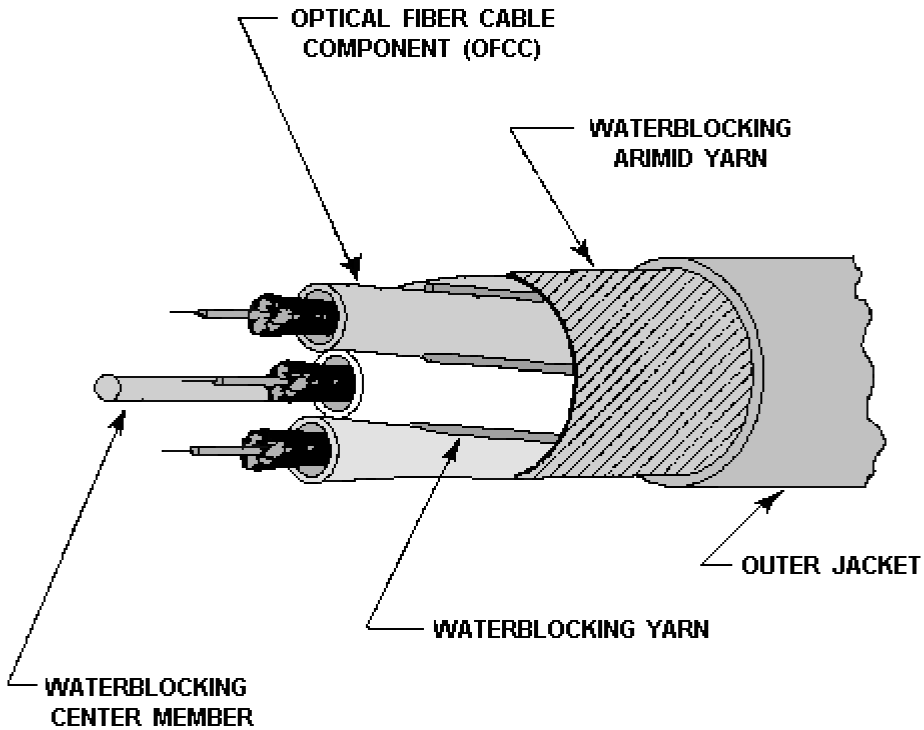

Figure 3-15.—An isometric view of a four-fiber shipboard OFCC cable.

OFCC cables are easy to handle because each cable contains its own subcable, the OFCC. These OFCC subcables make it easy to reconfigure systems and handle individual fibers. Rugged OFCC cable design permits cable use in harsh environments, including Navy applications. OFCC-type cable is recommended for use in low-density (less than 24 fibers) Navy applications. OFCC-type cable is also being evaluated for use in Navy applications with fiber counts up to 36 fibers.

Stranded Cable

A stranded cable is a fiber optic cable consisting of buffered fibers stranded down the center of the cable surrounded by strength members and a protective jacket. Figure 3-16 shows a cross-sectional view of the stranded cable. The fiber is typically buffered with a polyester elastomer to a total diameter of 900 μm. The recommended use of stranded cables is in medium-density (24 to 72 fibers) Navy applications. However, this recommendation is preliminary. Further test and evaluation of prototype stranded cable designs is continuing. Final approval of the stranded cable will occur only after prototype cables have passed all tests.

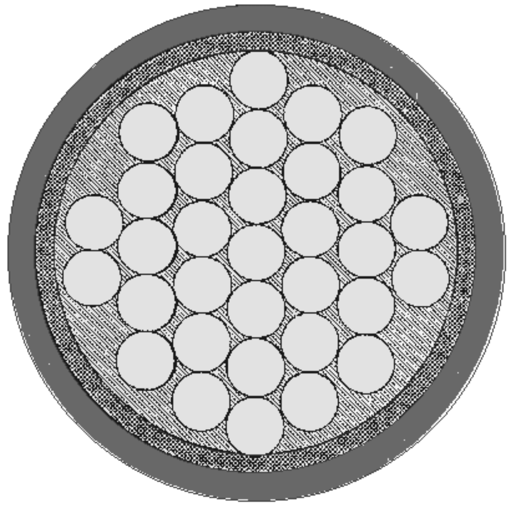

Figure 3-16.—Stranded cable design.

Stranded cable designs increase fiber counts without greatly increasing cable size. Stranded cables are used when fiber counts exceed the limits of OFCC-type cables. For example, the stranded cable design can accommodate about 48 fibers in a O.5-inch cable. The OFCC cable design can accommodate around 12 fibers. The individual fiber is not protected as well in the stranded design as in the OFCC design. For this reason more care is required in handling the individual fibers in the stranded design. The primary problem of the stranded cable design is in meeting the waterblocking requirements. Once manufacturers correct this design problem, the Navy expects that the stranded cable design will meet Navy performance requirements.

Ribbon Cable

A ribbon cable consists of optical fiber ribbons stranded down the center of the cable surrounded by a protective tube, strength members, and an outer jacket. The fiber optic ribbon consists of multiple-coated, 250 ∝m diameter fibers sandwiched in a plastic material. Figure 3-17 shows a cross-sectional view of a 12-fiber ribbon. Cable manufacturers stack these ribbons to form a rectangular cross-sectional array of fibers. Stacked ribbons are the basic building blocks of the ribbon cable. Figure 3-18 illustrates this cross-sectional array of ribbons. Manufacturers introduce a controlled twist to the stacked ribbons to minimize fiber stress when the cable is bent. An inner plastic tube, strength members, and an outer protective jacket surround the stacked ribbons, providing environmental protection.

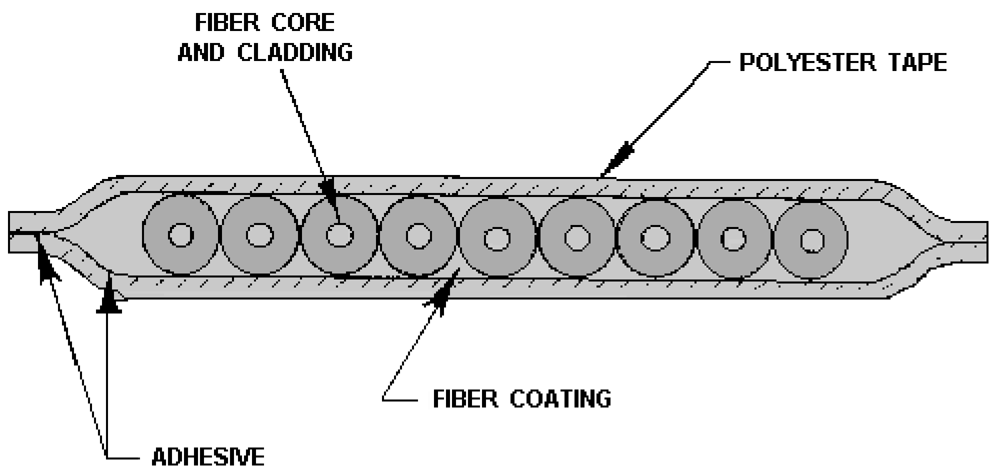

Figure 3-17.—Cross section of a fiber optic ribbon.

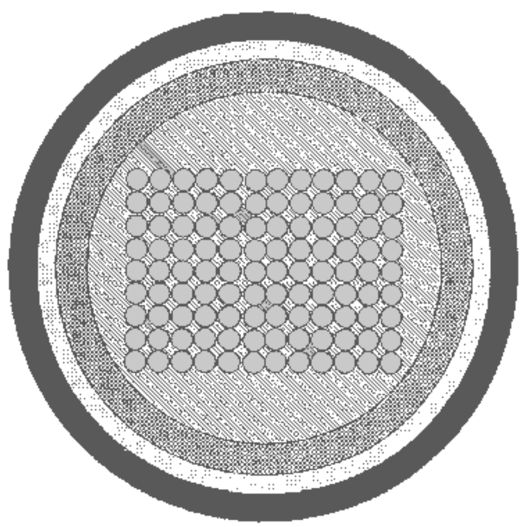

Figure 3-18.—Ribbon cable cross-sectional array of fibers.

The ribbon cable design has the highest fiber capacity. Ribbon cables can hold 204 fibers in a 0.5-inch cable. However, ribbon cables have worse bend performance than OFCC and stranded cables. Ribbon cables also have the poorest waterblocking capabilities of the three cable designs. The bend performance is expected to worsen if manufacturers add appropriate compounds to increase waterblocking capabilities.

Ribbon cables are also hard to handle. Individual fibers are highly susceptible to damage when separated from the ribbon. This susceptibility to fiber damage during fiber breakout makes it necessary to perform multifiber connections. Multifiber connections can introduce single points of failure in multiple systems. The use of multifiber terminations also introduces maintenance, reconfiguration, and repair problems. Currently, the Navy does not recommend the use of ribbon cables in shipboard systems.

Q30. List the three types of cable designs being considered by the Navy.

Q31. Describe an optical fiber cable component (OFCC).

Q32. Two layers of arimid yarn strength members encase the OFCC units. Why are these strength members stranded in opposing directions?

Q33. Why do cable manufacturers introduce a controlled twist to the stacked ribbons during the cabling process?

Q34. OFCC, stranded, and ribbon cables have different fiber capacities. What is the approximate number of fibers that each cable can accommodate in a 0.5-inch cable?

Q35. Which fiber optic cable (OFCC, stranded, or ribbon) has the worst bend performance?

SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas that you have learned. You should have a thorough understanding of these principles before moving on to chapter 4.

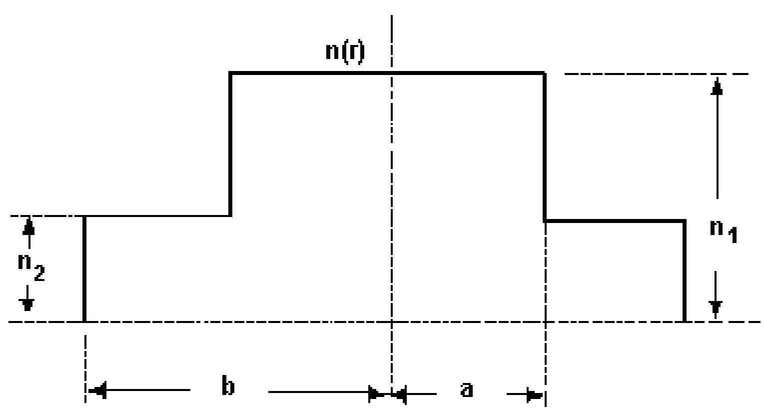
OPTICAL FIBER CLASSIFICATION depends on more than the number of modes that a fiber can propagate. The optical fiber's refractive index profile and core size further distinguish different types of single mode and multimode fibers.

The **REFRACTIVE INDEX PROFILE** describes the value of the fiber's refractive index as a function of axial distance at any fiber diameter.

In **STEP-INDEX** fibers, the refractive index of the core is uniform and undergoes an abrupt change at the core-cladding boundary.

In **GRADED-INDEX** fibers, the refractive index of the core varies gradually as a function of radial distance from the fiber center.

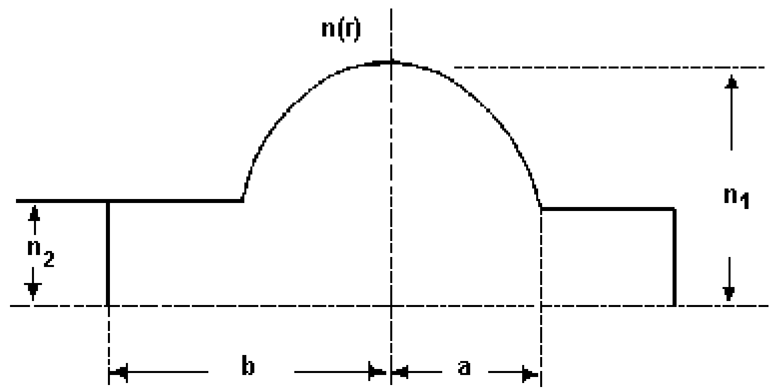
MULTIMODE STEP-INDEX FIBERS have a core of radius (a), and a constant refractive index n_1. A cladding of slightly lower refractive index n_2 surrounds the core.



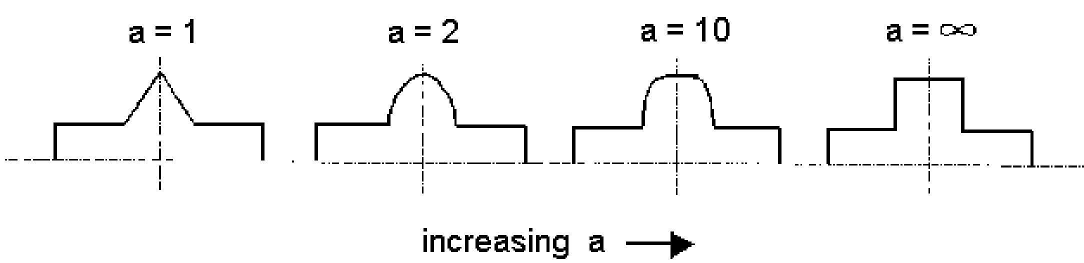
The **RELATIVE REFRACTIVE INDEX DIFFERENCE (Δ)** is the difference in the core and cladding refractive index. The ability of the fiber to accept optical energy from a light source is related to Δ.

MULTIMODE STEP-INDEX FIBERS have relatively large core diameters and large numerical apertures. Unfortunately, multimode step-index fibers have limited bandwidth capabilities and poor bend performance. Short-haul, limited bandwidth, low-cost applications use multimode step-index fibers.

MULTIMODE GRADED-INDEX FIBERS have a core of radius (a). Unlike step-index fibers, the value of the refractive index of the core (n_1) varies according to the radial distance (r). The value of n_1 decreases until it approaches the value of the refractive index of the cladding (n_2). Like the step-index fiber, the value of n_2 is constant and has a slightly lower refractive index than n_1.



The **PROFILE PARAMETER** (α) determines the shape of the core's refractive index profile. As the value of α increases, the shape of the core's profile changes from a triangular shape to a step.



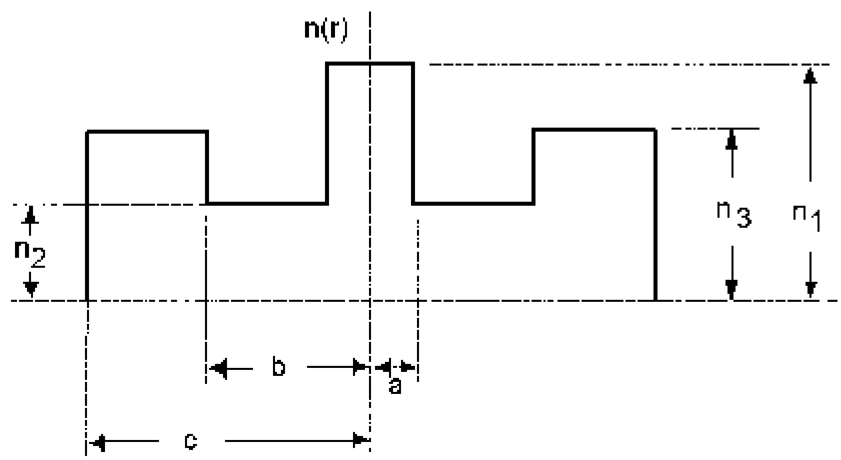
The gradual decrease in the core's refractive index from the center of the fiber causes propagating modes to be refracted many times.

Multimode graded-index fibers have less **MODAL DISPERSION** than multimode step-index fibers. Lower modal dispersion means that multimode graded-index fibers have higher bandwidth capabilities than multimode step-index fibers.

SOURCE-TO-FIBER COUPLING EFFICIENCY and **INSENSITIVITY TO MICROBENDING AND MACROBENDING LOSSES** are distinguishing characteristics of multimode graded-index fibers. 62.5 μm fibers offer the best overall performance for multimode graded-index fibers.

Coupled power increases with both core diameter and Δ, while bending losses increase directly with core diameter and inversely with Δ. However, a smaller Δ improves fiber bandwidth.

MATCHED-CLAD and **DEPRESSED-CLAD** are two types of single mode step-index fibers. Matched cladding means that the fiber cladding is a single homogeneous layer of dielectric material. Depressed cladding means that the fiber cladding consists of two regions: an inner and outer cladding region.



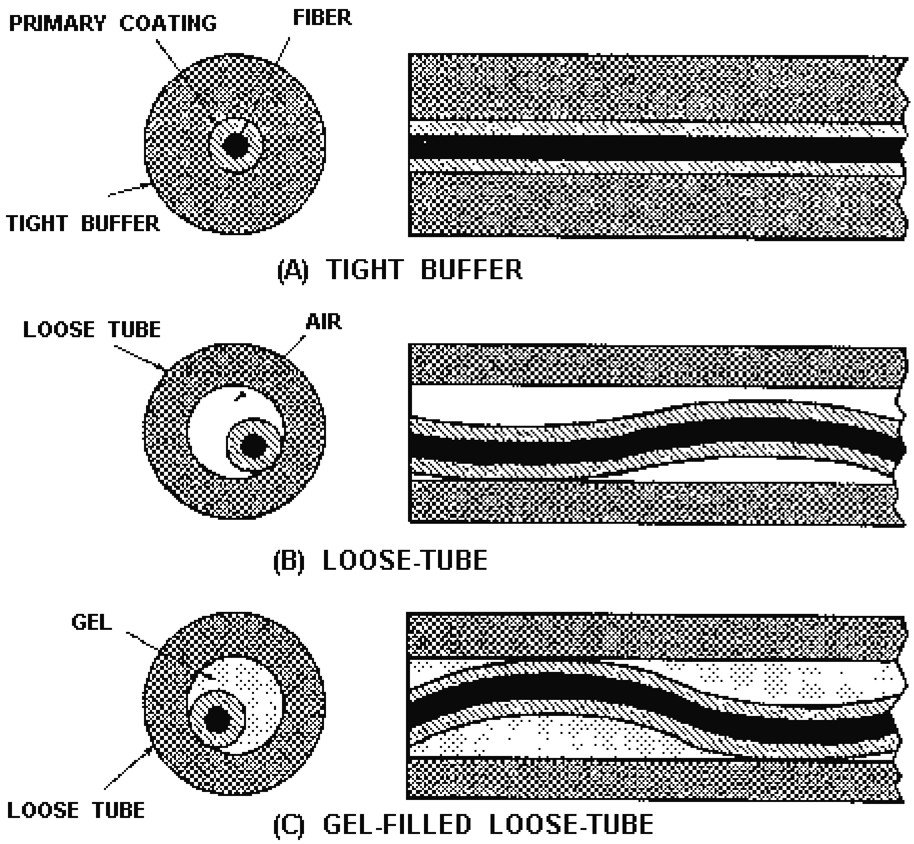
SINGLE MODE FIBER CUTOFF WAVELENGTH is the smallest operating wavelength where single mode fibers propagate only the fundamental mode. At this wavelength, the 2nd-order mode becomes lossy and radiates out of the fiber core.

SINGLE MODE FIBERS have low attenuation and high-bandwidth properties. Present applications for single mode fibers include long-haul, high-speed telecommunication systems.

VAPOR PHASE OXIDATION and **DIRECT-MELT PROCESS** are two methods of fabricating multimode and single mode optical fibers.

CABLE STRUCTURES include buffers, strength members, and the jacket, or sheath.

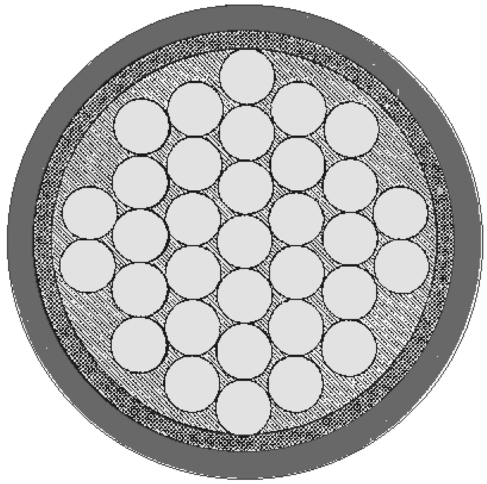
TIGHT-BUFFERED, **LOOSE-TUBE**, and **GEL-FILLED LOOSE-TUBE** are types of fiber optic buffering techniques.



FIBER OPTIC CABLES use strength members to increase the cable's strength and protect the optical fibers from strain.

JACKET MATERIAL should have low smoke generation, low toxicity, low-halogen content, flame retardance, fluid resistance, high abrasion resistance, and stable performance over temperature.

Navy systems require that fiber optic cables meet stringent environmental conditions. The types of cable designs considered by the Navy include the **OPTICAL FIBER CABLE COMPONENT (OFCC)**, **STRANDED**, and **RIBBON** cable designs.



ANSWERS TO QUESTIONS Q1. THROUGH Q35.

A1. Refractive index profile describes the value of refractive index as a function of radial distance at any fiber diameter.

A2. Step-index.

A3. Multimode graded-index fiber.

A4. Multimode step-index fibers: 50 μm and 100 μm. Multimode graded-index fibers: 50 μm, 62.5 μm, 85 μm, and 100 μm. Single mode fibers: between 8 μm and 10 μm.

A5. Cladding.

A6. Most modes in multimode step-index fibers propagate far from cutoff.

A7. Make it easier to couple light from a light-emitting diode (LED) into the fiber.

A8. From a triangular shape to step.

A9. When the angle of incidence becomes larger than the critical angle of incidence.

A10. Numerical aperture (NA), relative refractive index difference (Δ), profile parameter (α), and normalized frequency (V).

A11. Decreases the time difference between light rays, which reduces modal dispersion and increases fiber bandwidth.

A12. 62.5/125 μm multimode graded-index fiber.

A13. Source-to-fiber coupling efficiency and insensitivity to microbending and macrobending losses.

A14. Coupling efficiency increases with both core diameter and Δ, while bending losses increase directly with core diameter and inversely with Δ.

A15. Smaller.

A16. Matched-clad and depressed-clad.

A17. Depressed.

A18. Cladding material.

A19. The fundamental mode becomes increasingly lossy.

A20. To increase performance and reduce losses caused by bending and splicing.

A21. To increase performance and reduce cost.

A22. High NA, low bandwidth, tight bend radius, short length, and low cost.

A23. Heavy-metal fluorides, chalcogenide glasses, and crystalline materials.

A24. Vapor phase oxidation and direct-melt process.

A25. Vapor phase oxidation.

A26.

- *a. Protect optical fibers from damage or breakage during installation and over the fiber's lifetime.*
- *b. Provide stable fiber transmission characteristics compared with uncabled fibers.*
- *c. Maintain the physical integrity of the optical fiber.*

A27. To provide additional mechanical protection and preserve the fiber's inherent strength.

A28. Tight-buffered, loose-tube, and gel-filled loose-tube.

A29. Low smoke generation, low toxicity, low halogen content, flame retardance, fluid resistance, high abrasion resistance, and stable performance over temperature.

A30. Optical fiber cable component (OFCC), stranded, and ribbon cables designs.

A31. OFCCs are tight-buffer fiber surrounded by arimid yarn and a low-halogen outer jacket.

A32. To minimize microbending of the fibers.

A33. To minimize fiber stress when the cable is bent.

A34. OFCC (12 fibers), stranded (48 fibers), ribbon (204 fibers).

A35. Ribbon.

CHAPTER 4

OPTICAL SPLICES, CONNECTORS, AND COUPLERS

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to do the following:

1. Describe a fiber optic splice, connector, and coupler and the types of connections they form in systems.
2. List the types of extrinsic and intrinsic coupling losses.
3. Understand the degree to which fiber alignment and fiber mismatch problems increase system loss.
4. Detail the score-and-break cleaving process for fiber-end preparation.
5. Identify the types of fiber optic mechanical and fusion splices. Outline the basic splicing techniques for each type of fiber optic splice.
6. List the types of fiber optic connectors. Detail the procedure for installing a fiber optic connector on an optical fiber.
7. Discuss the types of fiber optic passive couplers.

FIBER OPTIC CONNECTIONS

Chapter 1 states that a fiber optic data link performs three basic functions. First, the data link transmitter converts an electrical input signal to an optical signal. Then, the optical fiber transmits this optical signal. Finally, the data link receiver converts the optical signal back to an electrical signal identical to the original input. However, chapter 1 does not describe how optical power transfers from one optical component to another.

This chapter describes how optical power is transferred from one fiber optic component to another. It describes how an optical source launches optical power into a fiber as well as how one optical fiber couples light into another fiber. In fiber optic system design, this launching or coupling of optical power from one component to the next is important.

Fiber optic connections permit the transfer of optical power from one component to another. Fiber optic connections also permit fiber optic systems to be more than just point-to-point data communication links. In fact, fiber optic data links are often of a more complex design than point-to-point data links.

A system connection may require either a fiber optic splice, connector, or coupler. One type of system connection is a permanent connection made by splicing optical fibers together. A fiber optic **splice** makes a permanent joint between two fibers or two groups of fibers. There are two types of fiber optic splices--mechanical splices and fusion splices. Even though removal of some mechanical splices is possible, they are intended to be permanent. Another type of connection that allows for system reconfiguration is a fiber optic **connector**. Fiber optic connectors permit easy coupling and uncoupling of optical fibers. Fiber optic connectors sometimes resemble familiar electrical plugs and sockets. Systems may also divide or combine optical signals between fibers. Fiber optic **couplers** distribute or combine optical signals between fibers. Couplers can distribute an optical signal from a single fiber into several fibers. Couplers may also combine optical signals from several fibers into one fiber.

Fiber optic connection losses may affect system performance. **Poor fiber end preparation** and **poor fiber alignment** are the main causes of coupling loss. Another source of coupling loss is differences in optical properties between the connected fibers. If the connected fibers have different optical properties, such as different numerical apertures, core and cladding diameters, and refractive index profiles, then coupling losses may increase.

Q1. Which fiber optic component (splice, connector, or coupler) makes a permanent connection in a distributed system?

Q2. What are the main causes of coupling loss?

OPTICAL FIBER COUPLING LOSS

Ideally, optical signals coupled between fiber optic components are transmitted with no loss of light. However, there is always some type of imperfection present at fiber optic connections that causes some loss of light. It is the amount of optical power lost at fiber optic connections that is a concern of system designers.

The design of fiber optic systems depends on how much light is launched into an optical fiber from an optical source and how much light is coupled between fiber optic components, such as from one fiber to another. The amount of power launched from a source into a fiber depends on the optical properties of both the source and the fiber. The amount of optical power launched into an optical fiber depends on the radiance of the optical source. An optical source's **radiance**, or brightness, is a measure of its optical power launching capability. Radiance is the amount of optical power emitted in a specific direction per unit time by a unit area of emitting surface. For most types of optical sources, only a fraction of the power emitted by the source is launched into the optical fiber.

The loss in optical power through a connection is defined similarly to that of signal attenuation through a fiber. Optical loss is also a log relationship. The loss in optical power through a connection is defined as:

$$\text{loss} = 10 \log_{10} \frac{P_i}{P_o}$$

For example, P_o is the power emitted from the source fiber in a fiber-to-fiber connection. P_i is the power accepted by the connected fiber. In any fiber optic connection, P_o and P_i are the optical power levels measured before and after the joint, respectively.

Fiber-to-fiber connection loss is affected by intrinsic and extrinsic coupling losses. **Intrinsic coupling losses** are caused by inherent fiber characteristics. **Extrinsic coupling losses** are caused by jointing techniques. Fiber-to-fiber connection loss is increased by the following sources of intrinsic and extrinsic coupling loss:

- Reflection losses
- Fiber separation
- Lateral misalignment
- Angular misalignment
- Core and cladding diameter mismatch
- Numerical aperture (NA) mismatch
- Refractive index profile difference
- Poor fiber end preparation

Intrinsic coupling losses are limited by reducing fiber mismatches between the connected fibers. This is done by procuring only fibers that meet stringent geometrical and optical specifications. Extrinsic coupling losses are limited by following proper connection procedures.

Some fiber optic components are modular devices that are designed to reduce coupling losses between components. Modular components can be easily inserted or removed from any system. For example, fiber optic transmitters and receivers are modular components. Fiber optic transmitters and receivers are devices that are generally manufactured with fiber pigtails or fiber optic connectors as shown in figure 4-1. A **fiber pigtail** is a short length of optical fiber (usually 1 meter or less) permanently fixed to the optical source or detector. Manufacturers supply transmitters and receivers with pigtails and connectors because fiber coupling to sources and detectors must be completed during fabrication. Reduced coupling loss results when source-to-fiber and fiber-to-detector coupling is done in a controlled manufacturing environment. Since optical sources and detectors are pigtailed or connectorized, launching optical power is reduced to coupling light from one fiber to another. In fact, most fiber optic connections can be considered fiber-to-fiber.

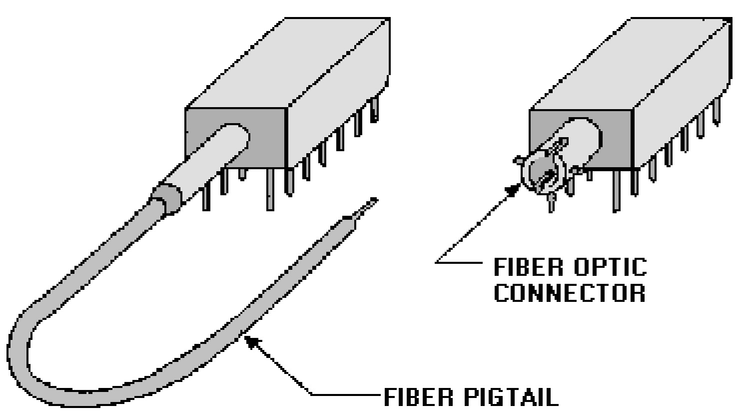


Figure 4-1.—Pigtailed and connectorized fiber optic devices.

Q3. Define the loss in optical power through a connection.

Q4. Fiber-to-fiber coupling loss is affected by intrinsic and extrinsic coupling losses. Can intrinsic coupling losses be limited by limiting fiber mismatches?

REFLECTION LOSSES

When optical fibers are connected, optical power may be reflected back into the source fiber. Light that is reflected back into the source fiber is lost. This reflection loss, called Fresnel reflection, occurs at every fiber interface. **Fresnel reflection** is caused by a step change in the refractive index that occurs at the fiber joint. In most cases, the step change in refractive index is caused by the ends of each fiber being separated by a small gap. This small gap is usually an air gap. In Fresnel reflection, a small portion of the incident light is reflected back into the source fiber at the fiber interface. The ratio (R), shown below, approximates the portion of incident light (light of normal incidence) that is reflected back into the source fiber.

$$R = \left(\frac{n_1 - n_0}{n_1 + n_0} \right)^2$$

R is the fraction of the incident light reflected at the fiber n_1 is the refractive index of the fiber core. n_0 is the refractive index of the medium between the two fibers.

Fresnel refraction occurs twice in a fiber-to-fiber connection. A portion of the optical power is reflected when the light first exits the source fiber. Light is then reflected as the optical signal enters the receiving fiber. Fresnel reflection at each interface must be taken into account when calculating the total fiber-to-fiber coupling loss. Loss from Fresnel reflection may be significant. To reduce the amount of loss from Fresnel reflection, the air gap can be filled with an index matching gel. The refractive index of the index matching gel should match the refractive index of the fiber core. **Index matching gel** reduces the step change in the refractive index at the fiber interface, reducing Fresnel reflection.

In any system, index matching gels can be used to eliminate or reduce Fresnel reflection. The choice of index matching gels is important. Fiber-to-fiber connections are designed to be permanent and require no maintenance. Over the lifetime of the fiber connection, the index matching material must meet specific optical and mechanical requirements. Index matching gels should remain transparent. They should also resist flowing or dripping by remaining viscous. Some index matching gels darken over time while others settle or leak out of fiber connections. If these requirements are not met, then the fiber-to-fiber connection loss will increase over time. In Navy applications, this variation in connection loss over time is unacceptable. In Navy systems, index matching gels are only used in fiber optic splice interfaces.

Q5. In fiber-to-fiber connections, Fresnel reflection is one source of coupling losses. Light is reflected back into the source fiber and is lost. What causes Fresnel reflection?

Q6. Reduction of Fresnel reflection is possible by reducing the step change in the refractive index at the fiber interface. What material reduces the step change in refractive index at a fiber interface?

FIBER ALIGNMENT

A main source of extrinsic coupling loss in fiber-to-fiber connections is poor fiber alignment. The three basic coupling errors that occur during fiber alignment are fiber separation (longitudinal misalignment), lateral misalignment, and angular misalignment. Most alignment errors are the result of mechanical imperfections introduced by fiber jointing techniques. However, alignment errors do result from installers not following proper connection procedures.

With **fiber separation**, a small gap remains between fiber-end faces after completing the fiber connection. Figure 4-2 illustrates this separation of the fiber-end faces.

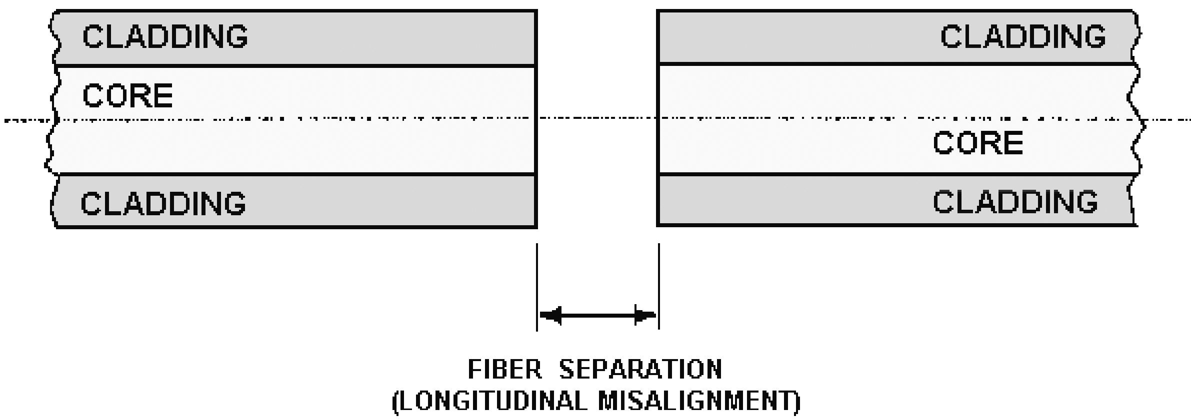

Figure 4-2.—Fiber separation.

Lateral, or axial, misalignment occurs when the axes of the two fibers are offset in a perpendicular direction. Figure 4-3 shows this perpendicular offset of the axes of two connecting fibers.

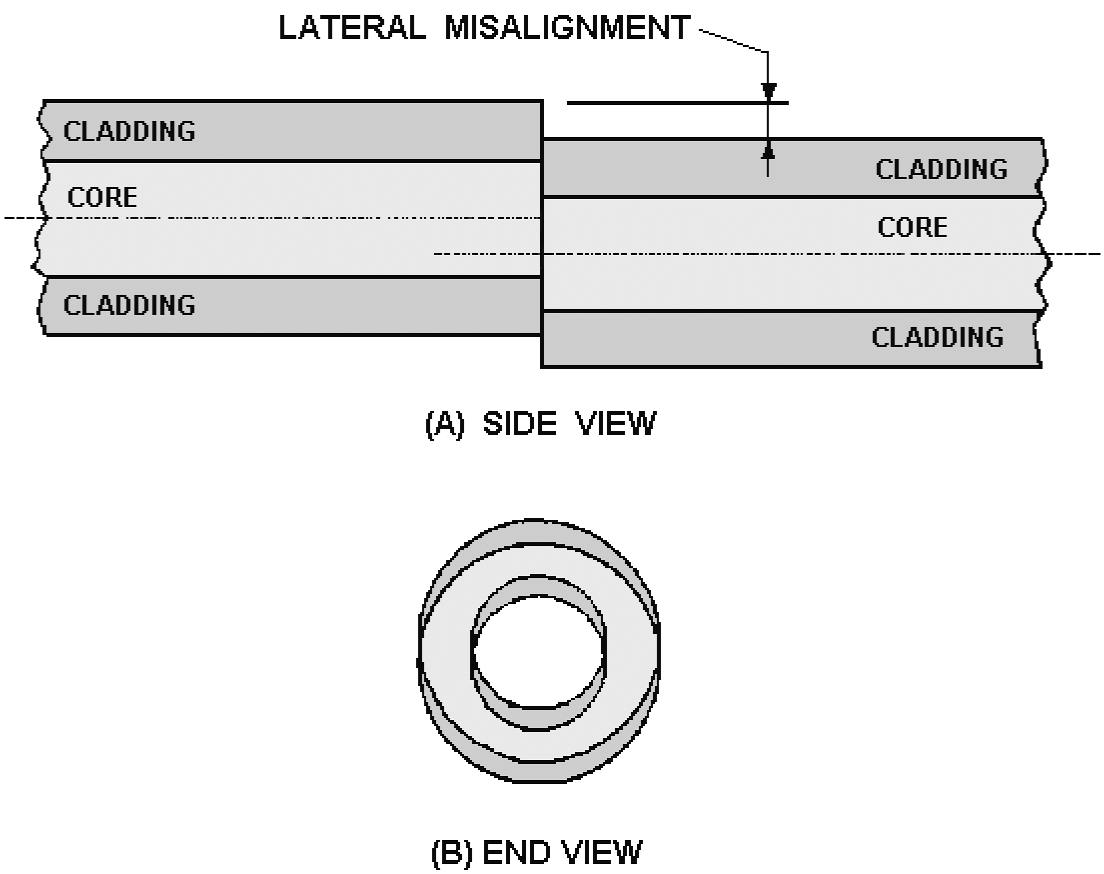

Figure 4-3.—Lateral misalignment.

Angular misalignment occurs when the axes of two connected fibers are no longer parallel. The axes of each fiber intersect at some angle (Θ). Figure 4-4 illustrates the angular misalignment between the core axes.

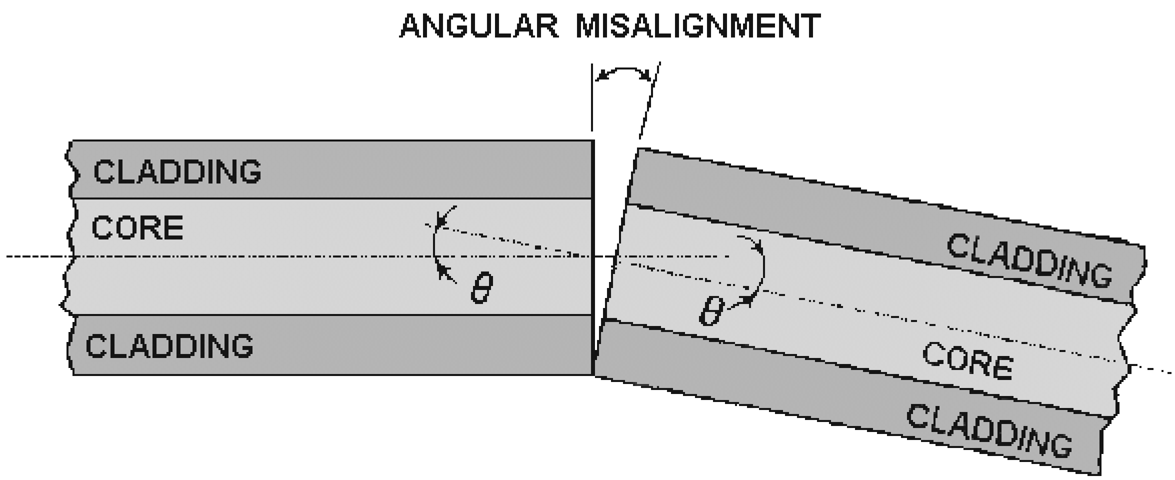

Figure 4-4.—Angular misalignment.

Coupling loss caused by lateral and angular misalignment typically is greater than the loss caused by fiber separation. Loss, caused by fiber separation, is less critical because of the relative ease in limiting the distance of fiber separation. However, in some cases, fiber optic connectors prevent fibers from actual contact. These fiber optic connectors separate the fibers by a small gap. This gap eliminates damage to fiber-end faces during connection. For connectors with an air gap, the use of index matching gel reduces the coupling loss.

Most newer connectors are designed so that the connector ferrule end faces contact when the connector is mated. The connector can be assembled onto the fiber so that the fibers also contact when mated. However, they also can be assembled so that the fibers do not. Whether or not the fibers contact is determined by whether the fiber sticks out slightly from the ferrule or is recessed inside the ferrule. The fiber position can be controlled by the connector polishing technique. The physical contact (PC) polish technique was developed for most connectors so that the fibers would touch when mated. In these types of connectors, index gel is not needed to reduce reflections.

While index matching gel reduces coupling loss from fiber separation, it does not affect loss in lateral misalignment. Additionally, index matching gel usually increases the fiber's coupling loss sensitivity to angular misalignment. Although angular misalignment involves fiber separation, index matching gel reduces the angle at which light is launched from the source fiber. Index matching gel causes less light to be coupled into the receiving fiber. To reduce coupling loss from angular misalignment, the angle Θ should be less than 1º.

Coupling losses due to fiber alignment depend on fiber type, core diameter, and the distribution of optical power among propagating modes. Fibers with large NAs reduce loss from angular misalignment and increase loss from fiber separation. Single mode fibers are more sensitive to alignment errors than multimode fibers because of their small core size. However, alignment errors in multimode fiber connections may disturb the distribution of optical power in the propagating modes, increasing coupling loss.

Q7. List the three basic errors that occur during fiber alignment.

Q8. When the axes of two connected fibers are no longer in parallel, the two connected fibers are in what kind of misalignment?

Q9. How does index matching gel affect the amount of coupling loss caused by (a) fiber separation, (b) lateral misalignment, and (c) angular misalignment?

Q10. Which are more sensitive to alignment errors, single mode or multimode fibers?

FIBER END PREPARATION

In fiber-to-fiber connections, a source of extrinsic coupling loss is poor fiber end preparation. An optical fiber-end face must be flat, smooth, and perpendicular to the fiber's axis to ensure proper fiber connection. Light is reflected or scattered at the connection interface unless the connecting fiber end faces are properly prepared. Figure 4-5 shows some common examples of poor fiber ends. It illustrates a fiber-end face **tilt, lip,** and **hackle**. Quality fiber-end preparation is essential for proper system operation.

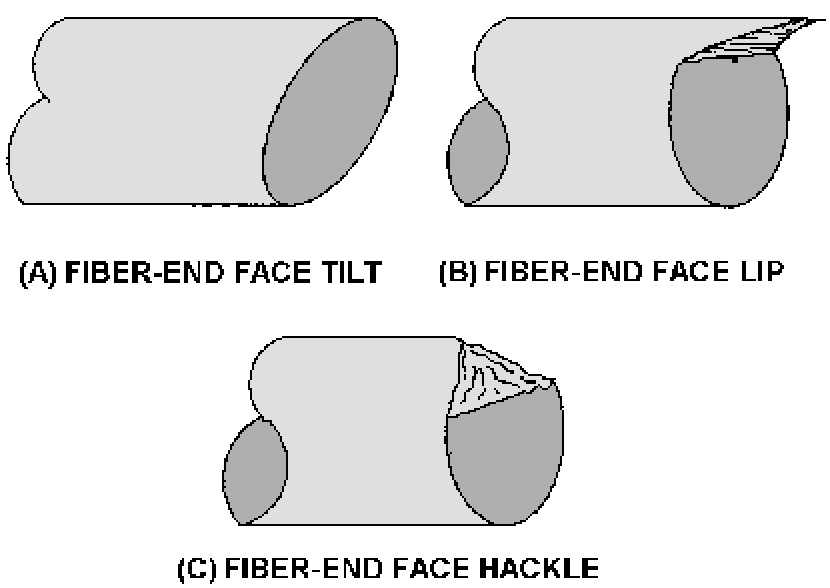

Figure 4-5.—Poor fiber-end preparation.

Fiber-end preparation begins by removing the fiber buffer and coating material from the end of the optical fiber. Removal of these materials involves the use of mechanical strippers or chemical solvents. When using chemical solvents, the removal process must be performed in a well-ventilated area. For this reason mechanical strippers are used for buffer and coating removal in the shipboard environment. After removing the buffer and coating material, the surface of the bare fiber is wiped clean using a wiping tissue. The wiping tissue must be wet with isopropyl alcohol before wiping.

The next step in fiber-end preparation involves cleaving the fiber end to produce a smooth, flat fiber-end face. The **score-and-break**, or scribe-and-break, method is the basic fiber cleaving technique for preparing optical fibers for coupling. The score-and-break method consists of lightly scoring (nicking) the outer surface of the optical fiber and then placing it under tension until it breaks. A heavy metal or diamond blade is used to score the fiber. Once the scoring process is complete, fiber tension is increased until the fiber breaks. The fiber is placed under tension either by pulling on the fiber or by bending the fiber over a curved surface.

Figure 4-6 shows the setup for the score-and-break procedure for fiber cleaving. Under constant tension, the score-and-break method for cleaving fibers produces a quality fiber end. This fiber end is good enough to use for some splicing techniques. However, additional fiber-end preparation is necessary to produce reliable low-loss connections when using fiber optic connectors.

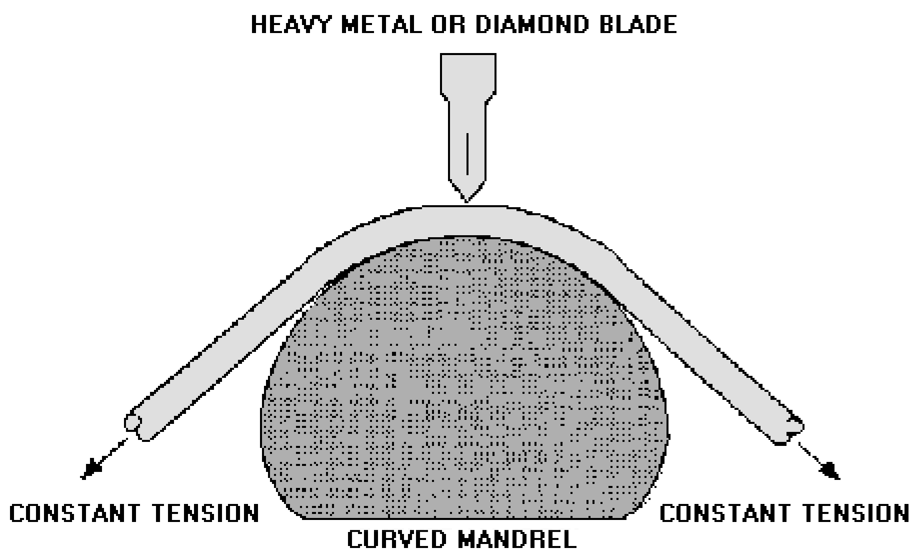

Figure 4-6.—Score-and-break procedure for fiber cleaving.

Polishing the fiber ends removes most surface imperfections introduced by the fiber cleaving process. Fiber polishing begins by inserting the cleaved fiber into the ferrule of a connector assembly. A ferrule is a fixture, generally a rigid tube, used to hold the stripped end of an optical fiber in a fiber optic connector. An individual fiber is epoxied within the ferrule. The connector with the optical fiber cemented within the ferrule can then be mounted into a special polishing tool for polishing.

Figure 4-7 shows one type of fiber polishing tool for finishing optical fibers in a connector assembly. Various types of connector assemblies are discussed later in this chapter. In this type of polishing tool, the connector assembly is threaded onto the polishing tool. The connector ferrule passes through the center of the tool allowing the fiber-end face to extend below the tool's circular, flat bottom. The optical fiber is now ready for polishing.

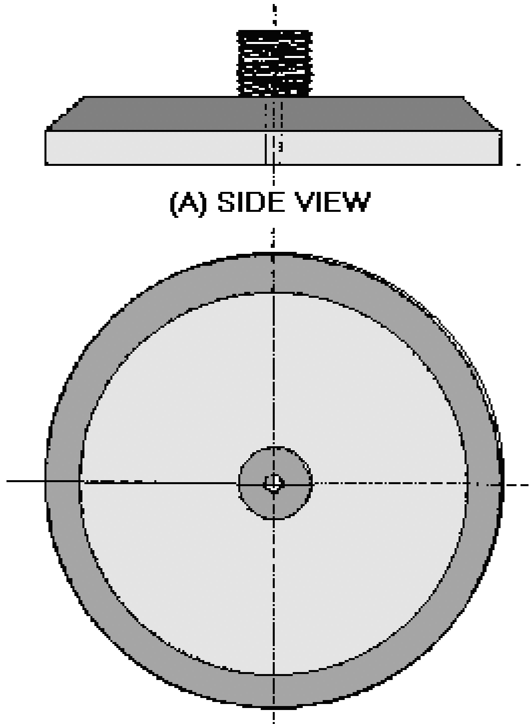

Figure 4-7.—Fiber polishing tool.

Fiber polishing involves a step-down approach. The first step is to give the surface of the fiber end a rough polish. **Rough-polishing** occurs when the fiber, mounted to the polishing tool, moves over a 5μ to 15μ grit abrasive paper. The mounted fiber moves over the abrasive paper in a figure-eight motion. The next step involves giving the surface of the fiber end a fine polish. **Fine-polishing** occurs when the mounted fiber moves over a 0.3μto 1μ grit abrasive paper in the same figure-eight motion. Fiber inspection and cleanliness are important during each step of fiber polishing. Fiber inspection is done visually by the use of a standard microscope at 200 to 400 times magnification.

A standard microscope can be used to determine if the fiber-end face is flat, concave, or convex. If different parts of the fiber-end face have different focus points, the end face is not flat. If all parts of the fiber-end face are in focus at the same time, the end face is flat.

Q11. Quality fiber-end preparation is essential for proper system operation. What properties must an optical fiber-end face have to ensure proper fiber connection?

Q12. What is the basic fiber cleaving technique for preparing optical fibers for coupling?

Q13. Using a standard microscope to inspect a fiber-end face, you observe that all parts of the fiber-end face are in focus at the same time. Is the fiber-end face flat, concave, or convex?

FIBER MISMATCHES

Fiber mismatches are a source of intrinsic coupling loss. As stated before, intrinsic coupling loss results from differences (mismatches) in the inherent fiber characteristics of the two connecting fibers. Fiber mismatches occur when manufacturers fail to maintain optical or structural (geometrical) tolerances during fiber fabrication.

Fiber mismatches are the result of inherent fiber characteristics and are independent of the fiber jointing techniques. Types of fiber mismatches include fiber geometry mismatches, NA mismatch, and refractive index profile difference. Fiber geometry mismatches include core diameter, cladding diameter, core ellipticity, and core-cladding concentricity differences. Figure 4-8 illustrates each type of optical and geometrical fiber mismatch. Navy fiber specifications tightly specify these parameters to minimize coupling losses from fiber mismatches.

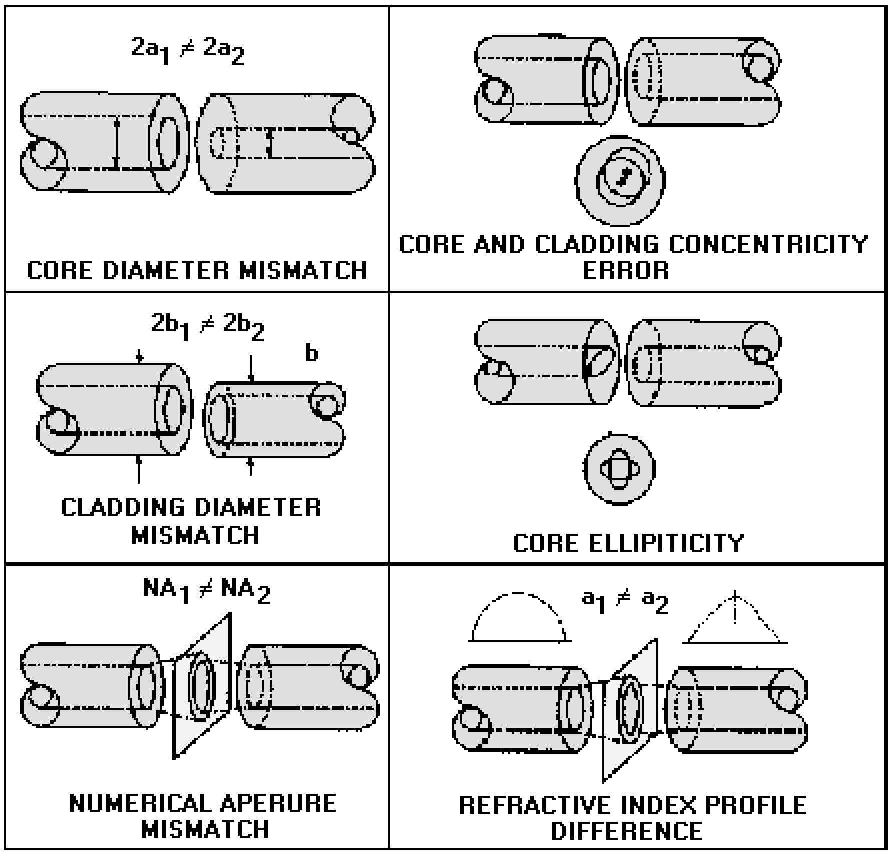

Figure 4-8.—Types of optical and geometrical fiber mismatches that cause intrinsic coupling loss.

Core diameter and NA mismatch have a greater effect on intrinsic coupling loss than the other types of fiber mismatches. In multimode fiber connections, the coupling loss resulting from core diameter mismatch, NA mismatch, and refractive index profile difference depends on the characteristics of the launching fiber. Coupling loss from **core diameter mismatch** results only if the launching fiber has a larger core radius (a) than the receiving fiber. Coupling loss from **NA mismatch** results only if the launching fiber has a higher NA than the receiving fiber. Coupling loss from **refractive index profile difference** results only if the launching fiber has a larger profile parameter (α) than the receiving fiber.

Q14. List six types of fiber mismatches.

Q15. Does coupling loss from refractive index profile difference result when the receiving fiber has a larger profile parameter (α) than the transmitting fiber?

FIBER OPTIC SPLICES

A **fiber optic splice** is a permanent fiber joint whose purpose is to establish an optical connection between two individual optical fibers. System design may require that fiber connections have specific optical properties (low loss) that are met only by fiber-splicing. Fiber optic splices also permit repair of optical fibers damaged during installation, accident, or stress. System designers generally require fiber splicing whenever repeated connection or disconnection is unnecessary or unwanted.

Mechanical and fusion splicing are two broad categories that describe the techniques used for fiber splicing. A **mechanical splice** is a fiber splice where mechanical fixtures and materials perform fiber alignment and connection. A **fusion splice** is a fiber splice where localized heat fuses or melts the ends of two optical fibers together. Each splicing technique seeks to optimize splice performance and reduce splice loss. Low-loss fiber splicing results from proper fiber end preparation and alignment.

Fiber splice alignment can involve passive or active fiber core alignment. Passive alignment relies on precision reference surfaces, either grooves or cylindrical holes, to align fiber cores during splicing. Active alignment involves the use of light for accurate fiber alignment. Active alignment may consist of either monitoring the loss through the splice during splice alignment or by using a microscope to accurately align the fiber cores for splicing. To monitor loss either an optical source and optical power meter or an optical time domain reflectometer (OTDR) are used. Active alignment procedures produce low-loss fiber splices.

Q16. Define a fiber optic splice.

Q17. Fiber splicing is divided into two broad categories that describe the techniques used for fiber splicing. What are they?

MECHANICAL SPLICES

Mechanical splicing involves using mechanical fixtures to align and connect optical fibers. Mechanical splicing methods may involve either passive or active core alignment. Active core alignment produces a lower loss splice than passive alignment. However, passive core alignment methods can produce mechanical splices with acceptable loss measurements even with single mode fibers.

In the strictest sense, a mechanical splice is a permanent connection made between two optical fibers. Mechanical splices hold the two optical fibers in alignment for an indefinite period of time without movement. The amount of splice loss is stable over time and unaffected by changes in environmental or mechanical conditions.

If high splice loss results from assembling some mechanical splices, the splice can be reopened and the fibers realigned. Realignment includes wiping the fiber or ferrule end with a soft wipe, reinserting the fiber or ferrule in a new arrangement, and adding new refractive index material. Once producing an acceptable mechanical splice, splice realignment should be unnecessary because most mechanical splices are environmentally and mechanically stable within their intended application.

The types of mechanical splices that exist for mechanical splicing include glass, plastic, metal, and ceramic tubes; and V-groove and rotary devices. Materials that assist mechanical splices in splicing fibers include transparent adhesives and index matching gels. **Transparent adhesives** are epoxy resins that seal mechanical splices and provide index matching between the connected fibers.

Glass or Ceramic Alignment Tube Splices

Mechanical splicing may involve the use of a glass or ceramic alignment tube, or capillary. The inner diameter of this glass or ceramic tube is only slightly larger than the outer diameter of the fiber. A transparent adhesive, injected into the tube, bonds the two fibers together. The adhesive also provides index matching between the optical fibers. Figure 4-9 illustrates fiber alignment using a glass or ceramic tube. This splicing technique relies on the inner diameter of the alignment tube. If the inner diameter is too large, splice loss will increase because of fiber misalignment. If the inner diameter is too small, it is impossible to insert the fiber into the tube.

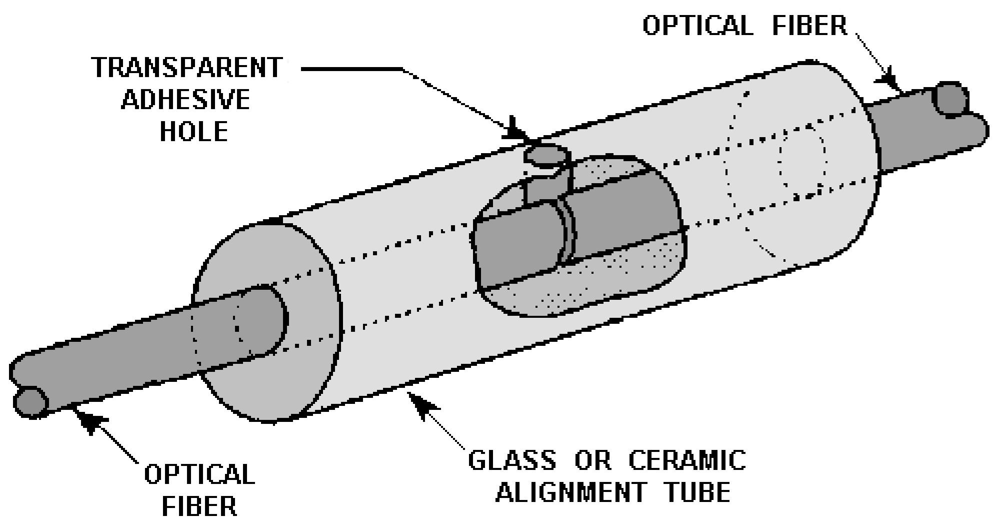

Figure 4-9.—A glass or ceramic alignment tube for mechanical splicing.

V-Grooved Splices

Mechanical splices may also use either a grooved substrate or positioning rods to form suitable V-grooves for mechanical splicing. The basic V-grooved device relies on an open grooved substrate to perform fiber alignment. When inserting the fibers into the grooved substrate, the V-groove aligns the cladding surface of each fiber end. A transparent adhesive makes the splice permanent by securing the fiber ends to the grooved substrate. Figure 4-10 illustrates this type of open V-grooved splice.

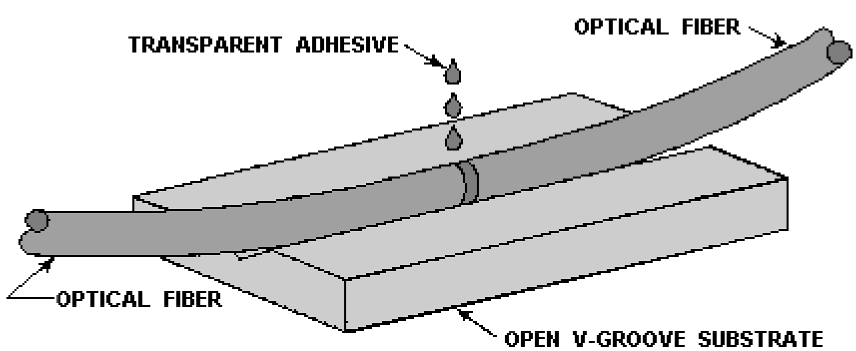

Figure 4-10.—Open V-grooved splice.

V-grooved splices may involve sandwiching the butted ends of two prepared fibers between a V-grooved substrate and a flat glass plate. Additional V-grooved devices use two or three positioning rods to form a suitable V-groove for splicing. The V-grooved device that uses two positioning rods is the spring V-grooved splice. This splice uses a groove formed by two rods positioned in a bracket to align the fiber ends. The diameter of the positioning rods permits the outer surface of each fiber end to extend above the groove formed by the rods. A flat spring presses the fiber ends into the groove maintaining fiber alignment. Transparent adhesive completes the assembly process by bonding the fiber ends and providing index matching. Figure 4-11 is an illustration of the spring V-grooved splice. A variation of this splice uses a third positioning rod instead of a flat spring. The rods are held in place by a heat-shrinkable band, or tube.

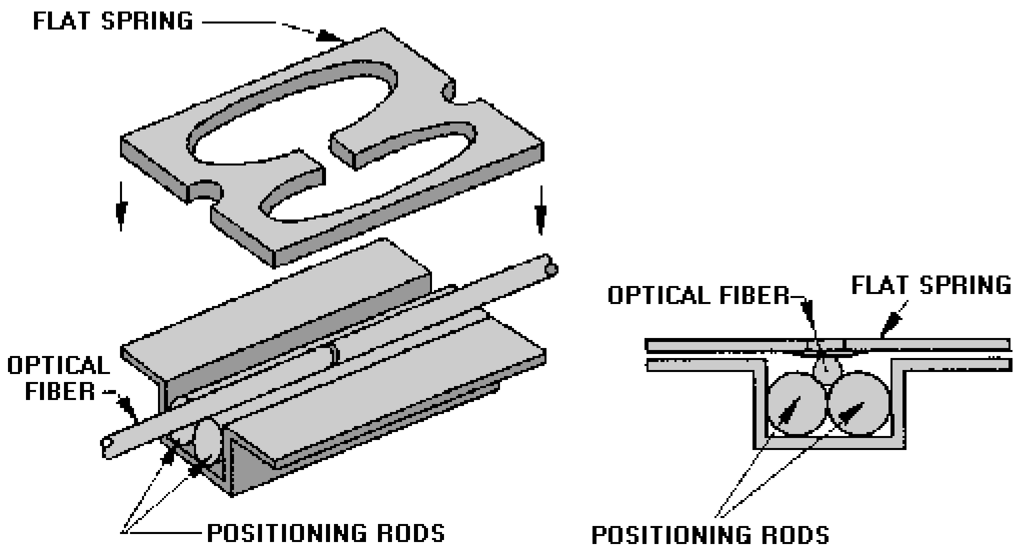

Figure 4-11.—Spring V-grooved mechanical splice.

Rotary Splices

In a rotary splice, the fibers are mounted into a glass ferrule and secured with adhesives. The splice begins as one long glass ferrule that is broken in half during the assembly process. A fiber is inserted into each half of the tube and epoxied in place using an ultraviolet cure epoxy. The endface of the tubes are then polished and placed together using the alignment sleeve. Figure 4-12 is an illustration of a rotary splice. The fiber ends retain their original orientation and have added mechanical stability since each fiber is mounted into a glass ferrule and alignment sleeve. The rotary splice may use index matching gel within the alignment sleeve to produce low-loss splices.

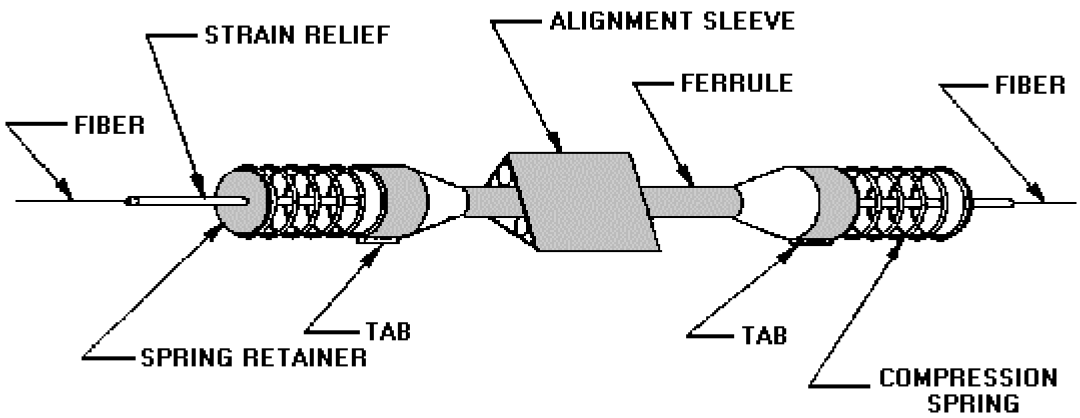

Figure 4-12.—Rotary mechanical splice.

In shipboard applications, the Navy recommends using the rotary splice. The rotary splice is a low-loss mechanical splice that provides stable environmental and mechanical performance in the Navy environment. Stable performance means that splice loss does not vary significantly with changes in temperature or other environmental or mechanical conditions. Completing a rotary splice also requires only a small amount of training, or expertise. This shorter training time is another reason why the Navy recommends using the rotary splice over other mechanical or fusion splicing techniques.

Q18. Describe a transparent adhesive.

Q19. The Navy recommends using the rotary splice for what two reasons?

FUSION SPLICES

The process of fusion splicing involves using localized heat to melt or fuse the ends of two optical fibers together. The splicing process begins by preparing each fiber end for fusion. Fusion splicing requires that all protective coatings be removed from the ends of each fiber. The fiber is then cleaved using the score-and-break method. The quality of each fiber end is inspected using a microscope. In fusion splicing, splice loss is a direct function of the angles and quality of the two fiber-end faces.

The basic fusion splicing apparatus consists of two fixtures on which the fibers are mounted and two electrodes. Figure 4-13 shows a basic fusion-splicing apparatus. An inspection microscope assists in the placement of the prepared fiber ends into a fusion-splicing apparatus. The fibers are placed into the apparatus, aligned, and then fused together. Initially, fusion splicing used nichrome wire as the heating element to melt or fuse fibers together. New fusion-splicing techniques have replaced the nichrome wire with carbon dioxide (CO_2) lasers, electric arcs, or gas flames to heat the fiber ends, causing them to fuse together. The small size of the fusion splice and the development of automated fusion-splicing machines have made **electric arc fusion** (arc fusion) one of the most popular splicing techniques in commercial applications.

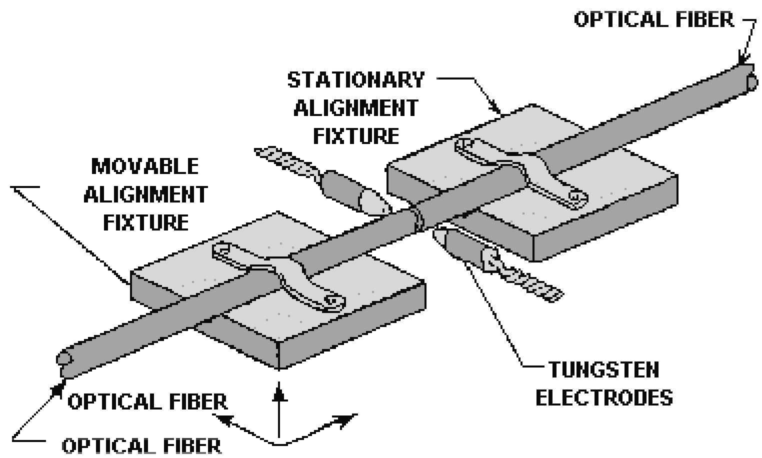

Figure 4-13.—A basic fusion splicing apparatus.

Arc fusion involves the discharge of electric current across a gap between two electrodes. By placing the fiber ends between the electrodes, the electric discharge melts or fuses the ends of each fiber. Figure 4-13 shows the placement of the fiber ends between tungsten electrodes during arc fusion. Initially, a small gap is present between the fiber ends. A short discharge of electric current is used to prepare the fiber ends for fusion. During this short discharge, known as **prefusion**, the fiber ends are cleaned and rounded to eliminate any surface defects that remain from fiber cleaving. Surface defects can cause core distortions or bubble formations during fiber fusion. A fusion splice results when the fiber ends are pressed together, actively aligned, and fused using a longer and stronger electric discharge. Automated fusion splicers typically use built-in local optical power launch/detection schemes for aligning the fibers.

During fusion, the surface tension of molten glass tends to realign the fibers on their outside diameters, changing the initial alignment. When the fusion process is complete, a small core distortion may be present. Small core distortions have negligible effects on light propagating through multimode fibers. However, a small core distortion can significantly affect single mode fiber splice loss. The core distortion, and the splice loss, can be reduced by limiting the arc discharge and decreasing the gap distance between the two electrodes. This limits the region of molten glass. However, limiting the region of molten glass reduces the tensile strength of the splice.

Fusion splicing yields typically vary between 25 and 75 percent depending on the strength and loss requirements for the splice and other factors. Other factors affecting splice yields include the condition of the splicing machine, the experience of the splice personnel, and environmental conditions. Since fusion splicing is inherently permanent, an unacceptable fusion splice requires breakage and refabrication of the splice.

In general, fusion splicing takes a longer time to complete than mechanical splicing. Also, yields are typically lower making the total time per successful splice much longer for fusion splicing. Both the yield and splice time are determined to a large degree by the expertise of the fusion splice operator. Fusion splice operators must be highly trained to consistently make low-loss reliable fusion splices. For these reasons the fusion splice is not recommended for use in Navy shipboard applications.

Q20. What fiber property directly affects splice loss in fusion splicing?

Q21. List two reasons why fusion splicing is one of the most popular splicing techniques in commercial applications.

Q22. What is a short discharge of electric current that prepares the fiber ends for fusion called?

Q23. Do small core distortions formed by arc fusion's self-alignment mechanism have more of an affect on light propagating through multimode or single mode fibers?

MULTIFIBER SPLICING

Normally, multifiber splices are only installed on ribbon type fiber optic cables. Multifiber splicing techniques can use arc fusion to restore connection, but most splicing techniques use mechanical splicing methods. The most common mechanical splice is the ribbon splice.

A ribbon splice uses an etched silicon chip, or grooved substrate, to splice the multiple fibers within a flat ribbon. The spacing between the etched grooves of the silicon chip is equal to the spacing between the fibers in the flat ribbon. Before placing each ribbon on the etched silicon chip, each fiber within the ribbon cable is cleaved. All of the fibers are placed into the grooves and held in place with a flat cover. Typically, an index matching gel is used to reduce the splice loss. Figure 4-14 shows the placement of the fiber ribbon on the etched silicon chip.

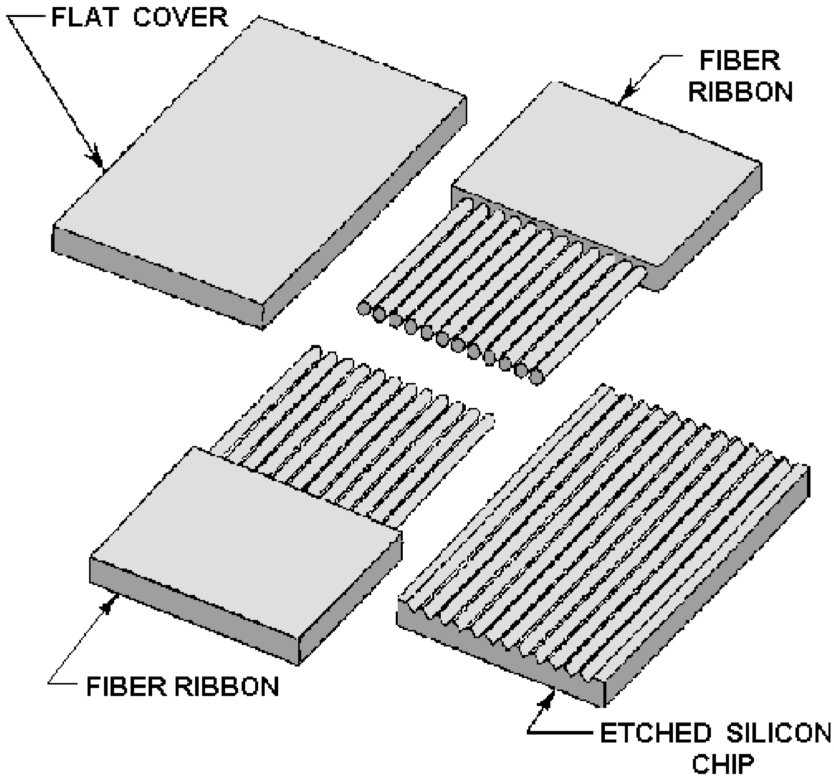

Figure 4-14.—Ribbon splice on etched silicon chip.

FIBER OPTIC CONNECTORS

A fiber optic connector is a demateable device that permits the coupling of optical power between two optical fibers or two groups of fibers. Designing a device that allows for repeated fiber coupling without significant loss of light is difficult. Fiber optic connectors must maintain fiber alignment and provide repeatable loss measurements during numerous connections. Fiber optic connectors should be easy to assemble (in a laboratory or field environment) and should be cost effective. They should also be reliable. Fiber optic connections using connectors should be insensitive to environmental conditions, such as temperature, dust, and moisture. Fiber optic connector designs attempt to optimize connector performance by meeting each of these conditions.

Fiber optic connector coupling loss results from the same loss mechanisms described earlier in this chapter. Coupling loss results from poor fiber alignment and end preparation (extrinsic losses), fiber mismatches (intrinsic loss), and Fresnel reflection. The total amount of insertion loss for fiber optic connectors should remain below 1 dB. Fiber alignment is the critical parameter in maintaining the total insertion loss below the required level. There is only a small amount of control over coupling loss resulting from fiber mismatches, because the loss results from inherent fiber properties. Index matching gels cannot be used to reduce Fresnel losses, since the index matching gels attract dust and dirt to the connection.

Fiber optic connectors can also reduce system performance by introducing modal and reflection noise. The cause of modal noise in fiber optic connectors is the interfering of the different wavefronts of different modes within the fiber at the connector interface. Modal noise is eliminated by using only single mode fiber with laser sources and only low-coherence sources such as light-emitting diodes with multimode fiber. Fiber optic connectors can introduce reflection noise by reflecting light back into the optical source. Reflection noise is reduced by index matching gels, physical contact polishes, or antireflection coatings. Generally, reflection noise is only a problem in high data rate single mode systems using lasers.

Butt-jointed connectors and **expanded-beam connectors** are the two basic types of fiber optic connectors. Fiber optic **butt-jointed connectors** align and bring the prepared ends of two fibers into close contact. The end-faces of some butt-jointed connectors touch, but others do not depending upon the connector design. Types of butt-jointed connectors include cylindrical ferrule and biconical connectors. Fiber optic **expanded-beam connectors** use two lenses to first expand and then refocus the light from the transmitting fiber into the receiving fiber. Single fiber butt-jointed and expanded beam connectors normally consist of two plugs and an adapter (coupling device). Figure 4-15 shows how to configure each plug and adapter when making the connection between two optical fibers.

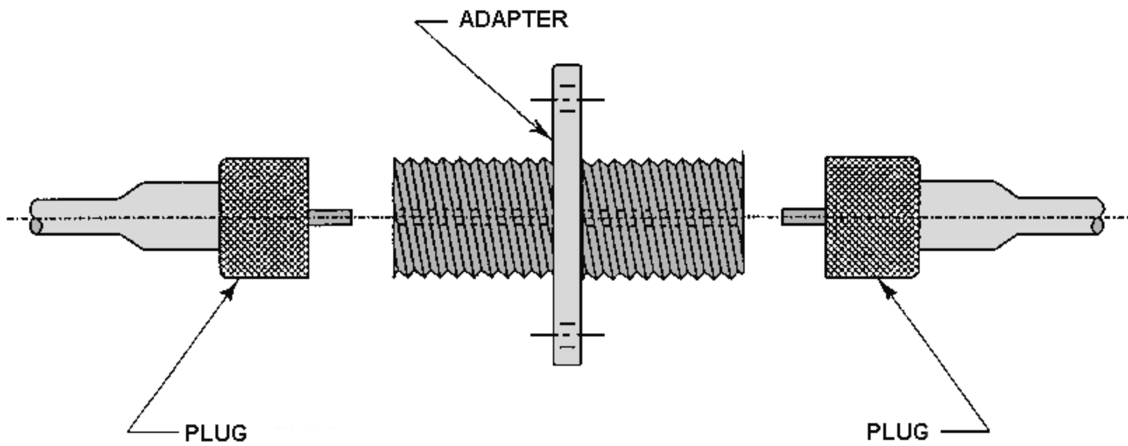

Figure 4-15.—Plug-adapter-plug configuration.

Ferrule connectors use two cylindrical plugs (referred to as ferrules), an alignment sleeve, and sometimes axial springs to perform fiber alignment. Figure 4-16 provides an illustration of this basic ferrule connector design. Precision holes drilled or molded through the center of each ferrule allow for fiber insertion and alignment. Precise fiber alignment depends on the accuracy of the central hole of each ferrule. When the fiber ends are inserted, an adhesive (normally an epoxy resin) bonds the fiber inside the ferrule. The fiber-end faces are polished until they are flush with the end of the ferrule to achieve a low-loss fiber connection. Fiber alignment occurs when the ferrules are inserted into the alignment sleeve. The inside diameter of the alignment sleeve aligns the ferrules, which in turn align the fibers. Ferrule connectors lock the ferrules in the alignment sleeve using a threaded outer shell or some other type of coupling mechanism.

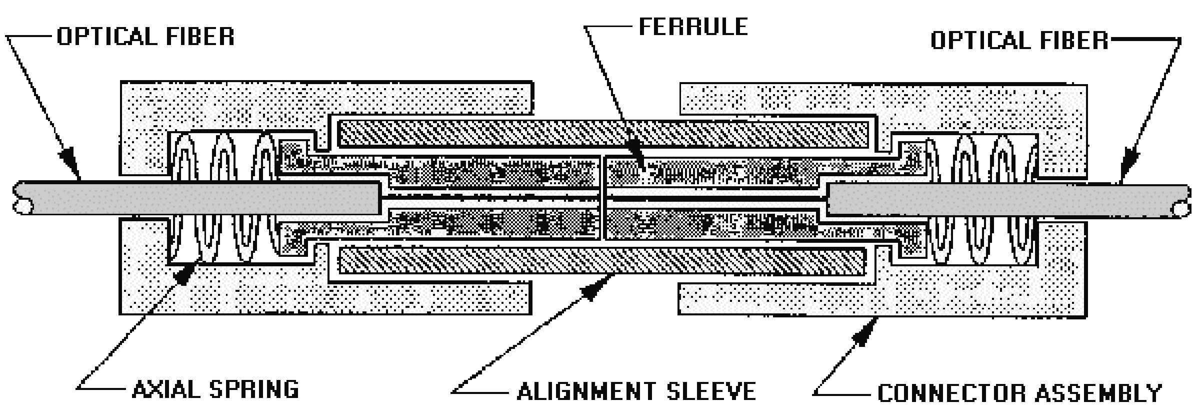

Figure 4-16.—Basic ferrule connector design.

As stated before, fiber alignment depends on an accurate hole through the center of the ferrule. Normally, ferrule connectors use ceramic or metal ferrules. The center hole is generally drilled in a metal ferrule. Drilling an accurate hole through the entire metal ferrule can be difficult. To improve fiber alignment, some metal ferrule connectors use precision watch-jeweled centering. In precision watch-jeweled centering, a watch jewel with a precision centered hole is placed in the tip of the ferrule. The central hole of the watch jewel centers the fiber with respect to the axis of the cylindrical ferrule. The watch jewel provides for better fiber alignment, because regulating the hole tolerance of the watch jewel is easier than maintaining a precise hole diameter when drilling through an entire ferrule.

The center hole in a ceramic ferrule is created by forming the ferrule around a precision wire, which is then removed. This method produces holes accurately centered in the ferrule. Most cylindrical ferrule connectors now use ceramic ferrules. The Straight Tip (ST® connector is an example of a ceramic ferrule connector. (ST is a registered trademark of AT&T.)

Other cylindrical ferrule connectors have a ferrule that contains both metal and ceramic. For these connectors a ceramic capillary is placed within the tip of a metal ferrule to provide for precision fiber alignment. The ceramic capillary is a ceramic tube with a small inner diameter that is just larger than the diameter of the fiber. Figure 4-17 shows the placement of the ceramic capillary within the metal ferrule.

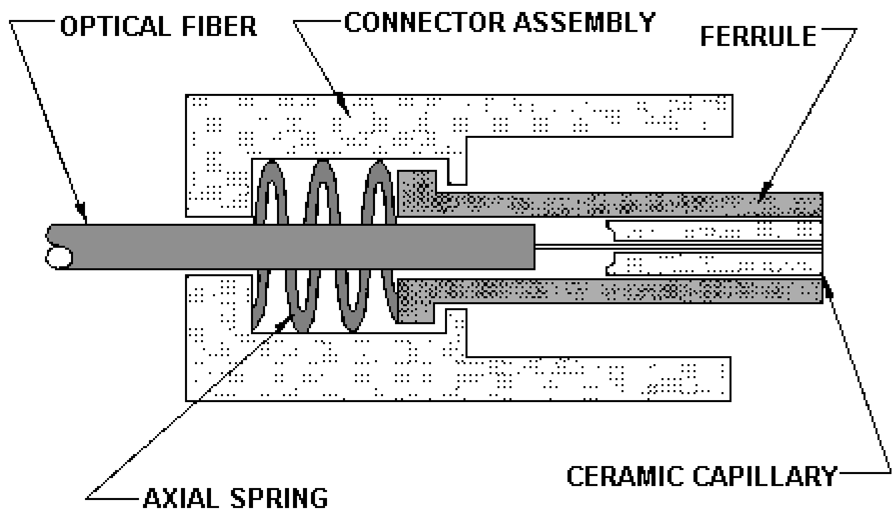

Figure 4-17.—A ceramic capillary set within a metal ferrule.

Another type of butt-jointed connector is the biconical connector. Biconical connectors use two conical plugs, a double conical alignment sleeve, and axial springs to perform fiber alignment. Figure 4-18 is an illustration of this basic biconical connector design. Formation of the plugs and alignment sleeve involves transfer molding. Transfer molding uses silica-filled epoxy resin to mold the conical plug directly to the fiber or around a cast (precision wire). After connecting the conical plugs to the optical fibers, the fiber-end faces are polished before the plugs are inserted into the molded alignment sleeve. During fiber insertion, the inside surface of the double conical sleeve performs fiber alignment, while the axial springs push the fiber ends into close contact. If the alignment sleeve permits the fibers to actually become in contact, then the axial spring provides enough force to maintain fiber contact but prevent damage to the fiber-end faces. Normally, biconical connectors lock the fibers in alignment using a threaded outer shell.

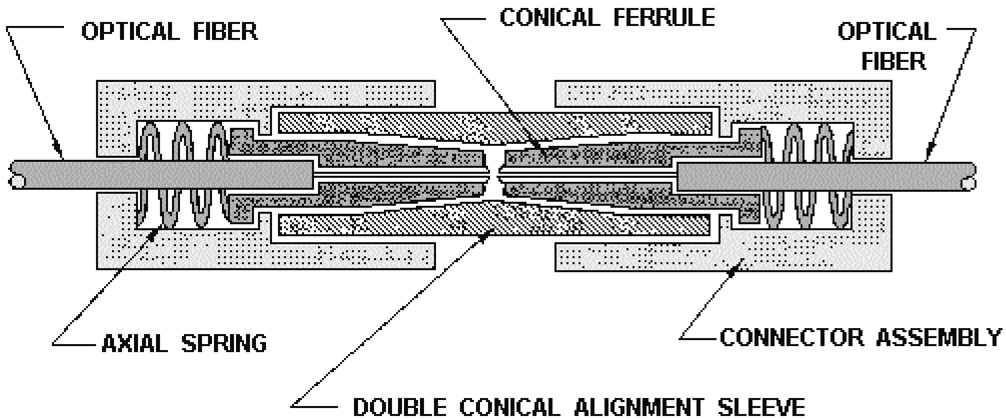

Figure 4-18.—Biconical connector design.

Multifiber connectors join and align multifiber cables to reduce the time it takes to connect multiple fibers. One type of multifiber connector is the array connector. The array connector is used to connect individual ribbons of ribbon-type cables. The array connector is similar to the ribbon splice. In the array connector, the fibers of each ribbon are epoxied into grooves of a silicon chip so that the fiber ends protrude from the end of the chip. The chip and the protruding fibers are polished flat for connection. Each half of the connector is prepared separately before being butt-jointed. A spring clip and two grooved metal-backed plates are used to align and connect the stacked ribbons of the two ribbon cables. Array connectors may also use an alignment sleeve with V-grooved silicon chips and metal springs to align and connect stacked ribbons. Figure 4-19 shows the spring clip method of array connector alignment. The multifiber array connector is only one example of a multiple connector. Many types of multiple connectors exist that connect different types of multifiber cables.

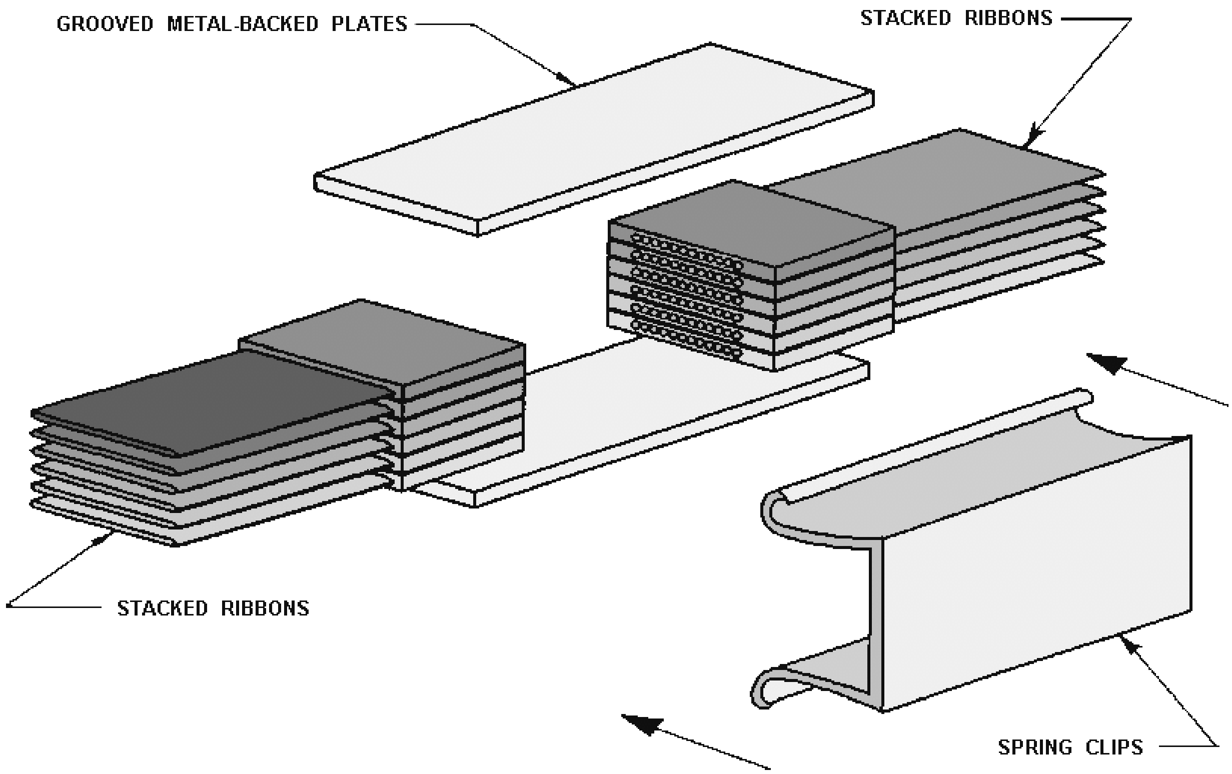

Figure 4-19.—Spring clip method of ribbon connection.

Figure 4-20 shows how an expanded-beam connector uses two lenses to expand and then refocus the light from the transmitting fiber into the receiving fiber. Expanded-beam connectors are normally plug-adapter-plug type connections. Fiber separation and lateral misalignment are less critical in expanded-beam coupling than in butt-jointing. The same amount of fiber separation and lateral misalignment in expanded beam coupling produces a lower coupling loss than in butt-jointing. However, angular misalignment is more critical. The same amount of angular misalignment in expanded-beam coupling produces a higher loss than in butt-jointing. Expanded-beam connectors are also much harder to produce. Present applications for expanded-beam connectors include multifiber connections, edge connections for printed circuit boards, and other applications.

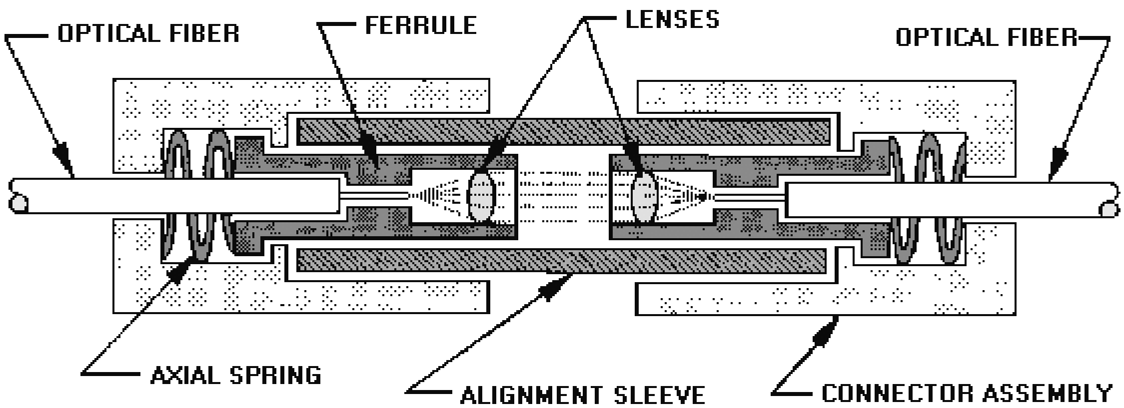

Figure 4-20.—Expanded-beam connector operation.

Q24. What connection properties result in fiber optic connector coupling loss?

Q25. Which is the more critical parameter in maintaining total insertion loss below the required level, fiber alignment or fiber mismatch?

Q26. Fiber optic connectors can reduce system performance by increasing what two types of noise?

Q27. Which type of fiber optic connector (butt-jointed or expanded beam) brings the prepared ends of two optical fibers into close contact?

Q28. Is coupling loss from fiber separation and lateral misalignment more critical in expanded-beam or butt-jointed connectors?

Q29. Is coupling loss from angular misalignment more critical in expanded beam or butt-jointed connectors?

MILITARY CONNECTORS

Light-duty connectors and **heavy-duty connectors** are two ways that the Navy classifies fiber optic connectors. Light-duty connector shipboard applications include locations that protect the connectors from the environment, such as in a junction box or equipment enclosure. Heavy-duty applications require a very rugged, stand-alone, sealed connector. A heavy-duty connector must also withstand pulls and tugs on the fiber cable without disrupting system operation. Light-duty connectors can be of the ferrule, biconical, or expanded-beam designs. Ferrule-type ST® connectors are becoming the commercial connector of choice for local area network (LAN) and data transfer links and are the standard connector for Navy light duty applications. This connector is described in specification sheets 16, 17, and 18 of MIL-C-83522. Figure 4-21 shows the ST type of light-duty connector.

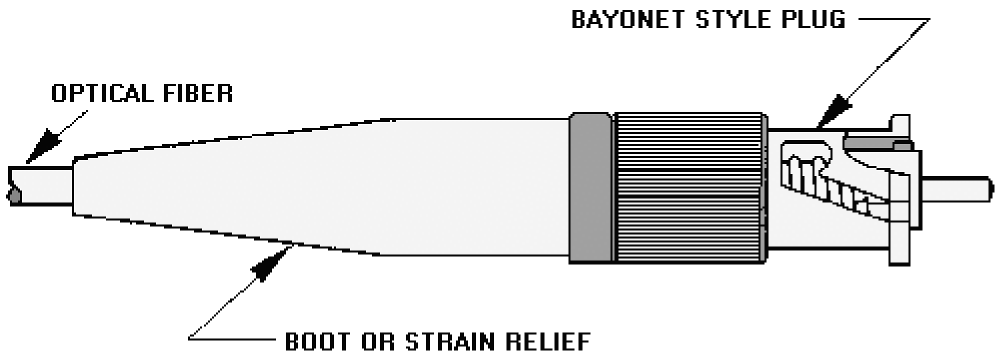

Figure 4-21.—ST light-duty connector.

Figure 4-22 shows one type of heavy-duty connector designed for use in harsh Navy environments. This connector is described by the military specification MIL-C-28876. This connector comes in various sizes capable of terminating 2, 4, 6, or 8 fibers. Each fiber termination, called a terminus, is of the cylindrical ferrule type. Two slightly different termini are used to form a connection; a pin terminus and a socket terminus. The pin terminus consists of a terminus body, which holds the terminus within the connector shell and a ceramic ferrule. The socket terminus consists of a terminus body, a ceramic ferrule, and an alignment sleeve, which attaches to the ceramic ferrule. Fiber alignment occurs when the pin terminus slides into the alignment sleeve of the socket terminus. The termini are held within an insert in the connector shell. When the connector halves are mated, the connector inserts align the mating termini, which then align the mating fibers. The connector shell and backshell protect the termini from the surrounding environment and provide strain relief for the multifiber cable.

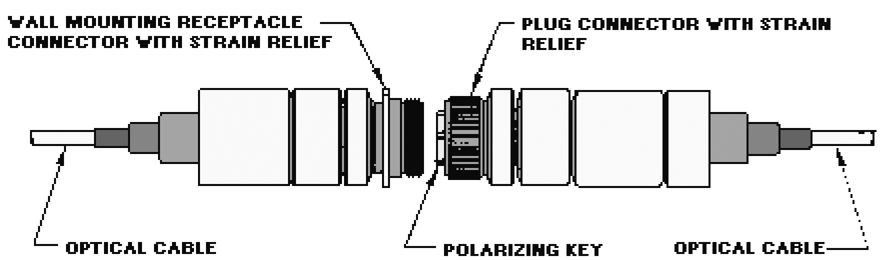

Figure 4-22.—MIL-C-28876 heavy-duty connector.

Q30. The Navy classifies fiber optic connectors in what two ways?

FIBER OPTIC COUPLERS

Some fiber optic data links require more than simple point-to-point connections. These data links may be of a much more complex design that requires multi-port or other types of connections. Figure 4-23 shows some example system architectures that use more complex link designs. In many cases these types of systems require fiber optic components that can redistribute (combine or split) optical signals throughout the system.

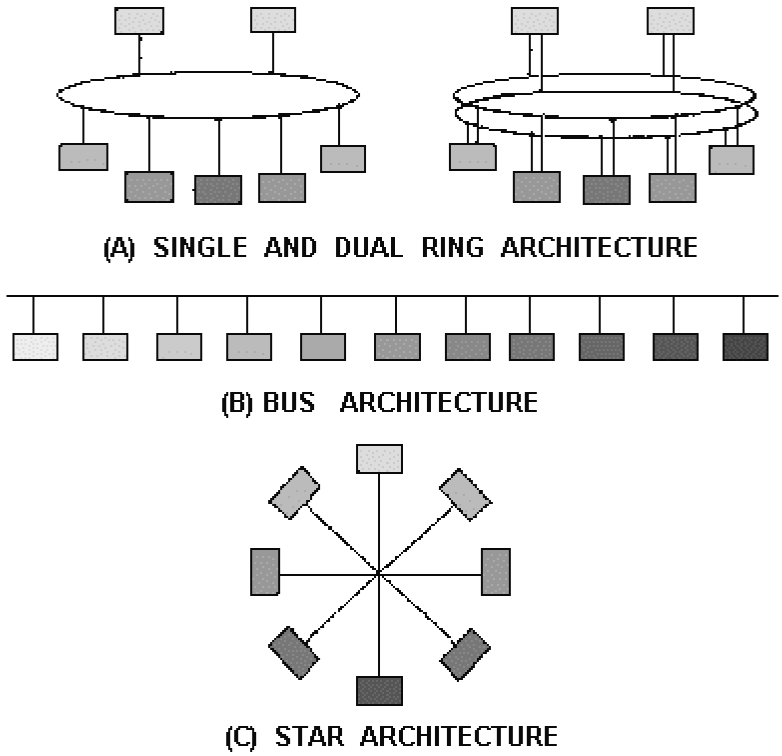

Figure 4-23.—Examples of complex system architectures.

One type of fiber optic component that allows for the redistribution of optical signals is a fiber optic coupler. A fiber optic coupler is a device that can distribute the optical signal (power) from one fiber among two or more fibers. A fiber optic coupler can also combine the optical signal from two or more fibers into a single fiber. Fiber optic couplers attenuate the signal much more than a connector or splice because the input signal is divided among the output ports. For example, with a 1×2 fiber optic coupler, each output is less than one-half the power of the input signal (over a 3 dB loss).

Fiber optic couplers can be either active or passive devices. The difference between active and passive couplers is that a **passive coupler** redistributes the optical signal without optical-to-electrical conversion. Active couplers are electronic devices that split or combine the signal electrically and use fiber optic detectors and sources for input and output.

Figure 4-24 illustrates the design of a basic fiber optic coupler. A basic fiber optic coupler has N input ports and M output ports. N and M typically range from 1 to 64. The number of input ports and output ports vary depending on the intended application for the coupler. Types of fiber optic couplers include optical splitters, optical combiners, X couplers, star couplers, and tree couplers.

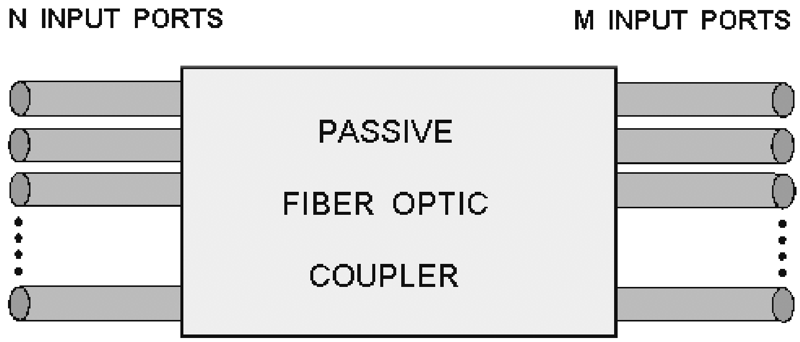

Figure 4-24.—Basic passive fiber optic coupler design.

An **optical splitter** is a passive device that splits the optical power carried by a single input fiber into two output fibers. Figure 4-25 illustrates the transfer of optical power in an optical splitter. The input optical power is normally split evenly between the two output fibers. This type of optical splitter is known as a **Y-coupler**. However, an optical splitter may distribute the optical power carried by input power in an uneven manner. An optical splitter may split most of the power from the input fiber to one of the output fibers. Only a small amount of the power is coupled into the secondary output fiber. This type of optical splitter is known as a T-coupler, or an optical tap.

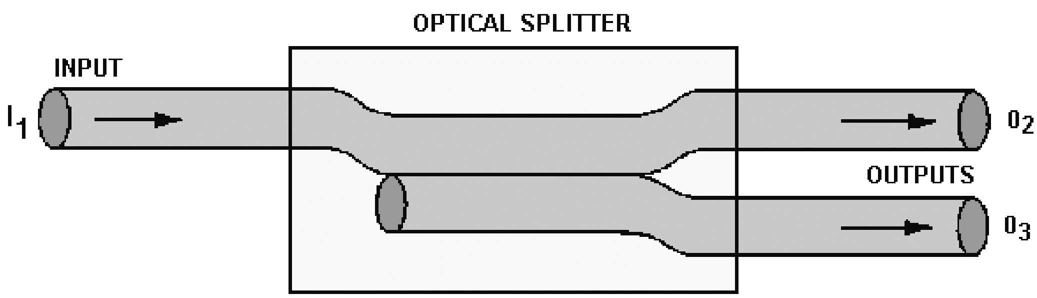

Figure 4-25.—Optical splitter.

An **optical combiner** is a passive device that combines the optical power carried by two input fibers into a single output fiber. Figure 4-26 illustrates the transfer of optical power in an optical combiner.

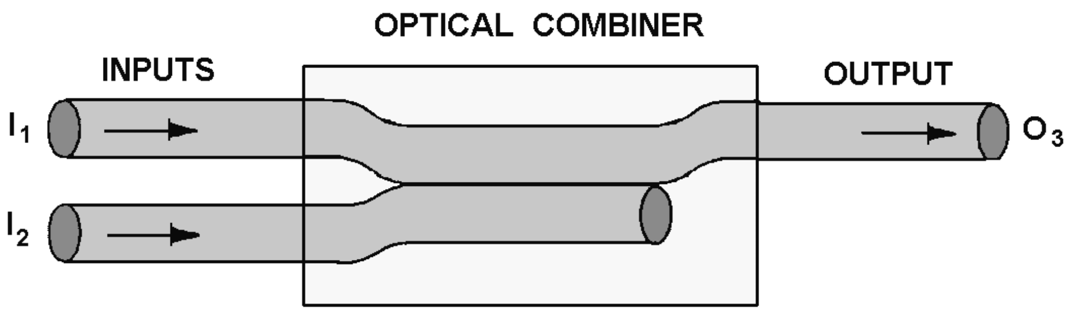

Figure 4-26.—Optical combiner.

An **X coupler** combines the functions of the optical splitter and combiner. The X coupler combines and divides the optical power from the two input fibers between the two output fibers. Another name for the X coupler is the 2×2 coupler.

Star and **tree couplers** are multiport couplers that have more than two input or two output ports. A **star coupler** is a passive device that distributes optical power from more than two input ports among several output ports. Figure 4-27 shows the multiple input and output ports of a star coupler. A **tree coupler** is a passive device that splits the optical power from one input fiber to more than two output fibers. A tree coupler may also be used to combine the optical power from more than two input fibers into a single output fiber. Figure 4-28 illustrates each type of tree coupler. Star and tree couplers distribute the input power uniformly among the output fibers.

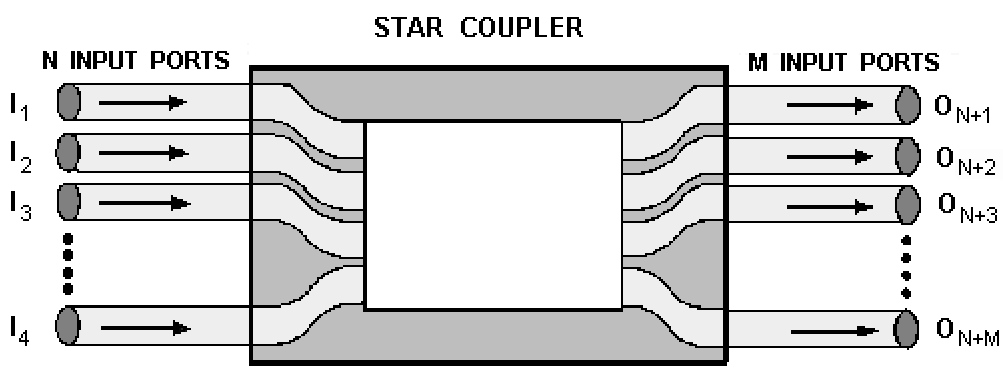

Figure 4-27.—Star coupler.

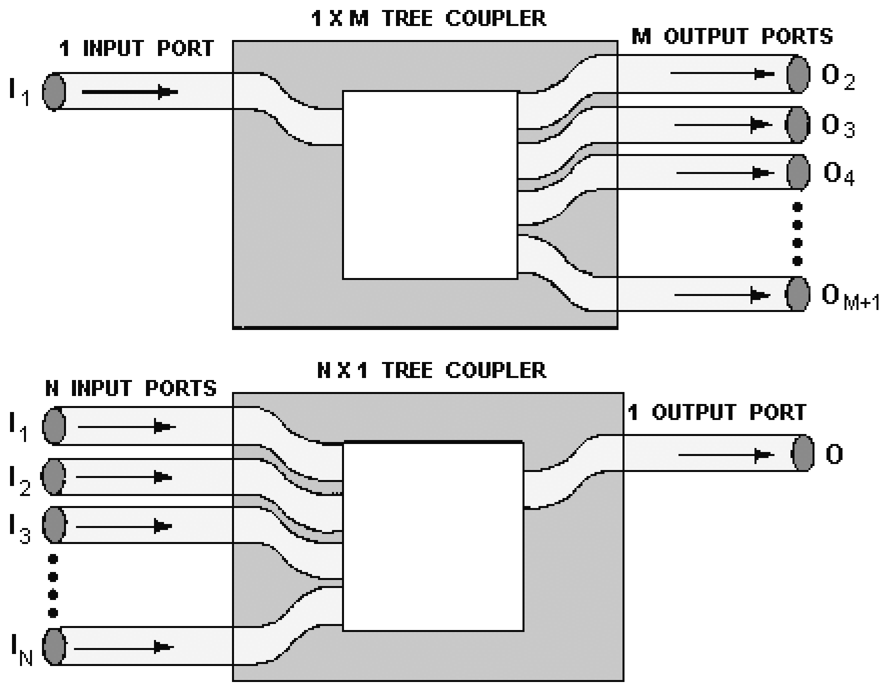

Figure 4-28.—(1 × M) and (N × 1) tree coupler designs.

Fiber optic couplers should prevent the transfer of optical power from one input fiber to another input fiber. **Directional couplers** are fiber optic couplers that prevent this transfer of power between input fibers. Many fiber optic couplers are also symmetrical. A **symmetrical coupler** transmits the same amount of power through the coupler when the input and output fibers are reversed.

Passive fiber optic coupler fabrication techniques can be complex and difficult to understand. Some fiber optic coupler fabrication involves beam splitting using microlenses or graded-refractive-index (GRIN) rods and beam splitters or optical mixers. These beamsplitter devices divide the optical beam into two or more separated beams. Fabrication of fiber optic couplers may also involve twisting, fusing, and tapering together two or more optical fibers. This type of fiber optic coupler is a fused biconical taper coupler. Fused biconical taper couplers use the radiative coupling of light from the input fiber to the output fibers in the tapered region to accomplish beam splitting. Figure 4-29 illustrates the fabrication process of a fused biconical taper coupler.

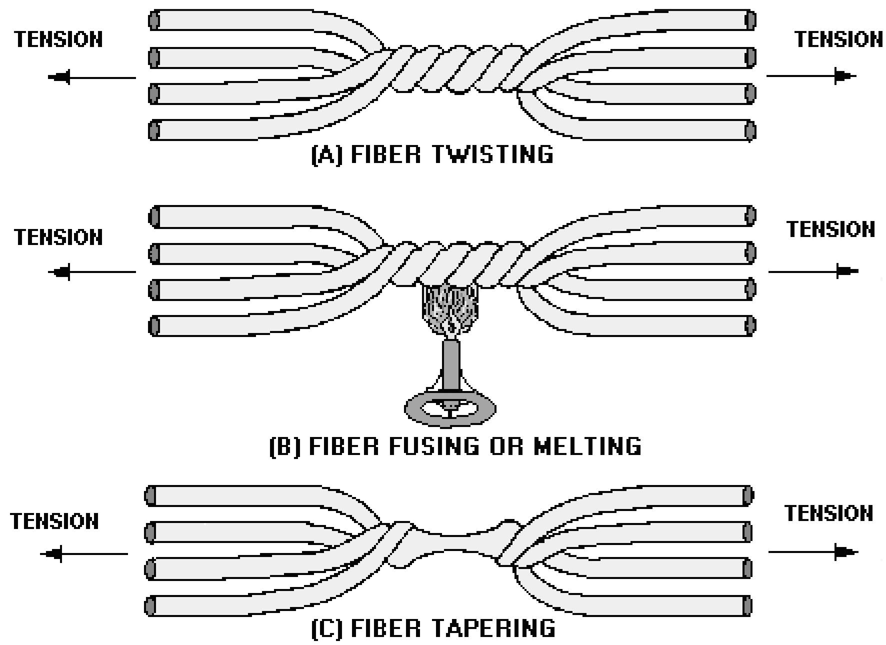

Figure 4-29.—Fabrication of a fused biconical taper coupler (star coupler).

Q31. What is the difference between passive and active fiber optic couplers?

Q32. Which type of optical splitter (Y-coupler or T-coupler) splits only a small amount of power from the input fiber to one of the output fibers?

Q33. Describe a directional coupler.

SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas you have learned. You should have a thorough understanding of these principles before moving on to chapter 5.

FIBER OPTIC CONNECTIONS transfer optical power from one component to another. Fiber optic connections also permit fiber optic systems to be more than just a point-to-point data link.

A **FIBER OPTIC SPLICE** is a permanent joint between two fibers or two groups of fibers.

FIBER OPTIC CONNECTORS permit easy coupling and uncoupling of optical fibers.

FIBER OPTIC COUPLERS distribute or combine optical signals between fibers.

POOR FIBER END PREPARATION and **POOR FIBER ALIGNMENT** are the main causes of coupling loss.

RADIANCE is the amount of optical power emitted by a unit area of emitting surface per unit time in a specified direction. An optical source's radiance, or brightness, is a measure of its optical power launching capability.

FIBER-TO-FIBER COUPLING LOSS is affected by intrinsic and extrinsic coupling losses. **INTRINSIC COUPLING LOSSES** are caused by inherent fiber characteristics. **EXTRINSIC COUPLING LOSSES** are caused by jointing techniques.

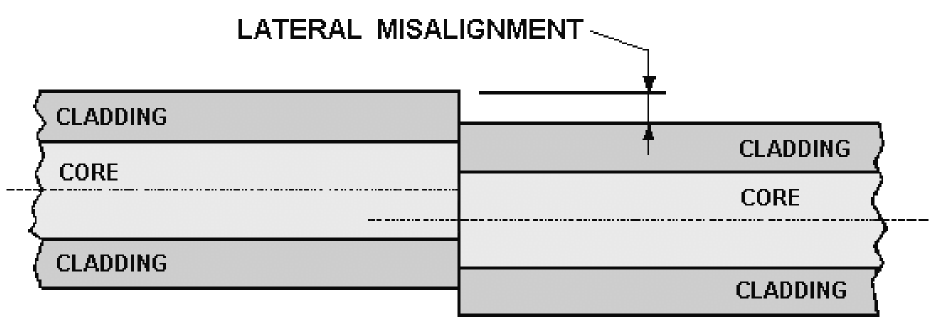
A **FIBER PIGTAIL** is a short length of optical fiber (usually 1 meter or less) permanently fixed to a fiber optic component, such as an optical source or detector.

FRESNEL REFLECTION occurs twice in a fiber-to-fiber connection. A portion of the optical power is reflected when the light first exits the source fiber. Light is then reflected as the optical signal enters the receiving fiber.

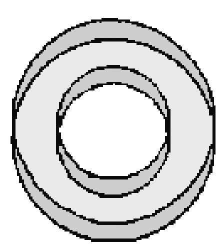
INDEX MATCHING GEL eliminates or reduces the step change in the refractive index at the fiber interface, reducing Fresnel reflection.

POOR FIBER ALIGNMENT is a main source of coupling loss in fiber-to-fiber connections. The three basic coupling errors that occur during fiber alignment are fiber separation (longitudinal misalignment), lateral misalignment, and angular misalignment.

In **FIBER SEPARATION** a small gap remains between fiber-end faces after completing the fiber connection. **LATERAL**, or **AXIAL**, **MISALIGNMENT** is when the axes of the two fibers are offset in a perpendicular direction. **ANGULAR MISALIGNMENT** is when the axes of the two fibers are no longer parallel.



(A) SIDE VIEW



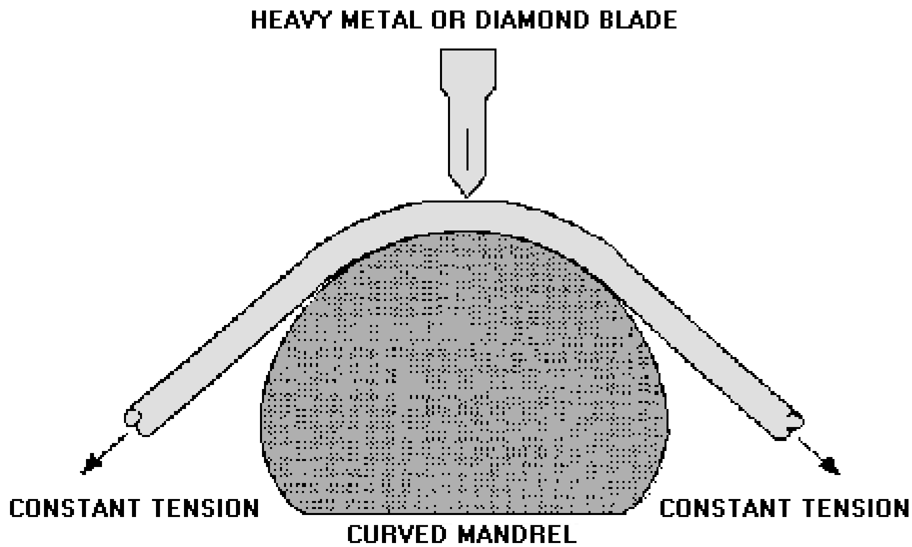
(B) END VIEW

SINGLE MODE FIBERS are more sensitive to alignment errors than multimode fibers because of their small core diameters and low numerical apertures.

The **MODE POWER DISTRIBUTION (MPD)** is the distribution of radiant power among the various modes propagating along the optical fiber.

Poor **FIBER END PREPARATION** is another source of extrinsic coupling loss. An optical fiber end face must be flat, smooth, and perpendicular to the fiber's axis to ensure proper fiber connection.

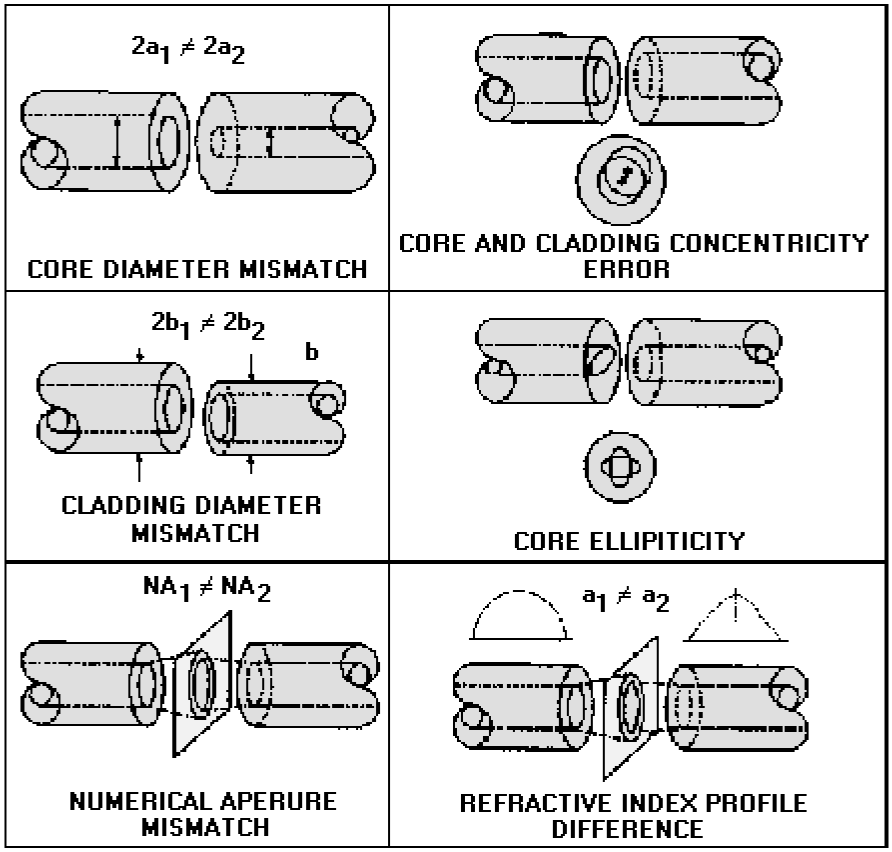
The **SCORE-AND-BREAK** method is the basic fiber cleaving technique for preparing optical fibers for coupling.



POLISHING the fiber ends removes most surface imperfections introduced by the fiber cleaving or cutting process. Fiber polishing involves a step-down approach. The first step is to give the surface of the fiber end a rough polish. The next step involves giving the surface of the fiber end a fine polish.

FIBER MISMATCHES are a source of intrinsic coupling loss. Types of fiber mismatches include fiber geometry mismatches, NA mismatch, and refractive index profile difference.

FIBER GEOMETRY MISMATCHES include core diameter, cladding diameter, core ellipticity, and core-cladding concentricity differences.



CORE DIAMETER MISMATCH causes coupling loss only if the launching fiber has a larger core radius than the receiving fiber.

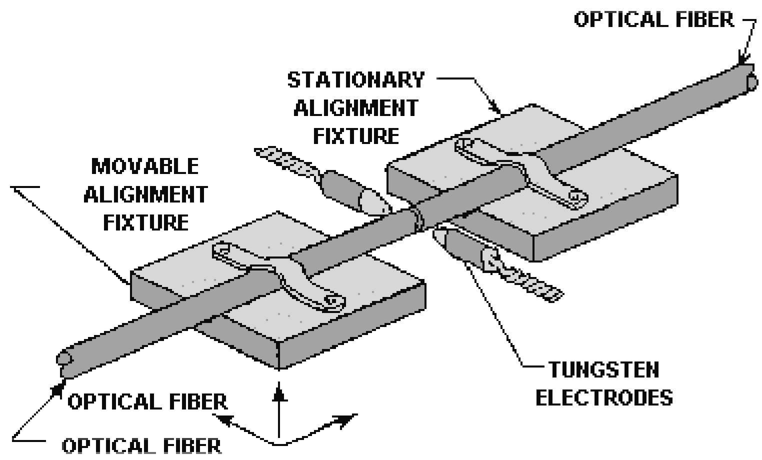
NA MISMATCH causes coupling loss only if the launching fiber has a higher NA than the receiving fiber.

A **REFRACTIVE INDEX PROFILE DIFFERENCE** causes coupling loss only if the launching fiber has a larger profile parameter than the receiving fiber.

MECHANICAL and **FUSION SPLICING** are two broad categories that describe the techniques used for fiber splicing. A mechanical splice is a fiber splice where mechanical fixtures perform fiber alignment and connection. A fusion splice is a fiber splice where localized heat fuses or melts the ends of two lengths of optical fiber together.

In **MECHANICAL SPLICING**, mechanical fixtures hold the two optical fibers in alignment for an indefinite period of time without movement. The amount of splice loss is stable over time and unaffected by changes in environmental or mechanical conditions.

ARC FUSION involves the discharge of electric current across a gap between two electrodes. By placing the fiber end between the electrodes, the electric discharge melts or fuses the ends of the fibers.



PREFUSION involves a short discharge of electric current across the gap between the electrodes. In prefusion the fiber ends are cleaned and rounded to eliminate any surface defects that remain from fiber cleaving.

A **FIBER OPTIC CONNECTOR** is a demateable device that permits the coupling of optical power between two optical fibers or two groups of fibers.

FIBER ALIGNMENT in a fiber optic connector is the critical parameter in maintaining total insertion loss below the required level.

FIBER OPTIC CONNECTORS can affect system performance by increasing modal and reflection noise.

MODAL NOISE is eliminated by using only single mode fiber with laser sources and only low-coherence sources such as light-emitting diodes with multimode fiber.

REFLECTION NOISE is reduced by index matching gels, physical contact polishes, or antireflection coatings.

BUTT-JOINTED and **EXPANDED BEAM CONNECTORS** are two ways to classify fiber optic connectors. Butt-jointed connectors bring the prepared ends of two fibers into close contact. Expanded beam connectors use two lenses to first expand and then refocus the light from the transmitting fiber into the receiving fiber.

LIGHT-DUTY and **HEAVY-DUTY CONNECTORS** are two ways that the Navy classifies fiber optic connectors. Light-duty connector shipboard applications include locations that protect the connectors from the environment such as in a junction box. Heavy-duty applications require a very rugged, stand-alone, sealed connector.

A **PASSIVE COUPLER** redistributes an optical signal without optical to electrical conversion.

An **OPTICAL SPLITTER** is a passive device that splits the optical power carried by a single input fiber into two output fibers.

An **OPTICAL COMBINER** is a passive device that combines the optical power from two input fibers into a single output fiber.

A **STAR COUPLER** is a passive device that distributes optical power from more than two input ports among several output ports.

A **TREE COUPLER** is a passive device that splits the optical power from one input fiber to more than two output fibers. A tree coupler may also be used to combine the optical power from more than two input fibers into a single output fiber.

DIRECTIONAL COUPLERS are fiber optic couplers that prevent the transfer of optical power from one input fiber to another input fiber.

A **SYMMETRICAL COUPLER** transmits the same amount of power through the coupler when the input and output fibers are reversed.

ANSWERS TO QUESTIONS Q1. THROUGH Q33.

A1. Splice.

A2. Poor fiber end preparation and poor fiber alignment.

A3.

$$\text{loss} = 10\log_{10}\frac{P_i}{P_o}$$

A4. Yes.

A5. A step change in refractive index that occurs at fiber joints, caused by fiber separation.

A6. Index matching gel.

A7. Fiber separation (longitudinal misalignment), lateral misalignment, and angular misalignment.

A8. Angular misalignment.

A9. (a) Reduces coupling loss, (b) does not change coupling loss, and (c) increases coupling loss.

A10. Single mode.

A11. Be flat, smooth, and perpendicular to the fiber axis.

A12. Score-and-break.

A13. Flat.

A14. Core diameter mismatch, cladding diameter mismatch, core ellipticity, core and cladding concentricity differences, NA mismatch, and refractive index profile differences.

A15. No.

A16. A permanent fiber joint whose purpose is to establish an optical connection between two individual optical fibers.

A17. Mechanical and fusion splicing.

A18. An epoxy resin that seals mechanical splices and provides index matching between the connected fibers.

A19. It is a low-loss mechanical splice that provides stable environmental and mechanical performance in the Navy environment, and it requires only a small amount of training.

A20. The angles and quality of the two fiber-end faces.

A21. The small size of the fusion splice and the development of automated fusion-splicing machines.

A22. Prefusion.

A23. Single mode fibers.

A24. Poor fiber alignment and end preparation, fiber mismatches, and Fresnel reflection.

A25. Fiber alignment.

A26. Modal and reflection.

A27. Butt-jointed connectors.

A28. Butt-jointed connectors.

A29. Expanded beam connectors.

A30. Light-duty and heavy-duty connectors.

A31. Passive couplers redistribute optical signals without optical-to-electrical conversion.

A32. T-coupler.

A33. A fiber optic coupler that prevents the transfer of power between input fibers.

CHAPTER 5

FIBER OPTIC MEASUREMENT TECHNIQUES

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to do the following:

1. Identify the prime reasons for conducting fiber optic manufacturing laboratory and field measurements.

2. Describe the optical fiber and optical connection laboratory measurements performed by the Navy to evaluate fiber optic component and system performance.

3. Describe the near-field and far-field optical power distribution of an optical fiber.

4. Describe optical fiber launch conditions and modal effects that affect optical fiber and optical connection measurements.

5. Understand the term optical time-domain reflectometry and the interpretation of an optical time-domain reflectometer (OTDR) trace.

6. Describe the procedure for locating a fiber fault using an OTDR.

FIBER OPTIC MEASUREMENTS

Fiber optic data links operate reliably if fiber optic component manufacturers and end users perform the necessary laboratory and field measurements. Manufacturers must test how component designs, material properties, and fabrication techniques affect the performance of fiber optic components. These tests can be categorized as design tests or quality control tests. Design tests are conducted during the development of a component. Design tests characterize the component's performance (optical, mechanical, and environmental) in the intended application. Once the component performance is characterized, the manufacturer generally only conducts quality control tests. Quality control tests verify that the parts produced are the same as the parts the design tests were conducted on. When manufacturers ship fiber optic components, they provide quality control data detailing the results of measurements performed during or after component fabrication.

End users (equipment manufacturers, shipbuilders, maintenance personnel, test personnel, and so on) should measure some of these parameters upon receipt before installing the component into the fiber optic data link. These tests determine if the component has been damaged in the shipping process. In addition, end users should measure some component parameters after installing or repairing fiber optic components in the field. The values obtained can be compared to the system installation specifications. These measurements determine if the installation or repair process has degraded component performance and will affect data link operation.

Whenever a measurement is made, it should be made using a standard measurement procedure. For most fiber optic measurements, these standard procedures are documented by the Electronics Industries Association/Telecommunications Industries Association (EIA/TIA). Each component measurement procedure is assigned a unique number given by EIA/TIA-455-X. The X is a sequential number assigned to that particular component test procedure. System level test procedures are assigned unique numbers given by EIA/TIA-526-X. Again the X is a sequential number assigned to that particular system test procedure.

LABORATORY MEASUREMENTS

Providing a complete description of every laboratory measurement performed by manufacturers and end users is impossible. This chapter only provides descriptions of optical fiber and optical connection measurements that are important to system operation. The list of optical fiber and optical connection laboratory measurements described in this chapter includes the following:

- Attenuation
- Cutoff wavelength (single mode)
- Bandwidth (multimode)
- Chromatic dispersion
- Fiber geometry
- Core diameter
- Numerical aperture (multimode)
- Mode field diameter (single mode)
- Insertion loss
- Return loss and reflectance

End users routinely perform optical fiber measurements to measure fiber power loss and fiber information capacity. End users may also perform optical fiber measurements to measure fiber geometrical properties. Optical fiber power loss measurements include attenuation and cutoff wavelength. Optical fiber information capacity measurements include chromatic dispersion and bandwidth. Fiber geometrical measurements include cladding diameter, core diameter, numerical aperture, and mode field diameter. Optical connection measurements performed by end users in the laboratory include insertion loss and reflectance or return loss.

Q1. List the fiber geometrical measurements performed in the laboratory.

Attenuation

Attenuation is the loss of optical power as light travels along the fiber. It is a result of absorption, scattering, bending, and other loss mechanisms as described in chapter 3. Each loss mechanism contributes to the total amount of fiber attenuation.

End users measure the total attenuation of a fiber at the operating wavelength (λ). The **total attenuation (A)** between an arbitrary point X and point Y located on the fiber is

$$A = 10\log\frac{P_x}{P_y}\,dB$$

P_x is the power output at point X. P_y is the power output at point Y. Point X is assumed to be closer to the optical source than point Y. The total amount of attenuation will vary with changes in wavelength λ.

The **attenuation coefficient (α)** or attenuation rate, is

$$a = \frac{A}{L}\,dB/km$$

L is the distance between points X and Y. α is a positive number because P_x is always larger than P_y. The attenuation coefficient will also vary with changes in λ.

CUTBACK METHOD.—In laboratory situations, end users perform the cutback method for measuring the total attenuation of an optical fiber. The cutback method involves comparing the optical power transmitted through a long piece of test fiber to the power present at the beginning of the fiber.

The cutback method for measuring multimode fiber attenuation is EIA/TIA-455-46. The cutback method for measuring single mode fiber attenuation is EIA/TIA-455-78. The basic measurement process is the same for both of these procedures. The test method requires that the test fiber of known length (L) be cut back to an approximate 2-m length. This cut back causes the destruction of 2-m of fiber. This method requires access to both fiber ends. Each fiber end should be properly prepared to make measurements. EIA/TIA-455-57 describes how to properly prepare fiber ends for measurement purposes.

Figure 5-1 illustrates the cutback method for measuring fiber attenuation. The cutback method begins by measuring, with an optical power meter, the output power P_1 of the test fiber of known length (L) (figure 5-1, view A). Without disturbing the input light conditions, the test fiber is cut back to an approximate 2-m length. The output power P_2 of the shortened test fiber is then measured (figure 5-1, view B). The fiber attenuation A_T and the attenuation coefficient α are then calculated.

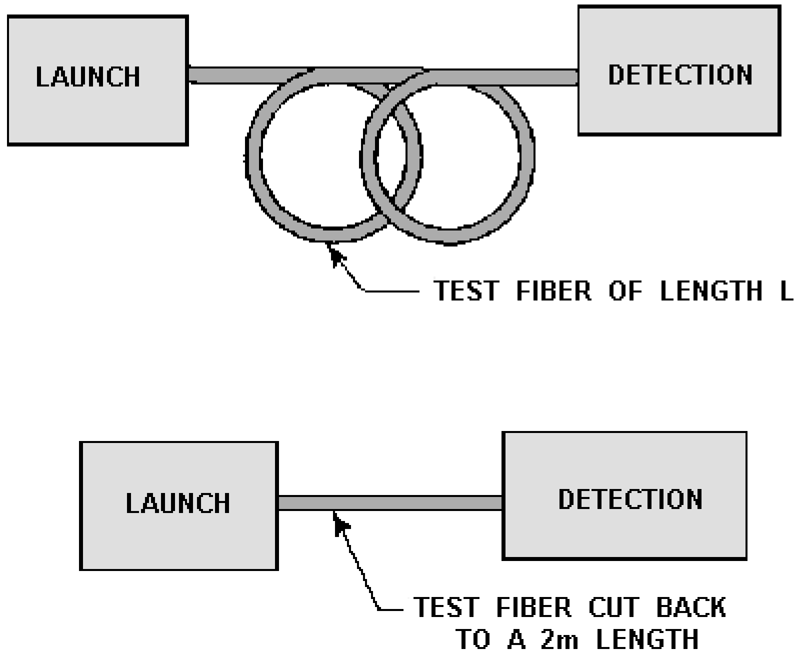


Figure 5-1.—Cutback method for measuring fiber attenuation: A. Test measurement; B. Cut-back measurement.

LAUNCH CONDITIONS.—Measurement personnel must pay attention to how optical power is launched into the fiber when measuring fiber attenuation. Different distributions of launch power (launch conditions) can result in different attenuation measurements. This is more of a problem with multimode fiber than single mode fiber. For single mode fiber, optical power must be launched only into the fundamental mode. This is accomplished using a mode filter on the fiber. For multimode fiber, the distribution of power among the modes of the fiber must be controlled. This is accomplished by controlling the launch spot size and angular distribution.

The **launch spot size** is the area of the fiber face illuminated by the light beam from the optical source. The diameter of the spot depends on the size of the optical source and the properties of the optical elements (lenses, and so on) between the source and the fiber end face. The **angular distribution** is the angular extent of the light beam from the optical source incident on the fiber end face. The launch angular distribution also depends on the size of the optical source and the properties of the optical elements between the optical source and the fiber end face.

Multimode optical fiber launch conditions are typically characterized as being underfilled or overfilled. An underfilled launch concentrates most of the optical power in the center of the fiber. An **underfilled** launch results when the launch spot size and angular distribution are smaller than that of the fiber core. Underfilling the fiber excites mainly low-order modes. Figure 5-2 illustrates an underfilled launch condition.

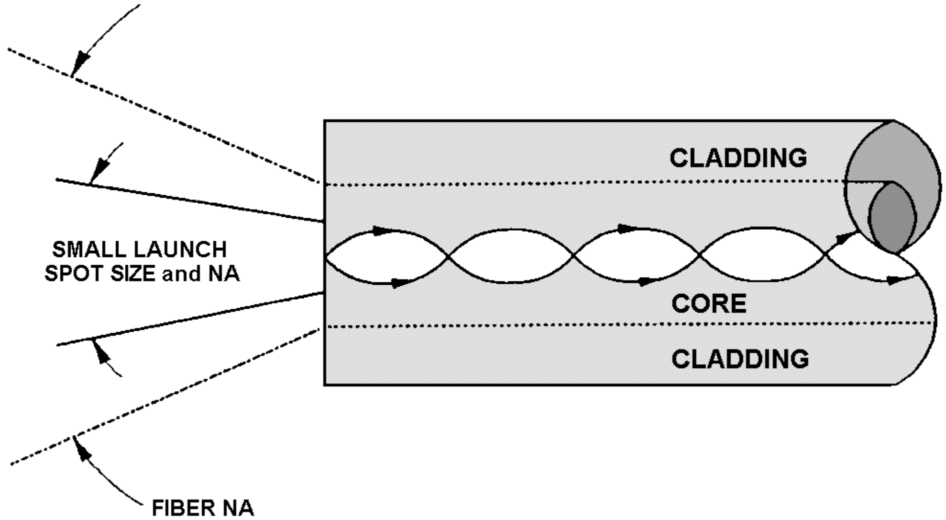

Figure 5-2.—Underfilled launch condition.

Overfilling the fiber excites both low-order and high-order modes. Figure 5-3 illustrates an overfilled launch condition. An **overfilled** launch condition occurs when the launch spot size and angular distribution are larger than that of the fiber core. Incident light that falls outside the fiber core is lost. In addition, light that is incident at angles greater than the angle of acceptance of the fiber core is lost.

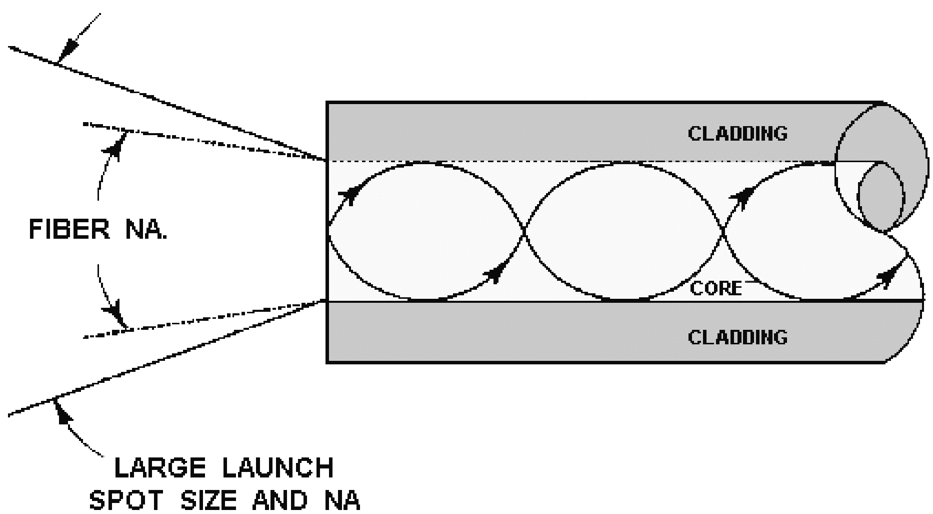

Figure 5-3.—Overfilled launch condition.

In attenuation measurements, cladding-mode strippers and mode filters eliminate the effects that high-order modes have on attenuation results. A **cladding-mode stripper** is a device that removes any cladding mode power from the fiber. Most cladding-mode strippers consist of a material with a refractive index greater than that of the fiber cladding. For most fibers, the fiber coating acts as an excellent cladding-mode stripper.

A **mode filter** is a device that attenuates specific modes propagating in the core of an optical fiber. Mode filters generally involve wrapping the test fiber around a mandrel. For multimode, tight bends tend to remove high-order modes from the fiber. This type of mode filter is known as a **mandrel wrap mode filter**. For multimode fibers, mode filters remove high-order propagating modes and are individually tailored and adjusted for a specific fiber type.

For single mode fibers, a mode filter is used to eliminate the second-order mode from propagating along the fiber. The propagation of the second-order mode will affect attenuation measurements. Fiber attenuation caused by the second-order mode depends on the operating wavelength, the fiber bend radius and length.

The two most common types of mode filters are free-form loops and mandrel wraps. Figure 5-4 illustrates the free-form loop and mandrel-wrap types of mode filters. Mandrel wraps for multimode fibers consist of several wraps (approximately 4 or 5) around a mandrel. A 20-mm diameter mandrel is typically used for 62.5 μm fiber. Mandrel wraps for single mode fibers consist of a single wrap around a 30-mm diameter mandrel. Another common mode filter for single mode fibers is a 30-mm diameter circular free-form loop. Additional information on multimode and single mode filters (and launch conditions) is available in EIA/TIA-455-50 and EIA/TIA-455-77, respectively.

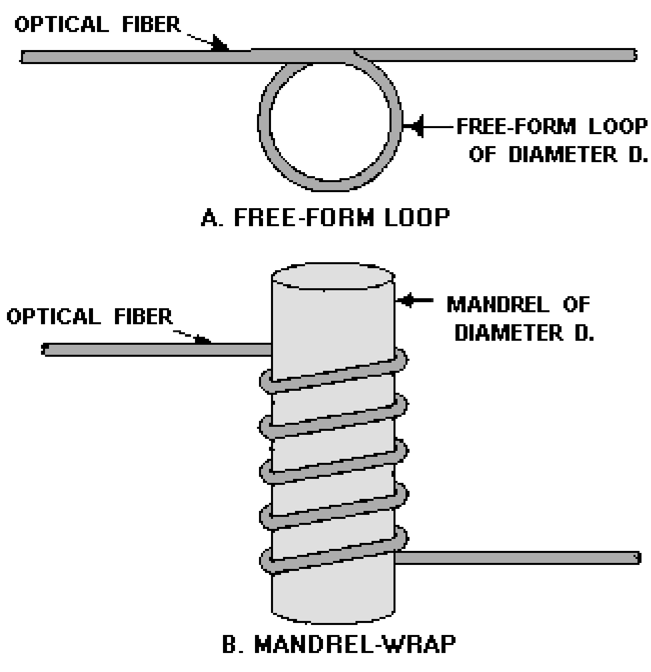

Figure 5-4.—Types of mode filters: A. Free-form loop; B. Mandrel-wrap.

Launch conditions significantly affect the results of multimode fiber attenuation measurements. If the fiber is underfilled, high-order-mode power loss has minimal effect on the measurement results. If too much power is launched into high-order modes, the high-order-mode power loss will dominate the attenuation results. Generally, fiber attenuation measurements are performed using an underfilled launch condition. Power in high-order modes is eliminated by either controlling the input spot size and angular distribution or using mode filters to remove high-order mode power.

Q2. End users measure the total attenuation of a fiber at the operating wavelength (λ). Write the equation for total attenuation (A), between an arbitrary point X and point Y located on an optical fiber.

Q3. Will an optical fiber's attenuation coefficient vary with changes in wavelength?

Q4. What two properties of the launch condition may affect multimode fiber attenuation measurements?

Q5. Does underfilling a multimode optical fiber excite mainly high-order or low-order modes?

Q6. Multimode optical fiber launch conditions are typically characterized as being overfilled or underfilled. Which of these optical launch conditions exists if the launch spot size and angular distribution are larger than that of the fiber core?

Q7. A mode filter is a device that attenuates specific modes propagating in the core of an optical fiber. What mode propagating along single mode fibers do mode filters eliminate?

Q8. What are the two most common types of mode filters?

Cutoff Wavelength

The wavelength at which a mode ceases to propagate is called the cutoff wavelength for that mode. However, an optical fiber is always able to propagate at least one mode, the fundamental mode. The fundamental mode can never be cut off. The **cutoff wavelength** of a single mode fiber is the wavelength above which the fiber propagates only the fundamental mode.

Determining the cutoff wavelength of a single mode fiber involves finding the wavelength above which the power transmitted through the fiber decreased abruptly. This power decrease occurs when the second-order mode propagating in the fiber is cut off. The cutoff wavelength of single mode fibers depends on the fiber length and bend conditions. The effects of length and bending are different on different fibers depending on whether they are matched-clad or depressed-clad in design. The cutoff wavelength of matched-clad fibers is more sensitive to bends than the cutoff wavelength of depressed-clad fibers. The cutoff wavelength of depressed-clad fibers is more sensitive to length than the cutoff wavelength of matched-clad fibers.

Cutoff wavelength may be measured on uncabled or cabled single mode fibers. A slightly different procedure is used in each case, but the basic measurement process is the same. The test method for uncabled single mode fiber cutoff wavelength is EIA/TIA-455-80. The test method for cabled single mode fiber cutoff wavelength is EIA/TIA-455-170. The fiber cutoff wavelength (λ) measured under EIA/TIA-455-80 will generally be higher than the cable cutoff wavelength (λ) measured under EIA/TIA-455-170. The difference is due to the fiber bends introduced during the cable manufacturing process.

Each test method describes the test equipment (input optics, mode filters, and cladding-mode strippers) necessary for the test. Cutoff wavelength measurements require an overfilled launch over the full range of test wavelengths. Since the procedures for measuring the cutoff wavelength of uncabled and cabled single mode fibers are essentially the same, only the test method for measuring the cutoff wavelength of uncabled fiber is discussed.

Measuring the cutoff wavelength involves comparing the transmitted power from the test fiber with that of a reference fiber at different wavelengths. The reference fiber can be the same piece of single mode fiber with small bends introduced or a piece of multimode fiber. If the same fiber with small bends is used as the reference fiber, the technique is called the **bend-reference technique**. If a piece of multimode fiber is used as the reference fiber, the technique is called the **multimode-reference technique**.

For both techniques, the test fiber is loosely supported in a single-turn with a constant radius of 140 mm. Figure 5-5 shows this single-turn configuration. The transmitted signal power $P_s(\lambda)$ is then recorded while scanning the wavelength range in increments of 10 nm or less. The launch and detection conditions are not changed while scanning over the range of wavelengths. The wavelength range scanned encompasses the expected cutoff wavelength.

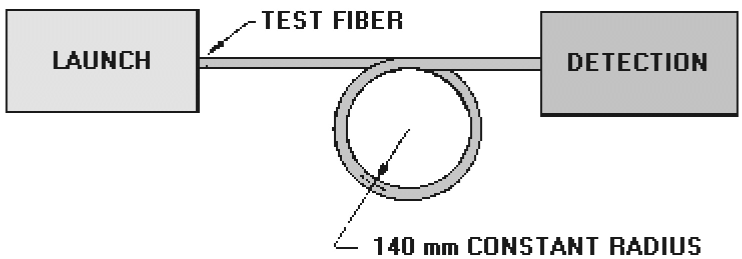

Figure 5-5.—Single-turn configuration for the test fiber.

The reference power measurement is then made. For the bend-reference technique, the launch and detection conditions are not changed, but an additional bend is added to the test fiber. The test fiber is bent to a radius of 30 mm or less to suppress the second-order mode at all the scanned wavelengths. For the multimode-reference technique, the single mode fiber is replaced with a 2-m length of multimode fiber. The transmitted signal power $P_r(\lambda)$ is recorded while scanning the same wavelength range in the same increments of 10 nm or less. The attenuation $A(\lambda)$ at each wavelength is calculated as follows:

$$A(\lambda) = 10 \log \frac{P_s(\lambda)}{P_r(\lambda)} \text{dB}$$

Figure 5-6 shows an example attenuation plot generated using the bend-reference technique. The longest wavelength at which $A(\lambda)$ is equal to 0.1 dB is the fiber cutoff wavelength (λ_{cf}). λ_{cf} is marked on figure 5-6.

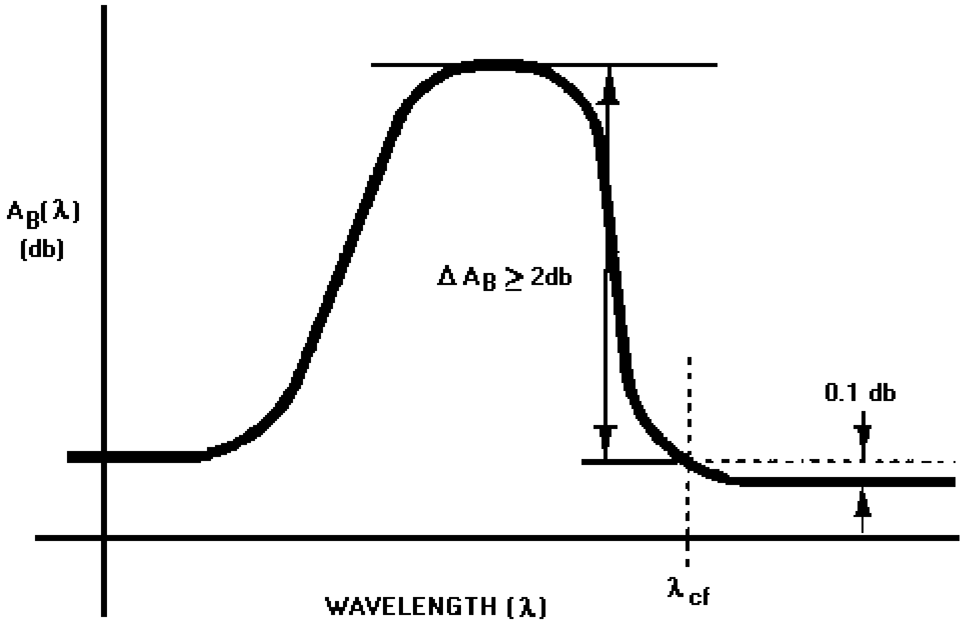

Figure 5-6.—Fiber cutoff wavelength determined by the bend-reference technique.

Figure 5-7 shows an attenuation plot generated using the multimode-reference technique. A straight line is fitted to the long-wavelength portion of A(λ). This straight line is then displaced upward by 0.1 dB. The point at which the straight line intersects the A(λ) plot defines the fiber cutoff wavelength (λ_{cf}).

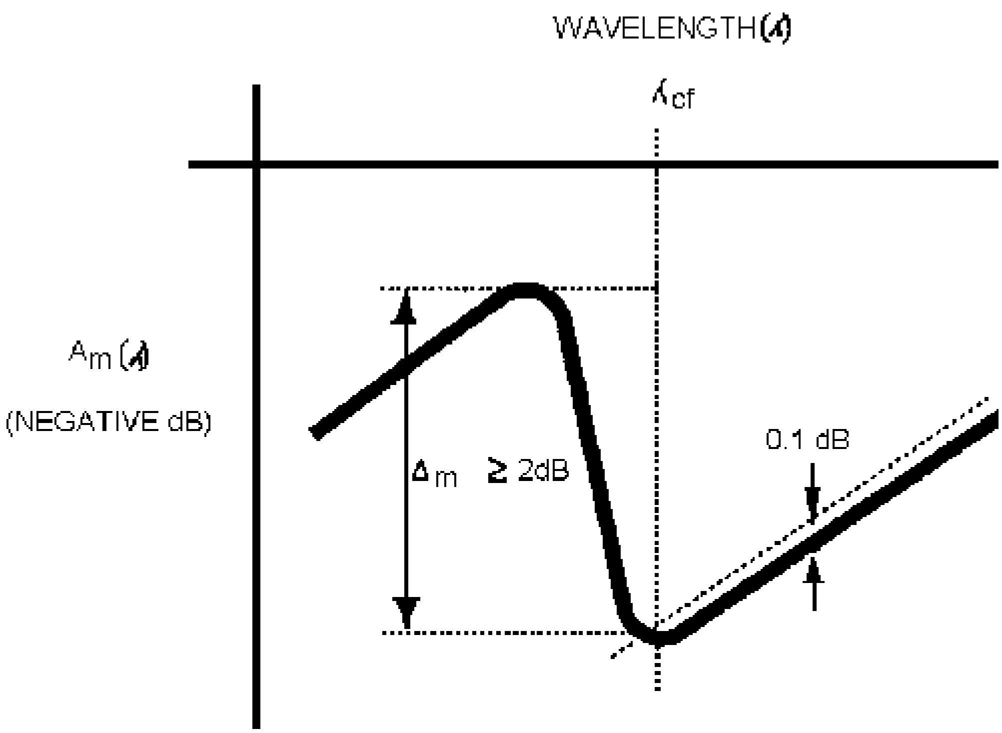

Figure 5-7.—Fiber cutoff wavelength determined by the multimode-reference technique.

Bandwidth

Dispersion reduces the bandwidth, or information-carrying capacity, of an optical fiber. **Dispersion** causes the spreading of the light pulse as it travels along the fiber (see figure 2-20). Fiber dispersion mechanisms include intramodal (chromatic) dispersion and intermodal (modal) dispersion. Multimode fiber bandwidth is a measure of the intermodal dispersion of the multimode fiber.

Intermodal dispersion is maximum when all fiber modes are excited. The source used for intermodal dispersion measurements must overfill the fiber. The optical source must also have a narrow spectral width to reduce the effects of chromatic dispersion in the measurement.

There are two basic techniques for measuring the modal bandwidth of an optical fiber. The first technique characterizes dispersion by measuring the **impulse response h(t)** of the fiber in the time domain. The second technique characterizes modal dispersion by measuring the **baseband frequency response H(*f*)** of the fiber in the frequency domain. H(*f*) is the **power transfer function** of the fiber at the baseband frequency (*f*). H(*f*) is also the Fourier transform of the power impulse response h(t). Only the frequency response method is described here.

The test method for measuring the bandwidth of multimode fibers in the frequency domain is EIA/TIA-455-30. Signals of varying frequencies (*f*) are launched into the test fiber and the power exiting the fiber at the launched fundamental frequency measured. This optical output power is denoted as $P_{out}(f)$. The test fiber is then cut back or replaced with a short length of fiber of the same type. Signals of the same frequency are launched into the cut-back fiber and the power exiting the cut-back fiber at the launched fundamental frequency measured. The optical power exiting the cutback or replacement fiber is denoted as $P_{in}(f)$. The magnitude of the optical fiber frequency response is

$$H(f) = \log_{10}\left[\frac{P_{out}(f)}{P_{in}(f)}\right]$$

The fiber bandwidth is defined as the lowest frequency at which the magnitude of the fiber frequency response has decreased to one-half its zero-frequency value. This is the -3 decibel (dB) optical power frequency (f_{3dB}). This frequency is referred to as the fiber bandwidth.

Bandwidth is normally given in units of megahertz-kilometers (MHz-km). Converting the –3 dB fiber bandwidth to a unit length assists in the analysis and comparison of optical fiber performance. For long lengths of fiber (>1km), the method for normalization is to multiply the length times the measured bandwidth.

Q9. The cutoff wavelength of matched-clad and depressed-clad single mode fibers varies according to the fiber's radius of curvature and length. The cutoff wavelength of which single mode fiber type is more sensitive to length?

Q10. Will the cutoff wavelength of uncabled fibers (λ_{cf}) generally have a value higher or lower than the cutoff wavelength of cabled fibers (λ_{cc})?

Q11. Describe the -3 decibel (dB) optical power frequency (f_{3dB}).

Chromatic Dispersion

Chromatic, or intramodal, dispersion occurs in both single mode and multimode optical fibers. Chromatic dispersion occurs because different colors of light travel through the fiber at different speeds.

Since the different colors of light have different velocities, some colors arrive at the fiber end before others. This delay difference is called the differential group delay $\tau(\lambda)$ per unit length. This differential group delay leads to pulse broadening.

Chromatic dispersion is measured using EIA/TIA-455-168 in the time domain. Chromatic dispersion is also measured in the frequency domain using EIA/TIA-455-169 and EIA/TIA-455-175. These methods measure the composite optical fiber material and waveguide dispersion. To understand the contribution that material and waveguide dispersive mechanisms have on multimode and single mode fiber dispersion, refer to chapter 2. In this chapter we limit the discussion on chromatic dispersion to the time domain method described in EIA/TIA-455-168.

The chromatic dispersion of multimode graded-index and single mode fiber is obtained by measuring fiber group delays in the time domain. These measurements are made using multiwavelength sources or multiple sources of different wavelengths. A multiwavelength source could be a wavelength-selectable laser.

The pulse delay for both a long test sample fiber and a short reference fiber are measured over a range of wavelengths. The pulse delay for the reference fiber as a function of wavelength is $\tau_{in}(\lambda)$. The pulse delay for the test fiber as a function of wavelength is $\tau_{out}(\lambda)$. The group delay $\tau(\lambda)$. per unit length at each wavelength is

$$\tau(\lambda) = \frac{\tau_{in}(\lambda) - \tau_{out}(\lambda)}{L_s - L_{ref}}$$

where L_s is the test sample fiber length in kilometers (km) and L_{ref} is the reference sample length in km.

The fiber chromatic dispersion is defined as the derivative, or slope, of the fiber group delay curve with respect to wavelength. Generally, the group delay as a function of wavelength is fit to a simple mathematical function and the derivative calculated. The range of wavelengths over which meaningful data is obtained depends on the wavelength range of optical source(s) used. The zero-dispersion wavelength (λ_0) and the zero-dispersion slope (S_0) are determined from the chromatic dispersion curve.

Q12. Delay differences between the source wavelengths occur as the optical signal propagates along the fiber. What is this called?

Q13. What determines the range of wavelengths over which meaningful data is obtained for calculating the chromatic dispersion?

Fiber Geometry

End users perform fiber geometry measurements to reduce system attenuation and coupling loss resulting from poor fiber fabrication. Fiber attenuation and intrinsic coupling loss result from mismatches in the inherent fiber characteristics of two connecting fibers. Fiber mismatches occur when manufacturers fail to maintain optical or structural (geometrical) tolerances during the fiber fabrication process. Fiber geometry measurements performed in the laboratory identify fiber mismatches before the optical fiber is installed.

The procedure for measuring multimode and single mode fiber geometry is detailed in EIA/TIA-455-176. The fiber-geometrical parameters measured include cladding diameter, cladding noncircularity, core-cladding concentricity error, and core noncircularity. Figure 4-8 (chapter 4) illustrates core noncircularity (ellipticity) and core-cladding concentricity error. The core noncircularity measurement is for multimode fibers only.

Other test methods are available for measuring other multimode and single mode fiber core parameters. Additional test methods exist for measuring multimode fiber core diameter and NA. For single mode fibers, the mode field diameter measurement replaces core diameter and NA measurements. Core diameter, numerical aperture, and mode field diameter measurements are identified and explained later in this chapter.

To make fiber geometry measurements, the input end of the fiber is overfilled and any cladding power stripped out. The output end of the fiber is prepared and viewed with a video camera. Generally the fiber is less than 10 m in length. An objective lens magnifies the output image (typically 20×) going to a video camera. The image from the video camera is displayed on a video monitor and is also sent to the computer for digital analysis.

The computer analyzes the image to identify the edges of the core and cladding. The centers r_c and r_g of the core and cladding, respectively, are found. The **cladding diameter** is defined as the average diameter of the cladding. The cladding diameter is twice the average radius (R_g). The **core diameter** is defined as the average diameter of the core. The core diameter is twice the average core radius (R_c).

Cladding noncircularity, or ellipticity, is the difference between the smallest radius of the fiber (R_{gmin}) and the largest radius (R_{gmax}) divided by the average cladding radius (R_g). The value of the cladding noncircularity is expressed as a percentage.

The **core-cladding concentricity error** for multimode fibers is the distance between the core and cladding centers divided by the core diameter. Multimode core-cladding concentricity error is expressed as a percentage of core diameter. The core-cladding concentricity error for single mode fibers is defined as the distance between the core and cladding centers.

Core noncircularity is the difference between the smallest core radius (R_{cmin}) and the largest core radius (R_{cmax}) divided by the core radius (R_c). The value of core noncircularity is expressed as a percentage. Core noncircularity is measured on multimode fibers only.

Q14. Why do end users perform fiber geometry measurements in the laboratory?

Q15. Define cladding diameter.

Q16. Explain the difference between multimode and single mode core-cladding concentricity errors.

Core Diameter

Core diameter is measured using EIA/TIA-455-58. The core diameter is defined from the refractive index profile n(r) or the output near-field radiation pattern. Our discussion is limited to measuring the core diameter directly from the output near-field radiation pattern obtained using EIA/TIA-455-43.

The near-field power distribution is defined as the emitted power per unit area (radiance) for each position in the plane of the emitting surface. For this chapter, the emitting surface is the output area of a fiber-end face. Near-field power distributions describe the emitted power per unit area in the near-field region. The near-field region is the region close to the fiber-end face. In the near-field region, the distance between the fiber-end face and detector is in the micrometers (μm) range.

EIA/TIA-455-43 describes the procedure for measuring the near-field power distribution of optical waveguides. Output optics, such as lenses, magnify the fiber-end face and focus the fiber's image on a movable detector. Figure 5-8 shows an example setup for measuring the near-field power distribution. The image is scanned in a plane by the movable detector. The image may also be scanned by using a detector array. Detector arrays of known element size and spacing may provide a display of the power distribution on a video monitor. A record of the near-field power is kept as a function of scan position.

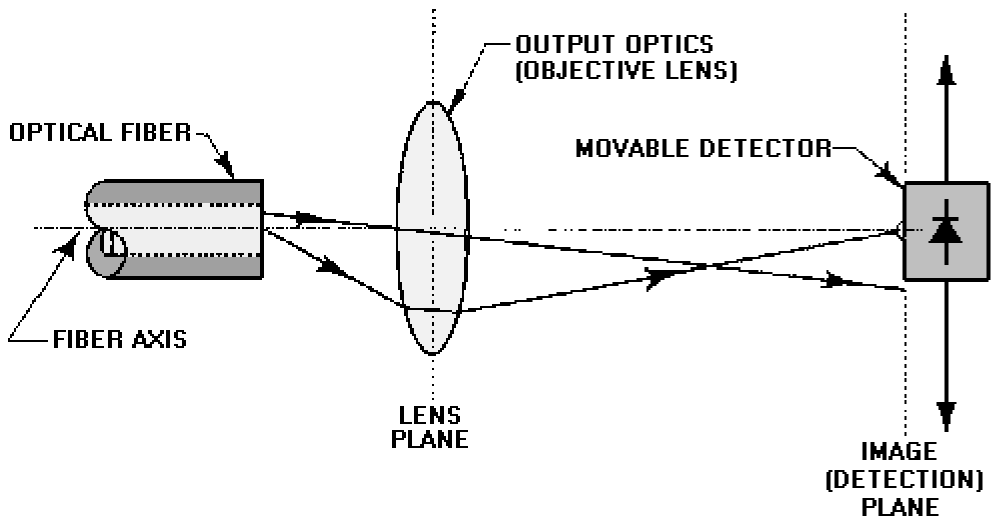

Figure 5-8.—The measurement of the near-field power distribution.

The core diameter (D) is derived from the normalized output near-field radiation pattern. The normalized near-field pattern is plotted as a function of radial position on the fiber-end face. Figure 5-9 shows a plot of the normalized near-field radiation pattern as a function of scan position.

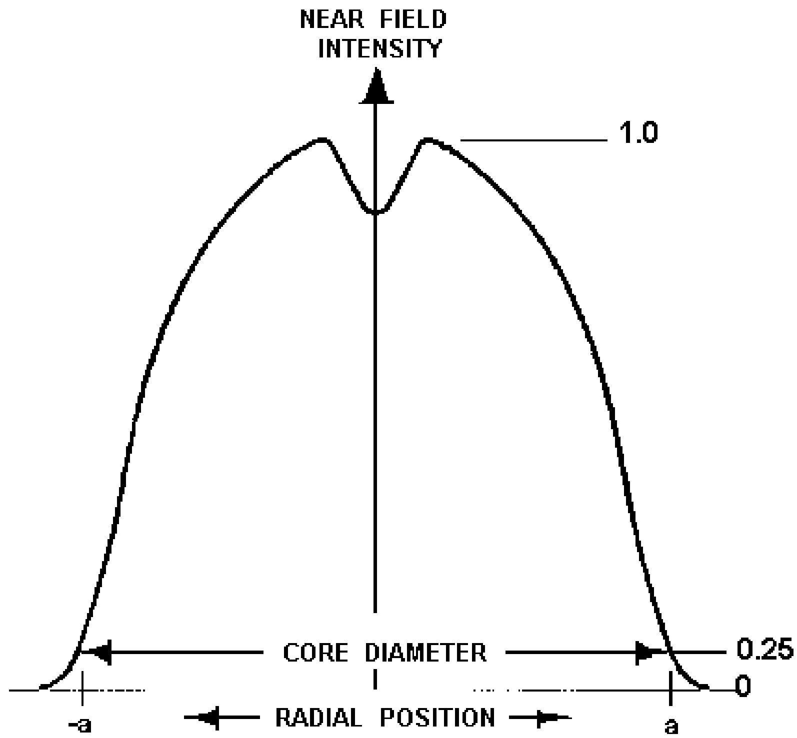

Figure 5-9.—Near-field radiation pattern.

The core diameter (D) is defined as the diameter at which the intensity is 2.5 percent of the maximum intensity (see figure 5-9). The 2.5 percent points, or the 0.025 level, intersects the normalized curve at radial positions –a and a. The core diameter is simply equal to 2a (D=2a).

Q17. Near-field power distributions describe the emitted power per unit area in the near-field region. Describe the near-field region.

Q18. How is the core diameter defined?

Numerical Aperture

The numerical aperture (NA) is a measurement of the ability of an optical fiber to capture light. The NA can be defined from the refractive index profile or the output far-field radiation pattern. Our discussion is limited to measuring the NA from the output far-field radiation pattern.

The NA of a multimode fiber having a near-parabolic refractive index profile is measured using EIA/TIA-455-177. In EIA/TIA-455-177, the fiber NA is measured from the output far-field radiation pattern. The far-field power distribution describes the emitted power per unit area in the far-field region. The far-field region is the region far from the fiber-end face. The far-field power distribution describes the emitted power per unit area as a function of angle Θ some distance away from the fiber-end face. The distance between the fiber-end face and detector in the far-field region is in the centimeters (cm) range for multimode fibers and millimeters (mm) range for single mode fibers.

EIA/TIA-455-47 describes various procedures, or methods, for measuring the far-field power distribution of optical waveguides. These procedures involve either an angular or spacial scan. Figure 5-10 illustrates an angular and spacial scan for measuring the far-field power distribution.

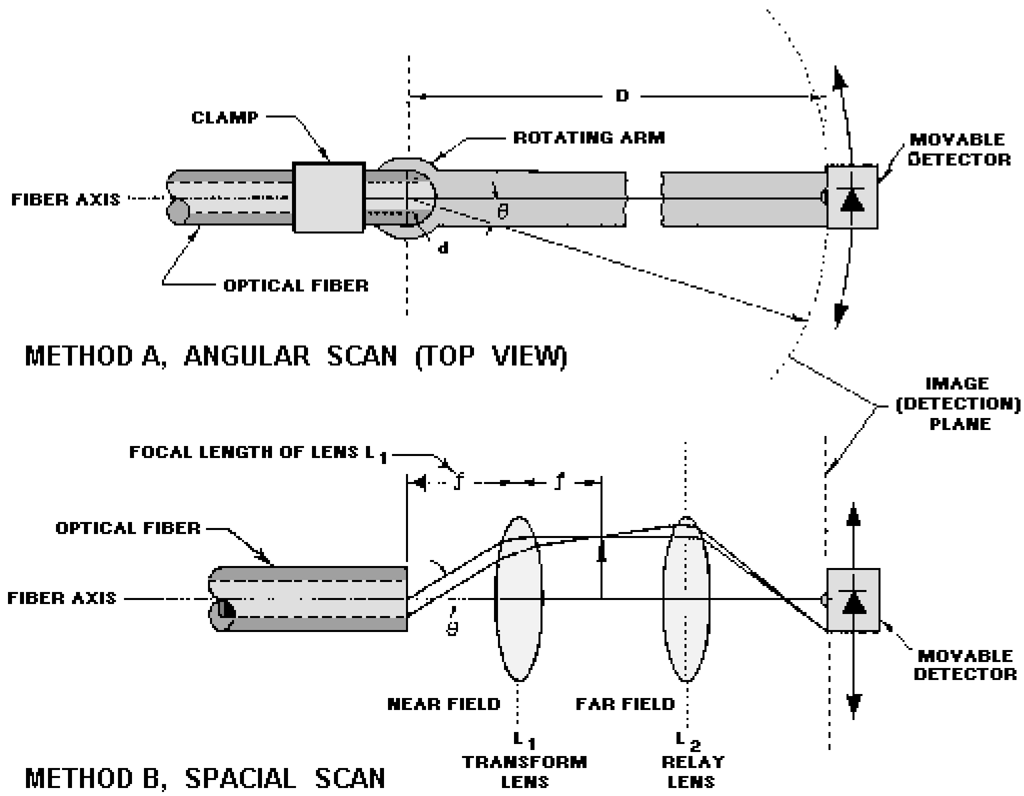

Figure 5-10.—Angular and spacial scan methods for measuring the far-field power distribution.

Figure 5-10 (method A) illustrates a far-field angular scan of the fiber-end face by a rotating detector. The fiber output radiation pattern is scanned by a rotating detector in the far-field. The detector rotates in a spherical manner. A record of the far-field power distribution is kept as a function of angle Θ.

Figure 5-10 (method B) illustrates a far-field spacial scan of the fiber-end face by a movable (planar) detector. In a far-field spacial scan, lens L_1 performs a Fourier transform of the fiber output near-field pattern. A second lens, L_2, is positioned to magnify and relay the transformed image to the detector plane. The image is scanned in a plane by a movable detector. The scan position y in the Fourier transform plane is proportional to the far-field scan angle Θ. A record of the far-field power distribution is kept as a function of the far-field scan angle.

The normalized far-field pattern is plotted as a function of the far-field scan angle Θ. Figure 5-11 shows the plot of the normalized far-field radiation pattern as a function of scan angle.

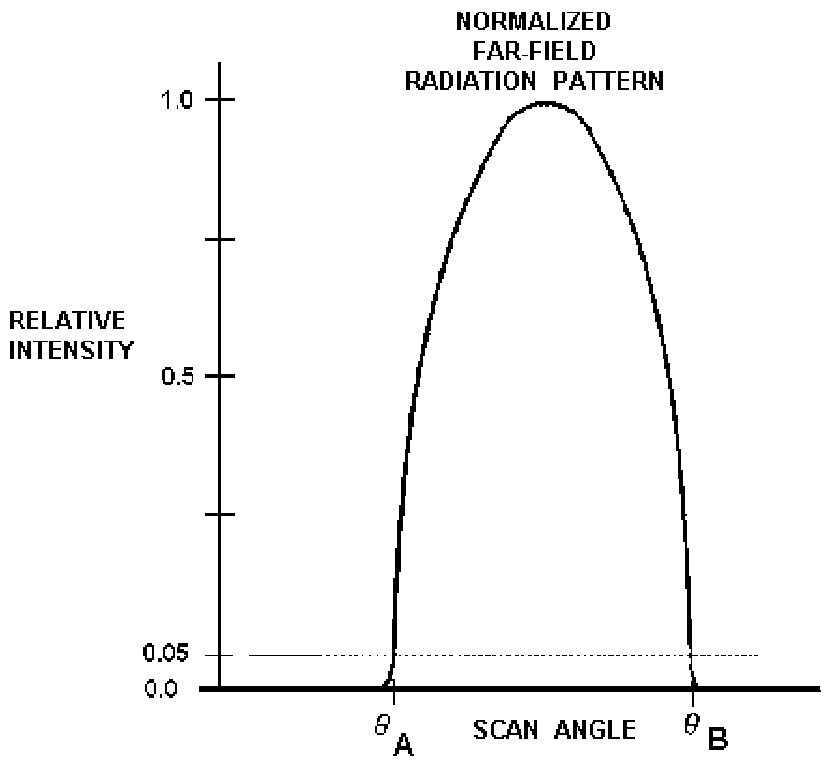

Figure 5-11.—Normalized far-field radiation pattern.

Fiber NA is defined by the 5 percent intensity level, or the 0.05 intensity level, as indicated in figure 5-11. The 0.05 intensity level intersects the normalized curve at scan angles Θ_A and Θ_B. The fiber NA is defined as

$$NA = \sin \Theta_5$$

where Θ_5 is the 5 percent intensity half angle. Θ_5 is determined from Θ_A and Θ_B as shown below:

$$\Theta_5 = \frac{\Theta_A - \Theta_B}{2}$$

Q19. Far-field power distributions describe the emitted power per unit area as a function of angle Θ in the far-field region. Describe the far-field region.

Mode Field Diameter

The mode field diameter (MFD) of a single mode fiber is related to the spot size of the fundamental mode. This spot has a mode field radius w_0. The mode field diameter is equal to $2w_0$. The size of the mode field diameter correlates to the performance of the single mode fiber. Single mode fibers with large mode field diameters are more sensitive to fiber bending. Single mode fibers with small mode field diameters show higher coupling losses at connections.

The mode field diameter of a single mode fiber can be measured using EIA/TIA-455-167. This method involves measuring the output far-field power distribution of the single mode fiber using a set of apertures of various sizes. This far-field power distribution data is transformed into the near-field before using complex mathematical procedures. The mode field diameter is calculated from the transformed near field data. The mathematics behind the transformation between the far-field and near-field is too complicated for discussion in this chapter. Refer to EIA/TIA-455-167 for information on this transformation procedure.

Q20. Will fiber coupling loss generally increase or decrease if the mode field diameter of a single mode fiber is decreased?

Insertion Loss

Insertion loss is composed of the connection coupling loss and additional fiber losses in the fiber following the connection. In multimode fiber, fiber joints can increase fiber attenuation following the joint by disturbing the fiber's mode power distribution (MPD). Fiber joints may increase fiber attenuation because disturbing the MPD may excite radiative modes. Radiative modes are unbound modes that radiate out of the fiber contributing to joint loss. In single mode fibers, fiber joints can cause the second-order mode to propagate in the fiber following the joint. As long as the coupling loss of the connection is small, neither radiative modes (multimode fiber) or the second-order mode (single mode fiber) are excited.

Insertion loss of both multimode and single mode interconnection devices is measured using EIA/TIA-455-34. For Navy applications, an overfill launch condition is used at the input fiber. For other applications a mandrel wrap may be used to strip out high-order mode power. The length of fiber before the connection and after the connection may be specified for some applications. Power measurements are made on an optical fiber or fiber optic cable before the joint is inserted and after the joint is made. Figure 5-12 illustrates the mandrel wrap method of measuring the insertion loss of an interconnecting device in EIA/TIA-455-34.

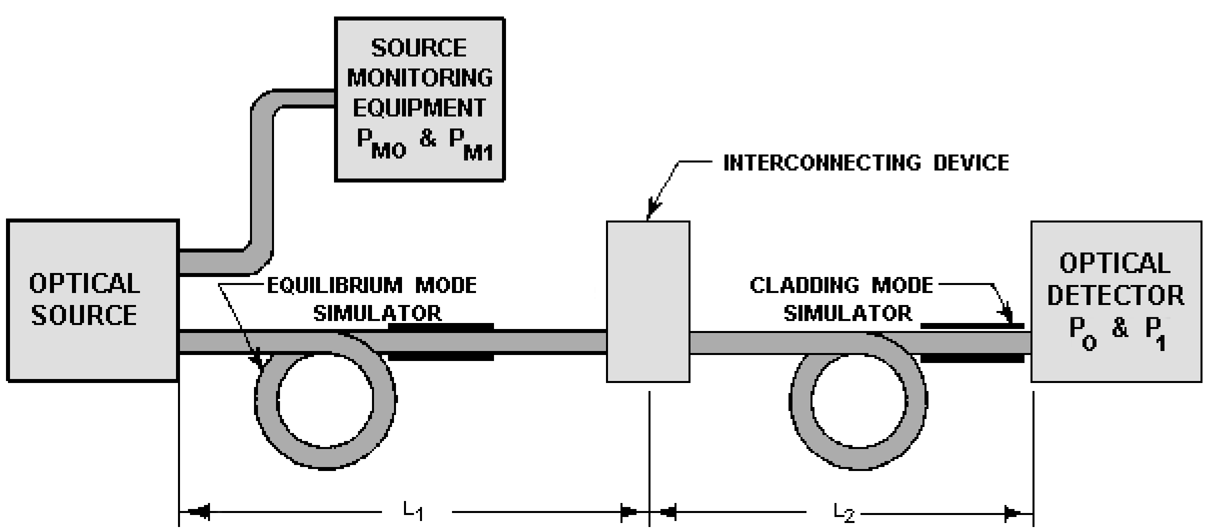

Figure 5-12.—Insertion loss measurement of an interconnecting device.

Initial power measurements at the detector (P_0) and at the source monitoring equipment (P_{M0}) are taken before inserting the interconnecting device into the test setup. The test fiber is then cut at the location specified by the end user. The cut results in a fiber of lengths L_1 and L_2 before and after the interconnection device that simulates the actual system configuration. After interconnection, the power at the detector (P_1) and at the source monitoring equipment (P_{M1}) is measured. The insertion loss is calculated as shown below:

$$\text{Insertion loss} = 10 \log \left\{ \frac{P_1}{P_o} \times \frac{P_{Mo}}{P_{M1}} \right\}$$

If the source power is constant, then the calculation of the insertion loss is similar to that of fiber attenuation.

Q21. In multimode fibers, how do fiber joints increase fiber attenuation following the joint?

Return Loss and Reflectance

Reflections occur at optical fiber connections. Optical power may be reflected back into the source fiber when connecting two optical fibers. In laser-based systems, reflected power reaching the optical source can reduce system performance by affecting the stability (operation) of the source. In addition, multiple reflections occur in fiber optic data links containing more than one connection. Multiple reflections can reduce data link performance by increasing the signal noise present at the optical detector.

Reflectance is a measure of the portion of incident light that is reflected back into the source fiber at the point of connection. Reflectance is given as a ratio (R) of the reflected light intensity to the incident light intensity. The reflectance ratio (R) for Fresnel reflection is discussed in chapter 4.

Return loss and reflectance are measured using EIA/TIA-455-107. They are measured using an optical source connected to one input of a 2×2 fiber optic coupler. Light is launched into the component under test through the fiber optic coupler. The light reflected from the component under test is transmitted back through the fiber optic coupler to a detector connected to the other input port. The optical power is measured at the output of the device under test (P_o) and at the input port of the coupler where the detector is located (P_r). P_o is corrected to account for the loss in power through the device under test. P_r is corrected to account for the loss in power through the coupler and any other connection losses in the path. The reflectance is then given by the ratio P_r/P_o.

Return loss is the amount of loss of the reflected light compared with the power of the incident beam at the interface. The optical return loss at the fiber interface is defined as

$$\text{Return loss} = -10 \text{ Log } R$$

Return loss is only the amount of optical power reflected and does not include power that is transmitted, absorbed, or scattered.

Q22. List two effects that reflections can have on a fiber optic data link.

Q23. Reflectance is given as what ratio?

Q24. Does return loss include power that is transmitted, absorbed, and/or scattered?

FIELD MEASUREMENTS

Field measurements differ from laboratory measurements because they measure the transmission properties of installed fiber optic components. Laboratory measurements can only attempt to simulate the actual operating conditions of installed components. Fiber optic component properties measured in the laboratory can change after the installation of these components on board ship. End users must perform field measurements to evaluate those properties most likely affected by the installation or repair of fiber optic components or systems.

The discussion on field measurements is limited to optical fiber and optical connection properties. Optical fiber and optical connection field measurements evaluate only the transmission properties affected by component or system installation or repair. Because optical fiber geometrical properties, such as core and cladding diameter and numerical aperture, are not expected to change, there is no need to remeasure these properties. The optical fiber properties that are likely to change include fiber attenuation (loss) and bandwidth. Bandwidth changes in the field tend to be beneficial, so field bandwidth measurement is generally not performed. If field bandwidth measurements are required, they are essentially the same as laboratory measurements so they will not be repeated. The optical connection properties that are likely to change are connection insertion loss and reflectance and return loss.

The installation and repair of fiber optic components on board ship can affect system operation. Microbends introduced during installation can increase fiber attenuation. Modal redistribution at fiber joints can increase fiber attenuation in the fiber after the joint. Fiber breaks or faults can prevent or severely disrupt system operation. Poor fiber connections can also increase insertion loss and degrade transmitter and receiver performance by increasing reflectance and return loss. End users should perform field measurements to verify that component performance is within allowable limits so system performance is not adversely affected.

There are additional differences in measuring optical fiber and optical connection properties in the field than in the laboratory. Field measurements require rugged, portable test equipment, unlike the sophisticated test equipment used in the laboratory. Field test equipment must provide accurate measurements in extreme environmental conditions. Since electrical power sources may not always be available in the field, test equipment should allow battery operation. In addition, while both fiber ends are available for conducting laboratory measurements, only one fiber end may be readily available for field measurements. Even if both fiber ends are available for field measurements, the fiber ends are normally located some distance apart. Therefore, field measurements may require two people.

The main field measurement technique involves optical time-domain reflectometry. An optical time-domain reflectometer (OTDR) is recommended for conducting field measurements on installed optical fibers or links of 50 meters or more in length. An OTDR requires access to only one fiber end. An OTDR measures the attenuation of installed optical fibers as a function of length. It also identifies and evaluates optical connection losses along a cable link and locates any fiber breaks or faults.

End users can also measure fiber attenuation and cable plant transmission loss using an optical power meter and a stabilized light source. End users use this measurement technique when optical time-domain reflectometry is not recommended. Measurements obtained with a stabilized light source and power meter are more accurate than those obtained with an OTDR. Measuring fiber attenuation and transmission loss using a power meter and light source requires access to both ends of the fiber or link. An optical loss test set (OLTS) combines the power meter and source functions into one physical unit.

Q25. Is it essential for end users to remeasure optical fiber geometrical properties after installation in the field?

Q26. When is an OTDR recommended for conducting field measurements on installed optical fibers or links?

Optical Time-Domain Reflectometry

End users use optical time-domain reflectometry to characterize optical fiber and optical connection properties in the field. In optical time-domain reflectometry, an OTDR transmits an optical pulse through an installed optical fiber. The OTDR measures the fraction of light that is reflected back due to Rayleigh scattering and Fresnel reflection. By comparing the amount of light scattered back at different times, the OTDR can determine fiber and connection losses. When several fibers are connected to form an installed cable plant, the OTDR can characterize optical fiber and optical connection properties along the entire length of the cable plant. A fiber optic cable plant consists of optical fiber cables, connectors, splices, mounting panels, jumper cables, and other passive components. A cable plant does not include active components such as optical transmitters or receivers.

The OTDR displays the backscattered and reflected optical signal as a function of length. The OTDR plots half the power in decibels (dB) versus half the distance. Plotting half the power in dB and half the distance corrects for round trip effects. By analyzing the OTDR plot, or trace, end users can measure fiber attenuation and transmission loss between any two points along the cable plant. End users can also measure insertion loss and reflectance of any optical connection. In addition, end users use the OTDR trace to locate fiber breaks or faults.

Figure 5-13 shows an example OTDR trace of an installed cable plant. OTDR traces can have several common characteristics. An OTDR trace begins with an initial input pulse. This pulse is a result of Fresnel reflection occurring at the connection to the OTDR. Following this pulse, the OTDR trace is a gradual downsloping curve interrupted by abrupt shifts. Periods of gradual decline in the OTDR trace result from Rayleigh scattering as light travels along each fiber section of the cable plant. Periods of gradual decline are interrupted by abrupt shifts called point defects. A point defect is a temporary or permanent local deviation of the OTDR signal in the upward or downward direction. Point defects are caused by connectors, splices, or breaks along the fiber length. Point defects, or faults, can be reflective or nonreflective. An output pulse at the end of the OTDR trace indicates the end of the fiber cable plant. This output pulse results from Fresnel reflection occurring at the output fiber-end face.

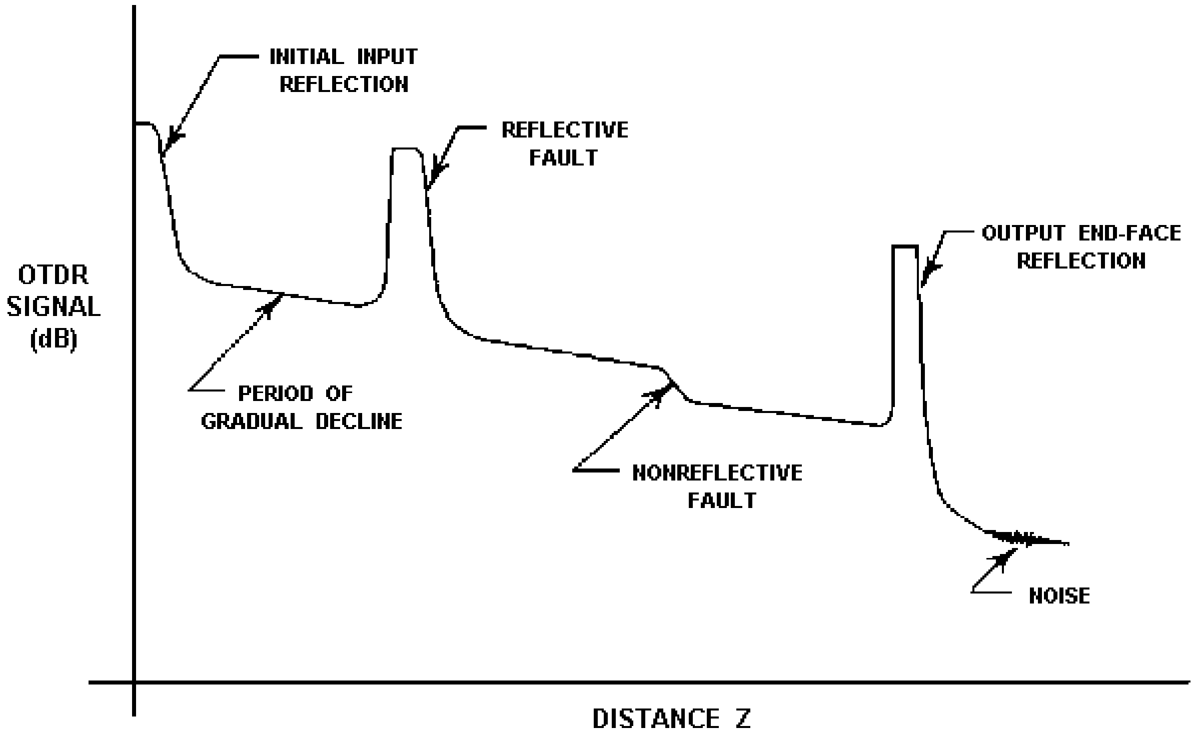

Figure 5-13.—OTDR trace of an installed cable plant.

ATTENUATION.—The fiber optic test method for measuring the attenuation of an installed optical fiber using an OTDR is EIA/TIA-455-61. The accuracy of this test method depends on the user entering the appropriate source wavelength, pulse duration, and fiber length (test range) into the OTDR. In addition, the effective group index of the test fiber is required before the attenuation coefficient and accurate distances can be recorded. The group index (N) is provided by fiber manufacturers or is found using EIA/TIA-455-60. By entering correct test parameters, OTDR fiber attenuation values will closely coincide with those measured by the cutback technique.

Test personnel can connect the test fiber directly to the OTDR or to a dead-zone fiber. This dead-zone fiber is placed between the test fiber and OTDR to reduce the effect of the initial reflection at the OTDR on the fiber measurement. The dead-zone fiber is inserted because minimizing the reflection at a fiber joint is easier than reducing the reflection at the OTDR connection.

Figure 5-14 illustrates the OTDR measurement points for measuring the attenuation of the test fiber using a dead-zone fiber. Fiber attenuation between two points along the test fiber is measured on gradual downsloping sections on the OTDR trace. There should be no point defects present along the portion of fiber being tested.

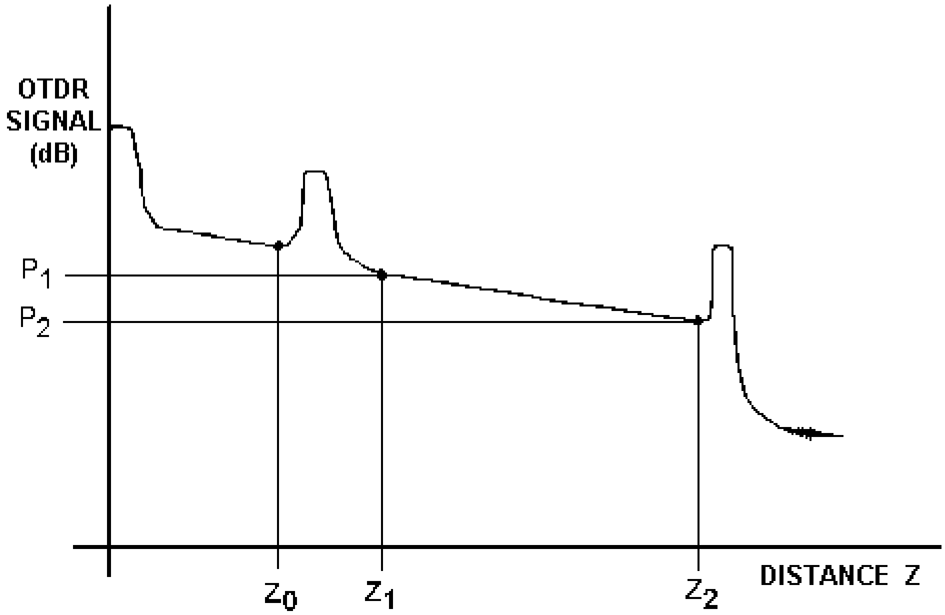

Figure 5-14.—OTDR measurement points for measuring fiber attenuation using a dead-zone fiber.

OTDRs are equipped with either manual or automatic cursors to locate points of interest along the trace. In figure 5-14, a cursor is positioned at a distance z_o on the rising edge of the reflection at the end of the dead-zone fiber. Cursors are also positioned at distances z_1 and z_2. The cursor positioned at z_1 is just beyond the recovery from the reflection at the end of the dead-zone fiber. Since no point defects are present in figure 5-14, the cursor positioned at z_2 locates the end of the test fiber. Cursor z_2 is positioned just before the output pulse resulting from Fresnel reflection occurring at the end of the test fiber.

The attenuation of the test fiber between points z_1 and z_2 is $(P_1 - P_2)$ dB. The attenuation coefficient (α) is

$$a = \frac{(P_1 - P_2}{(z_2 - z_1)} \text{dB/km.}$$

The total attenuation of the fiber including the dead zone after the joint between the dead-zone fiber and test fiber is

$$\text{Attenuation} = (P_1 - P_2)\frac{(z_1 - z_o)}{(z_2 - z_1)} \text{dB.}$$

If fiber attenuation is measured without a dead-zone fiber, z_0 is equal to zero ($z_0 = 0$).

At any point along the length of fiber, attenuation values can change depending on the amount of optical power backscattered due to Rayleigh scattering. The amount of backscattered optical power at each point depends on the forward optical power and its backscatter capture coefficient. The backscatter capture coefficient varies with length depending on fiber properties. Fiber properties that may affect the backscatter coefficient include the refractive index profile, numerical aperture (multimode), and mode-field diameter (single mode) at the particular measurement point. The source wavelength and pulse width may also affect the amount of backscattered power.

By performing the OTDR attenuation measurement in each direction along the test fiber, test personnel can eliminate the effects of backscatter variations. Attenuation measurements made in the opposite direction at the same wavelength (within 5 nm) are averaged to reduce the effect of backscatter variations. This process is called bidirectional averaging. Bidirectional averaging is possible only if test personnel have access to both fiber ends. OTDR attenuation values obtained using bidirectional averaging should compare with those measured using the cutback technique in the laboratory.

POINT DEFECTS.—Point defects are temporary or local deviations of the OTDR signal in the upward or downward direction. A point defect, or fault, can be reflective or nonreflective. A point defect normally exhibits a loss of optical power. However, a point defect may exhibit an apparent power gain. In some cases, a point defect can even exhibit no loss or gain. Refer back to figure 5-13; it illustrates a reflective fault and a nonreflective fault, both exhibiting loss. Figure 5-15 shows a nonreflective fault with apparent gain and a reflective fault with no apparent loss or gain.

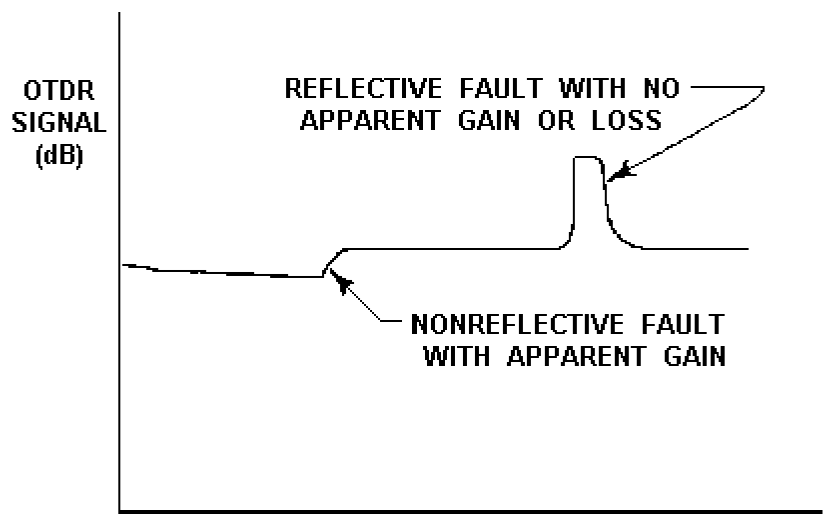

Figure 5-15.—An OTDR trace showing a nonreflective fault with apparent gain and a reflective fault with no apparent loss or gain.

Point defects are located and measured using EIA/TIA-455-59. Test personnel must enter the appropriate input parameters including the source wavelength, the pulse duration, and the fiber or cable group index into the OTDR. The nature of fiber point defects depends on the value of each parameter entered by the end user. The pulse duration usually limits the length of the point defect while other input parameters, such as the wavelength, can vary its shape.

If the length of the fiber point defect changes with the pulse duration, then the OTDR signal deviation is in fact a point defect. If the length remains the same, then the OTDR signal deviation is a region of high fiber attenuation. Regions of high fiber attenuation are referred to as attenuation non-uniformities.

Fiber point defects occur from factory fiber splices or bends introduced during cable construction or installation. For shipboard applications, manufacturers are not allowed to splice fibers during cable construction. Fiber joints are natural sources of OTDR point defects. However, fiber breaks, cracks, or microbends introduced during cable installation are additional sources of point defects.

Point defects that occur at fiber joints are relatively easy to identify because the location of a fiber joint is generally known. A reflective or nonreflective fault occurs at a distance equal to fiber joint location. In most circumstances, an optical connector produces a reflective fault, while an optical splice produces a nonreflective fault.

Reflective and nonreflective faults occurring at distances other than fiber joint locations identify fiber breaks, cracks, or microbends. A fiber break produces a reflective fault because fiber breaks result in complete fiber separation. Fiber cracks and microbends generally produce nonreflective faults.

A point defect may exhibit apparent gain because the backscatter coefficient of the fiber present before the point defect is higher than that of the fiber present after. Test personnel measure the signal loss or gain by positioning a pair of cursors, one on each side of the point defect. Figure 5-16 illustrates the positioning of the cursors for a point defect showing an apparent signal gain. The trace after the point defect is extrapolated as shown in figure 5-16. The vertical distance between the two lines in figure 5-16 is the apparent gain of the point defect.

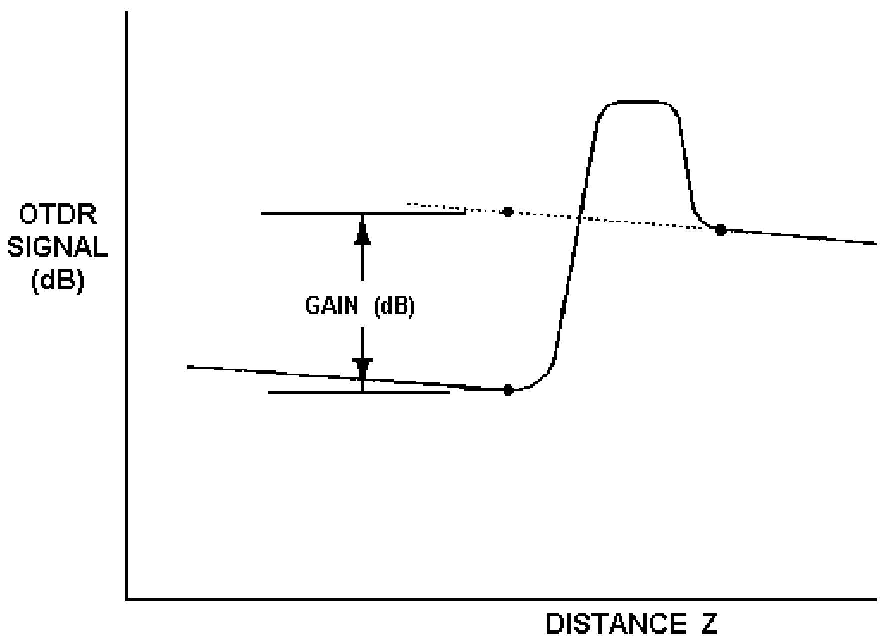

Figure 5-16.—Extrapolation for a point defect showing an apparent signal gain.

Point defects exhibiting gain in one direction will exhibit an exaggerated loss in the opposite direction. Figure 5-17 shows the apparent loss shown by the OTDR for the same point defect shown in figure 5-16 when measured in the opposite direction. Bidirectional measurements are conducted to cancel the effects of backscatter coefficient variations. Bidirectional averaging combines the two values to identify the true signal loss. Bidirectional averaging is possible only if test personnel have access to both ends of the test sample.

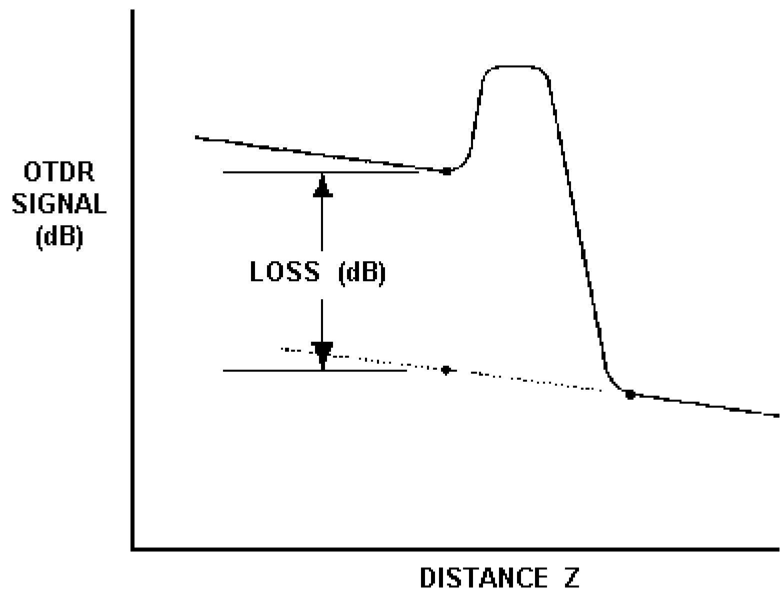

Figure 5-17.—The exaggerated loss obtained at point defects exhibiting gain in one direction by conducting the OTDR measurement in the opposite direction.

OTDRs can also measure the return loss of a point defect. However, not all OTDRs are configured to make the measurement. To measure the return loss of a point defect, the cursors are placed in the same places as for measuring the loss of the point defect. The return loss of the point defect is displayed when the return loss option is selected on the OTDR. The steps for selecting the return loss option depend upon the OTDR being used.

Q27. An OTDR measures the fraction of light that is reflected back from the fiber or link under test. What causes light to be reflected back into the OTDR?

Q28. List the types of fiber optic components considered part of a fiber optic cable plant.

Q29. What is a temporary or permanent local deviation of the OTDR signal in the upward or downward direction called?

Q30. Why is a dead-zone fiber placed between the test fiber and OTDR when conducting attenuation measurements?

Q31. The amount of backscattered optical power at each point depends on what two properties?

Q32. How can test personnel eliminate the effects of backscatter variations?

Q33. If the length of the fiber point defect changes with pulse duration, is the OTDR signal deviation a point defect or a region of high fiber attenuation?

Q34. Give the type of fault (reflective or nonreflective) normally produced by: (a) fiber breaks, (b) fiber cracks, and (c) fiber microbends.

Q35. Explain how a point defect may exhibit an apparent gain.

Q36. A point defect exhibiting an apparent gain in one direction will exhibit what, when measured in the opposite direction?

Power Meter

Test personnel also use an optical power meter and stabilized light source to measure fiber attenuation and transmission loss in the field. Optical power meter measurements are recommended when the length of an installed optical fiber cable or cable plant is less than 50 meters. A test jumper is used to couple light from the stabilized source to one end of the optical fiber (or cable plant) under test. An additional test jumper is also used to connect the other end of the optical fiber (or cable plant) under test to the power meter. Optical power meter measurements may be conducted using an optical loss test set (OLTS). An OLTS combines the power meter and source functions into one physical unit. When making measurements, it does not matter whether the stabilized source and power meter are in one physical unit or two.

Power meter measurements are conducted on individual optical fiber cables installed on board ship. The installed optical fiber cable must have connectors or terminations on both ends to make the measurement. If the installed optical fiber cable does not have connectors or terminations on both ends, an OTDR should be used to evaluate the cable. If the cable is too short for evaluation with an OTDR, cable continuity can be verified using a flashlight.

Power meter measurements for cable assembly link loss require that test personnel clean all optical connections at test jumper interfaces before performing any measurement. Test personnel should use cotton wipes dampened with alcohol to clean connectors and blow dry before making connections. End users should also ensure that test equipment calibration is current.

Power meter measurements connecting a test reference cable between the light source and power meter. The test reference cable has the same nominal fiber characteristics as the cable under test. The optical power present at the power meter is the reference power (P_1). Disconnect the test reference cable and connect the optical fiber cable under test between the light source and power meter using test jumpers. If possible, the test reference cable should be used as the input jumper cable for the test cable measurement. The test jumper fiber properties, such as core diameter and NA, should be nominally equal to the fiber properties of the cable being tested. The optical power present at the power meter is test power (P_2).

Test personnel use P_1 and P_2 to calculate the cable assembly link loss. The cable assembly link loss (B_{CA}) of optical fiber installed with connectors or terminations on both ends is

$$B_{CA} = (P_1 = P_2)\ \mathrm{dB}$$

The cable assembly link loss should always be less than the specified link loss for that particular link.

Besides measuring individual cables, test personnel measure the transmission loss of installed fiber optic cable plants. The transmission loss of fiber optic cable plants is measured using EIA/TIA-526-14 method B (multimode fiber) or EIA/TIA-526-7 (single mode fiber). The procedure measures the internal loss of the cable plant between points A and B, plus two connection losses. Figure 5-18 (A) illustrates the method described in EIA/TIA-526-14 method B for measuring the reference power (P_1). Figure 5-18 (B) shows the final test configuration for measuring the cable plant test power (P_2).

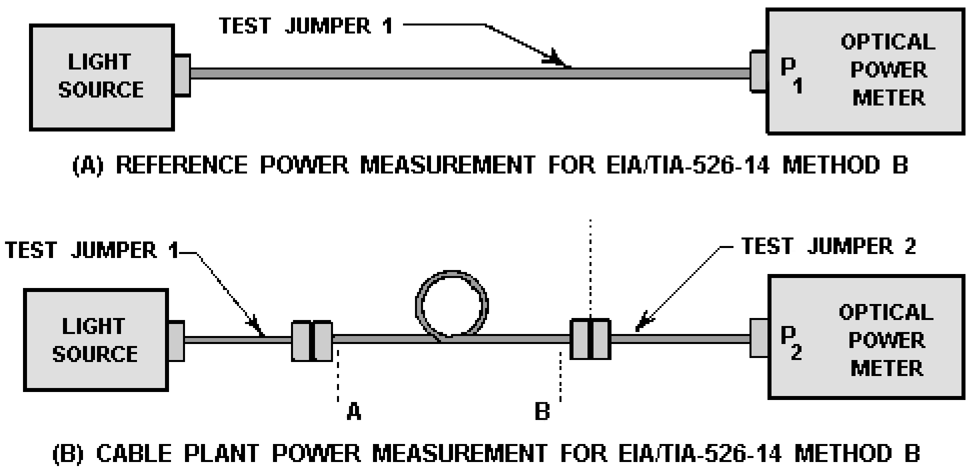

Figure 5-18.—EIA/TIA-526-14 methods for measuring the reference power (P_1).

The procedure is exactly the same as described for measuring the link loss of an individual cable assembly. The total optical loss between any two termination points, including the end terminations, of the optical fiber cable plant link is measured. The measured cable plant link loss should always be less than the specified cable plant link loss.

Test personnel should conduct cable assembly link loss, and cable plant transmission loss measurements in both directions and at each system operational wavelength. By performing these measurements in each direction, test personnel can better characterize cable and link losses. Unlike optical time-domain reflectometry, bidirectional readings are always possible when performing power meter measurements. In power meter measurements, by definition, end users have access to both ends of the cable or cable plant.

Q37. When is an optical power meter measurement recommended for conducting field measurements on installed optical fiber cables or cable plants?

Q38. If an installed optical fiber cable does not have connectors or terminations on both ends, how should the cable be tested?

SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas that you have learned. You should have a thorough understanding of these principles before moving on to chapter 6.

END USERS (equipment manufacturers, shipbuilders, maintenance personnel, test personnel, and so on) should measure some component parameters upon receipt before installing the component into the fiber optic data link. In addition, they should measure some component parameters after installing or repairing fiber optic components in the field.

LABORATORY MEASUREMENTS of the optical fiber and optical connections performed by end users in the laboratory include attenuation, cutoff wavelength (single mode), bandwidth (multimode), chromatic dispersion, fiber geometry, core diameter, numerical aperture (multimode), mode field diameter (single mode), insertion loss, and reflectance and return loss.

ATTENUATION is the loss of optical power as light travels along the fiber. It is a result of absorption, scattering, bending, and other loss mechanisms.

The **LAUNCH SPOT SIZE** and the **ANGULAR DISTRIBUTION** may affect multimode fiber attenuation measurement results by affecting modal distributions.

An **UNDERFILLED** launch results when the launch spot size and angular distribution are smaller than that of the fiber core.

An **OVERFILLED** launch condition occurs when the launch spot size and angular distribution are larger than that of the fiber core.

A **CLADDING-MODE STRIPPER** is a device that removes any cladding mode power from the fiber.

A **MODE FILTER** is a device that attenuates a specific mode or modes propagating in the core of an optical fiber.

The **CUTOFF WAVELENGTH** of a single mode fiber is the wavelength above which the fiber propagates only the fundamental mode. The cutoff wavelength of a single mode fiber varies according to the fiber's radius of curvature and length. The fiber cutoff wavelength (λ_{cf}) will generally be higher than the cable cutoff wavelength (λ_{cc}).

PULSE DISTORTION is the spreading of the light pulse as it travels along the fiber caused by dispersion. It reduces the bandwidth, or information-carrying capacity, of an optical fiber.

Two **BASIC TECHNIQUES** are used for measuring the modal bandwidth of an optical fiber. The first characterizes dispersion by measuring the **IMPULSE RESPONSE h(t)** of the fiber in the time domain. The second characterizes modal dispersion by measuring the **BASEBAND FREQUENCY RESPONSE H(*f*)** of the fiber in the frequency domain.

The **LOWEST FREQUENCY** at which the magnitude of the fiber frequency response has decreased to one half its zero-frequency value is the -3 decibel (dB) optical power frequency (f_{3dB}).

CHROMATIC DISPERSION occurs because different colors of light travel through the fiber at different speeds. Since the different colors of light have different velocities, some colors arrive at the fiber end before others.

The **DIFFERENTIAL GROUP DELAY** $\tau(\lambda)$ is the variation in propagation delay that occurs because of the different group velocities of each wavelength in an optical fiber.

The **RANGE OF WAVELENGTHS** over which meaningful chromatic dispersion data is obtained depends on the wavelength range of optical source(s) used.

FIBER GEOMETRY MEASUREMENTS are performed by end users to reduce system attenuation and coupling loss resulting from poor fiber fabrication.

The **CLADDING DIAMETER** is the average diameter of the cladding.

CLADDING NONCIRCULARITY, or ellipticity, is the difference between the smallest radius of the fiber (R_{gmin}) and the largest radius of the fiber (R_{gmax}) divided by the average cladding radius (R_g).

The **CORE-CLADDING CONCENTRICITY ERROR** for multimode fibers is the distance between the core and cladding centers divided by the core diameter. The core-cladding concentricity error for single mode fibers is defined as the distance between the core and cladding centers.

CORE NONCIRCULARITY is the difference between the smallest radius of the core (R_{cmin}) and the largest radius of the core (R_{cmax}) divided by the core radius (R_c).

The **NEAR-FIELD POWER DISTRIBUTION** is defined as the emitted power per unit area (radiance) for each position in the plane of the emitting surface.

The **NEAR-FIELD REGION** is the region close to the fiber-end face.

The **CORE DIAMETER** is derived from the normalized output near-field radiation pattern. The core diameter (D) is defined as the diameter at the 2.5 percent (0.025) level.

The **NUMERICAL APERTURE (NA)** is a measurement of the ability of a multimode optical fiber to capture light.

The **FAR-FIELD POWER DISTRIBUTION** describes the emitted power per unit area as a function of angle Θ some distance away from the fiber-end face.

The **FAR-FIELD REGION** is the region far from the fiber-end face.

Single mode fibers with large **MODE FIELD DIAMETERS** are more sensitive to fiber bending. Single mode fibers with small mode field diameters show higher coupling losses at connections.

INSERTION LOSS is composed of the connection coupling loss and additional fiber losses in the fiber following the connection.

REFLECTANCE is a measure of the portion of incident light that is reflected back into the source fiber at the point of connection.

RETURN LOSS is the amount of loss of the reflected light compared with the power of the incident beam at the interface.

OPTICAL FIBER and **OPTICAL CONNECTION FIELD MEASUREMENTS** measure only the transmission properties affected by component or system installation or repair.

OPTICAL TIME-DOMAIN REFLECTOMETRY is recommended for conducting field measurements on installed optical fibers or cable plants of 50 meters or more in length.

An **OPTICAL LOSS TEST SET (OLTS)** combines the power meter and source functions into one physical unit.

An **OPTICAL TIME-DOMAIN REFLECTOMETER (OTDR)** measures the fraction of light that is reflected back because of Rayleigh scattering and Fresnel reflection.

A **FIBER OPTIC CABLE PLANT** consists of optical fiber cables, connectors, splices, mounting panels, jumper cables, and other passive components. A cable plant does not include active components such as optical transmitters or receivers.

A **POINT DEFECT** is a temporary or permanent local deviation of the OTDR signal in the upward or downward direction. Point defects are caused by connectors, splices, or fiber breaks. Point defects, or faults, can be reflective or nonreflective.

A **DEAD-ZONE** fiber is placed between the test fiber and OTDR to reduce the influence of the initial pulse resulting from Fresnel reflection at the OTDR connection.

The **AMOUNT OF OPTICAL POWER BACKSCATTERED** because of Rayleigh scattering at one point depends on the forward optical power and the fibers backscatter capture coefficient.

The **EFFECTS OF BACKSCATTER VARIATIONS** can be eliminated by test personnel by performing the OTDR attenuation measurement in each direction along the test fiber and averaging (bidirectional readings).

A **POINT DEFECT** may exhibit apparent gain because the backscatter coefficient of the fiber present before the point defect is higher than that of the fiber present after.

To **MEASURE FIBER ATTENUATION** and **TRANSMISSION LOSS** in the field, test personnel use an optical power meter and stabilized light source.

OPTICAL POWER METER MEASUREMENTS are recommended when the length of an installed optical fiber cable or cable plant is less than 50 meters.

ANSWERS TO QUESTIONS Q1. THROUGH Q38.

A1. Cladding diameter, core diameter, numerical aperture, and mode field diameter.

A2.

$$A = 10\log\frac{P_x}{P_y}\,\mathrm{dB}$$

A3. Yes.

A4. Launch spot size and angular distribution.

A5. Low-order modes.

A6. Overfilled.

A7. Second-order mode.

A8. Free-form loop and mandrel wrap.

A9. Depressed-clad.

A10. Higher.

A11. The -3 decibel (dB) is the lowest frequency at which the magnitude of the fiber frequency response has decreased to one half its zero-frequency value.

A12. Differential group delay $\tau(\lambda)$.

A13. The wavelength range of the optical source(s) used.

A14. To reduce system attenuation and coupling loss resulting from poor fiber fabrication.

A15. The cladding diameter is the average diameter of the cladding.

A16. Multimode core-cladding concentricity error is the distance between the core and cladding centers expressed as a percentage of core diameter while the single mode core-cladding concentricity error is just the distance between the core and cladding centers.

A17. The near-field region is the region close to the fiber-end face.

A18. The core diameter is defined as the diameter at which the near-field intensity is 2.5 percent of the maximum intensity.

A19. The far-field region is the region far from the fiber-end face.

A20. Increase.

A21. By disturbing the fiber's mode power distribution (MPD).

A22. Reduce the stability of the system source and increase the signal noise present at the optical detector.

A23. The ratio of reflected optical power to incident optical power.

A24. No.

A25. No.

A26. When installed optical fiber cables or links are 50 meters or more in length.

A27. Rayleigh scattering and Fresnel reflection.

A28. Optical fiber cables, connectors, splices, mounting panels, jumper cables, and other passive components.

A29. A point defect.

A30. To reduce the effect of the initial reflection at the OTDR.

A31. Forward optical power and backscatter capture coefficient.

A32. By performing the OTDR attenuation measurements in each direction along the test fiber.

A33. A point defect.

A34. (a) Reflective, (b) nonreflective, and (c) nonreflective.

A35. A point defect may exhibit apparent gain because the backscatter coefficient of the fiber present before the point defect is higher than that of the fiber present after.

A36. An exaggerated loss.

A37. When an installed optical fiber cable or cable plant is less than 50 meters in length.

A38. With an OTDR unless it is less than 50 meters in length. If it is less than 50 meters in length, continuity should be verified with a flashlight.

CHAPTER 6

OPTICAL SOURCES AND FIBER OPTIC TRANSMITTERS

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to do the following:

1. Explain the principal properties of an optical source and fiber optic transmitter.
2. Discuss the optical emission properties of semiconductor light-emitting diodes (LEDs) and laser diodes (LDs).
3. Describe the operational differences between surface-emitting LEDs (SLEDs), edge-emitting LEDs (ELEDs), superluminescent diodes (SLDs), and laser diodes.
4. Describe typical fiber optic transmitter packages.

INTRODUCTION TO OPTICAL SOURCES AND FIBER OPTIC TRANSMITTERS

Chapter 1 taught you that a fiber optic data link has three basic functions. One function is that a fiber optic data link must convert an electrical signal to an optical signal permitting the transfer of data along an optical fiber. The fiber optic device responsible for that signal conversion is a fiber optic transmitter.

A fiber optic transmitter is a hybrid device. It converts electrical signals into optical signals and launches the optical signals into an optical fiber. A fiber optic transmitter consists of an interface circuit, a source drive circuit, and an optical source. The interface circuit accepts the incoming electrical signal and processes it to make it compatible with the source drive circuit. The source drive circuit intensity modulates the optical source by varying the current through the source.

An optical source converts electrical energy (current) into optical energy (light). Light emitted by an optical source is launched, or coupled, into an optical fiber for transmission. Fiber optic data link performance depends on the amount of optical power (light) launched into the optical fiber. This chapter attempts to provide an understanding of light-generating mechanisms within the main types of optical sources used in fiber optics.

Q1. What are the three parts of a fiber optic transmitter?

Q2. Which part of a fiber optic transmitter converts the processed electrical signal to an optical signal?

OPTICAL SOURCE PROPERTIES

The development of efficient semiconductor optical sources, along with low-loss optical fibers, led to substantial improvements in fiber optic communications. Semiconductor optical sources have the physical characteristics and performance properties necessary for successful implementations of fiber optic systems. It is desirable that optical sources:

- Be compatible in size to low-loss optical fibers by having a small light-emitting area capable of launching light into fiber

- Launch sufficient optical power into the optical fiber to overcome fiber attenuation and connection losses allowing for signal detection at the receiver

- Emit light at wavelengths that minimize optical fiber loss and dispersion. Optical sources should have a narrow spectral width to minimize dispersion

- Allow for direct modulation of optical output power

- Maintain stable operation in changing environmental conditions (such as temperature)

- Cost less and be more reliable than electrical devices, permitting fiber optic communication systems to compete with conventional systems

Semiconductor optical sources suitable for fiber optic systems range from inexpensive light-emitting diodes (LEDs) to more expensive semiconductor lasers. Semiconductor LEDs and laser diodes (LDs) are the principal light sources used in fiber optics.

OPERATING WAVELENGTH

Fiber optic communication systems operate in the 850-nm, the 1300-nm, and the 1550-nm wavelength windows. Semiconductor sources are designed to operate at wavelengths that minimize optical fiber absorption and maximize system bandwidth. By designing an optical source to operate at specific wavelengths, absorption from impurities in the optical fiber, such as hydroxyl ions (OH^-), can be minimized. Maximizing system bandwidth involves designing optical fibers and sources that minimize chromatic and intermodal dispersion at the intended operational wavelength.

Initially, the material properties of semiconductor optical sources provided for optical emission in the 850-nm wavelength region. An 850-nm operational wavelength avoids fiber absorption loss from OH^- impurities near the 900-nm wavelength. Light sources for 850-nm systems were originally semiconductor LEDs and lasers. Currently, most 850-nm systems use LEDs as a light source. LEDs operating at 850-nm provide sufficient optical power for short-distance, low-bandwidth systems. However, multimode fiber dispersion, the relatively high fiber attenuation, and the LED's relatively low optical output power prevent the use of these devices in longer-distance, higher bandwidth systems.

The first development allowing the operational wavelength to move from 850 nm to 1300 nm was the introduction of multimode graded-index fibers. Multimode graded-index fibers have substantially lower intermodal dispersion than multimode step-index fibers. Systems operating at 850 nm cannot take full advantage of the fiber's low intermodal dispersion because of high chromatic dispersion at 850 nm. However, the use of multimode graded-index fibers allow 850-nm LEDs to operate satisfactorily in short-distance, higher bandwidth systems.

Following the enhancements in multimode fiber design, next generation LEDs were designed to provide optical emission in the 1300-nm region. Multimode graded-index fiber systems using these LEDs can operate over longer distances and at higher bandwidths than 850-nm systems. Longer distances and higher bandwidths are possible because fiber material losses and dispersion are significantly reduced at the 1300-nm region.

Advances in single mode fiber design and construction sped the development of semiconductor LEDs and LDs optimized for single mode fibers. Single mode fibers have very low dispersion values. However, existing LEDs were unable to focus and launch sufficient optical power into single mode fibers for long-haul, very high-bandwidth communication systems. New semiconductor LEDs and LDs capable of operating with single mode fibers at 1300 nm were developed to take advantage of single mode fiber's very low value of dispersion. Additionally, LEDs and LDs operating at 1550 nm were developed to take advantage of the fiber's lowest loss.

Q3. LEDs operating at 850 nm provide sufficient optical power for short-distance, low-bandwidth multimode systems. List three conditions that prevent the use of LEDs in longer distance, higher bandwidth multimode systems.

Q4. Why can multimode graded-index fiber 1300-nm systems using LEDs operate over longer distances and at higher bandwidths than 850-nm systems?

SEMICONDUCTOR LIGHT-EMITTING DIODES AND LASER DIODES

Semiconductor LEDs emit incoherent light. Spontaneous emission of light in semiconductor LEDs produces light waves that lack a fixed-phase relationship. Light waves that lack a fixed-phase relationship are referred to as incoherent light. Spontaneous emission of light is discussed in more detail later in this chapter. The use of LEDs in single mode systems is severely limited because they emit unfocused incoherent light. Even LEDs developed for single mode systems are unable to launch sufficient optical power into single mode fibers for many applications. LEDs are the preferred optical source for multimode systems because they can launch sufficient power at a lower cost than semiconductor LDs.

Semiconductor LDs emit coherent light. LDs produce light waves with a fixed-phase relationship (both spatial and temporal) between points on the electromagnetic wave. Light waves having a fixed-phase relationship are referred to as coherent light. Stimulated emission of light is discussed later in this chapter. Since semiconductor LDs emit more focused light than LEDs, they are able to launch optical power into both single mode and multimode optical fibers. However, LDs are usually used only in single mode fiber systems because they require more complex driver circuitry and cost more than LEDs.

Optical power produced by optical sources can range from microwatts (μW) for LEDs to tens of milliwatts (mW) for semiconductor LDs. However, it is not possible to effectively couple all the available optical power into the optical fiber for transmission.

The amount of optical power coupled into the fiber is the relevant optical power. It depends on the following factors:

- The angles over which the light is emitted
- The size of the source's light-emitting area relative to the fiber core size
- The alignment of the source and fiber
- The coupling characteristics of the fiber (such as the NA and the refractive index profile)

Typically, semiconductor lasers emit light spread out over an angle of 10 to 15 degrees. Semiconductor LEDs emit light spread out at even larger angles. Coupling losses of several decibels can easily occur when coupling light from an optical source to a fiber, especially with LEDs.

Source-to-fiber coupling efficiency is a measure of the relevant optical power. The coupling efficiency depends on the type of fiber that is attached to the optical source. Coupling efficiency also depends on the coupling technique. Source-to-fiber coupling involves centering a flat fiber-end face over the emitting region of the light source. If the fiber end face is directly placed over the source emitting region, it is referred to as butt coupling. If the source's output light pattern is larger than the fiber's acceptance pattern, source-to-fiber coupling efficiency may be improved by placing a small lens between the source and fiber. Lensing schemes improve coupling efficiency when coupling both LEDs and LDs to optical fibers.

Q5. Semiconductor LEDs emit incoherent light. Define incoherent light.

Q6. Which semiconductor sources (LD or LED) emit more focused light and are capable of launching sufficient optical power into both single mode and multimode fibers?

Q7. The amount of optical power coupled into an optical fiber depends on what four factors?

SEMICONDUCTOR MATERIAL AND DEVICE OPERATING PRINCIPLES

Understanding optical emission in semiconductor lasers and LEDs requires knowledge of semiconductor material and device properties. Providing a complete description of semiconductor properties is beyond the scope of this introductory manual. In this chapter we only discuss the general properties of semiconductor LEDs and LDs.

Semiconductor sources are diodes, with all of the characteristics typical of diodes. However, their construction includes a special layer, called the active layer, which emits photons (light particles) when a current passes through the layer. The particular properties of the semiconductor are determined by the materials used and the layering of the materials within the semiconductor. Silicon (Si) and gallium arsenide (GaAs) are the two most common semiconductor materials used in electronic and electro-optic devices. In some cases other elements, such as aluminum (Al), indium (In) and phosphorus (P), are added to the base semiconductor material to modify the semiconductor properties. These elements are called dopants.

Current flowing through a semiconductor optical source causes it to produce light. An in-depth description of either of the two processes by which this occurs is beyond the scope of this module. However, we discuss elementary descriptions in the following paragraphs.

LEDs generally produce light through spontaneous emission when a current is passed through them. Spontaneous emission is the random generation of photons within the active layer of the LED. The emitted photons move in random directions. Only a certain percentage of the photons exit the semiconductor and are coupled into the fiber. Many of the photons are absorbed by the LED materials and the energy dissipated as heat. This process causes the light output from an LED to be incoherent, have a broad spectral width, and have a wide output pattern.

Laser diodes are much more complex than LEDs. Laser is an acronym for light amplification by the stimulated emission of radiation. Laser diodes produce light through stimulated emission when a current is passed through them. Stimulated emission describes how light is produced in any type of laser. In the laser diode, photons, initially produced by spontaneous emission interact with the laser material to produce additional photons. This process occurs within the active area of the diode called the laser cavity. The process does not affect the original photon. The stimulated photon has many of the same properties (wavelength, direction, phase) as the original photon.

As with the LED, not all of the photons produced are emitted from the laser diode. Some of the photons are absorbed and the energy dissipated as heat. The emission process and the physical characteristics of the diode cause the light output to be coherent, have a narrow spectral width, and have a narrow output pattern.

It is important to note that in both LED and laser diodes all of the electrical energy is not converted into optical energy. A substantial portion is converted to heat. Different LED and laser diode structures convert differing amounts of electrical energy into optical energy.

Q8. What are the two most common semiconductor materials used in electronic and electro-optic devices?

Q9. What is a laser?

Q10. .Describe stimulated emission.

LIGHT-EMITTING DIODES

A light-emitting diode (LED) is a semiconductor device that emits incoherent light, through spontaneous emission, when a current is passed through it. Typically LEDs for the 850-nm region are fabricated using GaAs and AlGaAs. LEDs for the 1300-nm and 1550-nm regions are fabricated using InGaAsP and InP.

The basic LED types used for fiber optic communication systems are the surface-emitting LED (SLED), the edge-emitting LED (ELED), and the superluminescent diode (SLD). LED performance differences help link designers decide which device is appropriate for the intended application. For short-distance (0 to 3 km), low-data-rate fiber optic systems, SLEDs and ELEDs are the preferred optical source. Typically, SLEDs operate efficiently for bit rates up to 250 megabits per second (Mb/s). Because SLEDs emit light over a wide area (wide far-field angle), they are almost exclusively used in multimode systems.

For medium-distance, medium-data-rate systems, ELEDs are preferred. ELEDs may be modulated at rates up to 400 Mb/s. ELEDs may be used for both single mode and multimode fiber systems. Both SLDs and ELEDs are used in long-distance, high-data-rate systems. SLDs are ELED-based diodes designed to operate in the superluminescence mode. A further discussion on superluminescence is provided later in this chapter. SLDs may be modulated at bit rates of over 400 Mb/s.

Surface-Emitting LEDs

The surface-emitting LED (shown in figure 6-1) is also known as the Burrus LED in honor of C. A. Burrus, its developer. In SLEDs, the size of the primary active region is limited to a small circular area of 20 μm to 50 μm in diameter. The active region is the portion of the LED where photons are emitted. The primary active region is below the surface of the semiconductor substrate perpendicular to the axis of the fiber. A well is etched into the substrate to allow direct coupling of the emitted light to the optical fiber. The etched well allows the optical fiber to come into close contact with the emitting surface. In addition, the epoxy resin that binds the optical fiber to the SLED reduces the refractive index mismatch, increasing coupling efficiency.

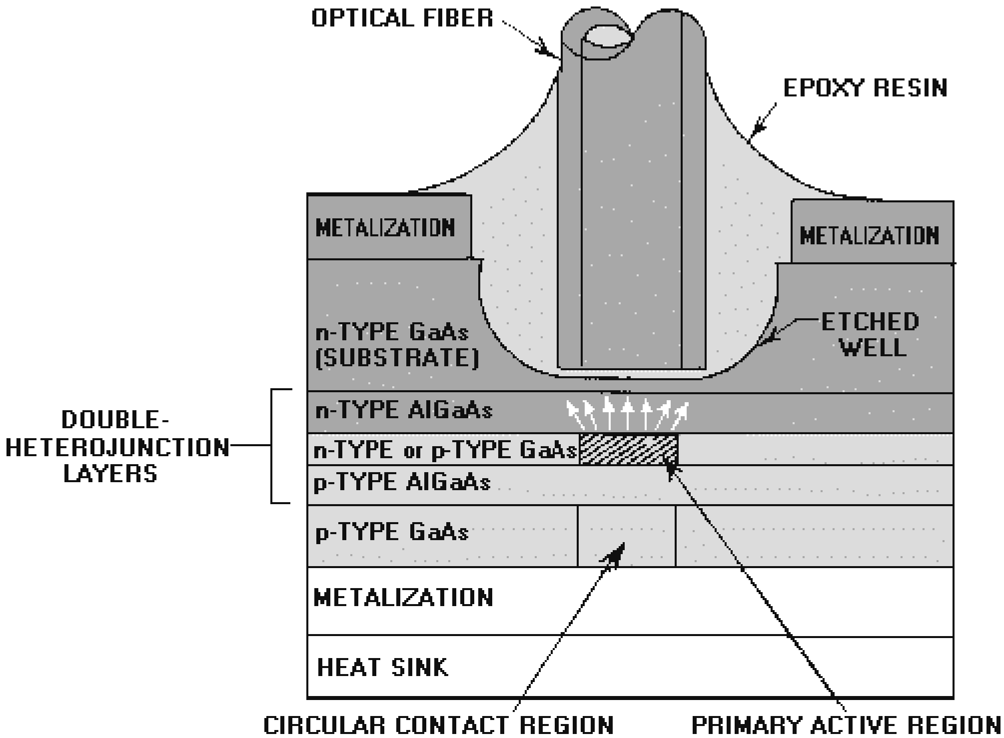

Figure 6-1.—Example of the SLED structure.

Edge-Emitting LEDs

The demand for optical sources for longer distance, higher bandwidth systems operating at longer wavelengths led to the development of edge-emitting LEDs. Figure 6-2 shows a typical ELED structure. It shows the different layers of semiconductor material used in the ELED. The primary active region of the ELED is a narrow stripe, which lies below the surface of the semiconductor substrate. The semiconductor substrate is cut or polished so that the stripe runs between the front and back of the device. The polished or cut surfaces at each end of the stripe are called facets.

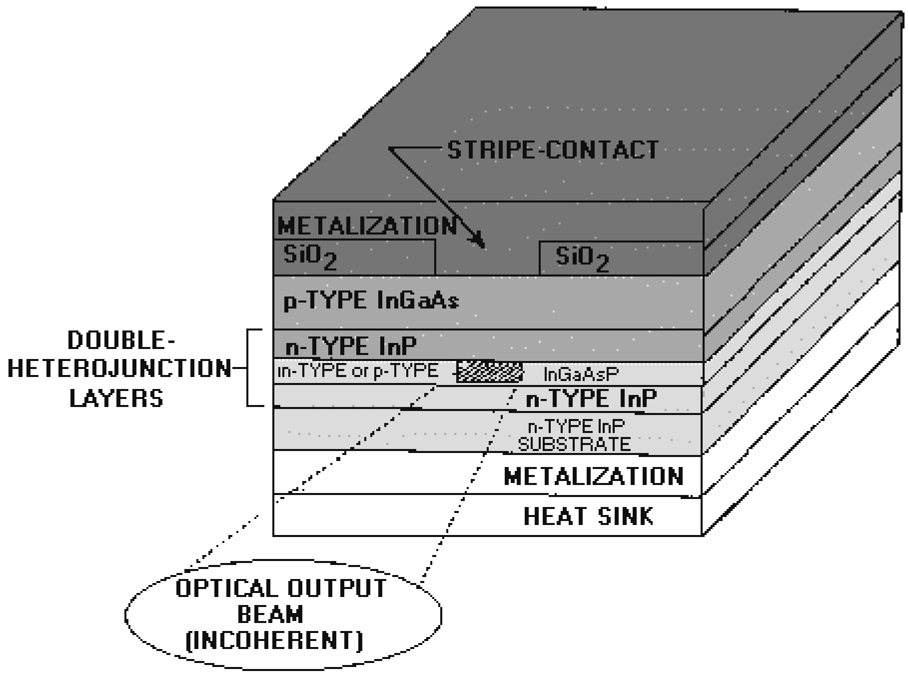

Figure 6-2.—Example of the ELED structure.

In an ELED the rear facet is highly reflective and the front facet is antireflection-coated. The rear facet reflects the light propagating toward the rear end-face back toward the front facet. By coating the front facet with antireflection material, the front facet reduces optical feedback and allows light emission. ELEDs emit light only through the front facet.

ELEDs emit light in a narrow emission angle allowing for better source-to-fiber coupling. They couple more power into small NA fibers than SLEDs. ELEDs can couple enough power into single mode fibers for some applications. ELEDs emit power over a narrower spectral range than SLEDs. However, ELEDs typically are more sensitive to temperature fluctuations than SLEDs.

LASER DIODES

A laser is a device that produces optical radiation by the process of stimulated emission. It is necessary to contain photons produced by stimulated emission within the laser active region. Figure 6-3 shows an optical cavity formed to contain the emitted photons by placing one reflecting mirror at each end of an amplifying medium. One mirror is made partially reflecting so that some radiation can escape from the cavity for coupling to an optical fiber.

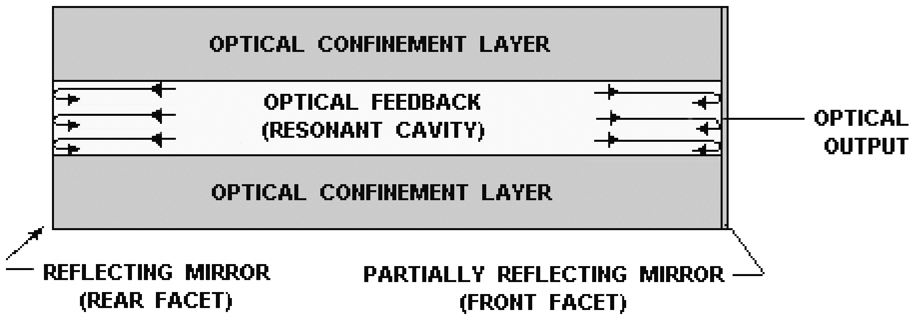

Figure 6-3.—Optical cavity for producing lasing.

Only a portion of the optical radiation is amplified. For a particular laser structure, there are only certain wavelengths that will be amplified by that laser. Amplification occurs when selected wavelengths, also called laser modes, reflect back and forth through the cavity. For lasing to occur, the optical gain of the selected modes must exceed the optical loss during one round-trip through the cavity. This process is referred to as optical feedback.

The lasing threshold is the lowest drive current level at which the output of the laser results primarily from stimulated emission rather than spontaneous emission. Figure 6-4 illustrates the transition from spontaneous emission to stimulated emission by plotting the relative optical output power and input drive current of a semiconductor laser diode. The lowest current at which stimulated emission exceeds spontaneous emission is the threshold current. Before the threshold current is reached, the optical output power increases only slightly with small increases in drive current. However, after the threshold current is reached, the optical output power increases significantly with small changes in drive currents.

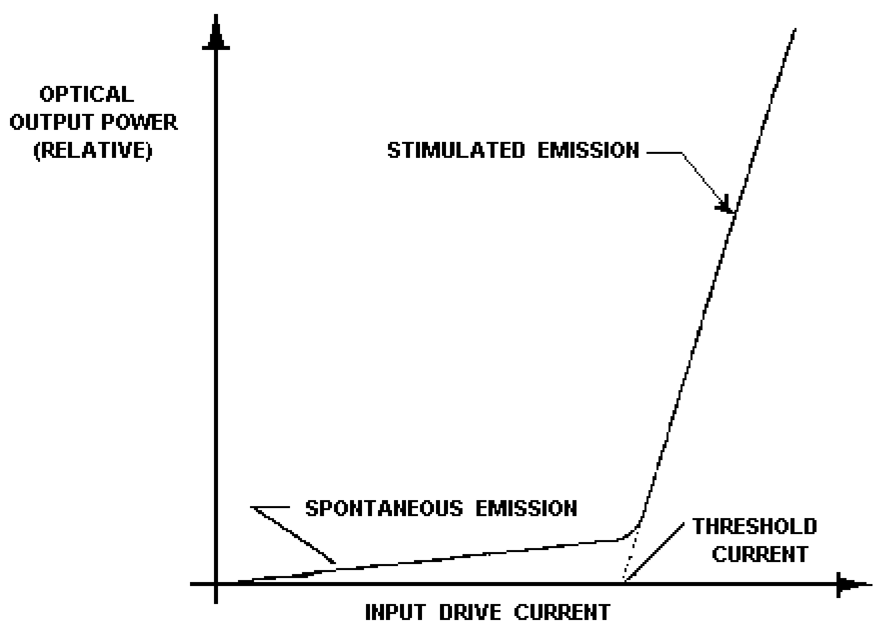

Figure 6-4.—The optical output power as a function of input drive current of a semiconductor laser diode.

Many types of materials including gas, liquid, and semiconductors can form the lasing medium. However, in this chapter we only discuss semiconductor laser diodes. Semiconductor laser diodes are the primary lasers used in fiber optics. A laser diode emits light that is highly monochromatic and very directional. This means that the LD's output has a narrow spectral width and small output beam angle.

A semiconductor LD's geometry is similar to an ELED with light-guiding regions surrounding the active region. Optical feedback is established by making the front facet partially reflective. This chapter provides no diagram detailing LD structures because they are similar to ELEDs in design. The rear facet is typically coated with a reflective layer so that all of the light striking the facet is reflected back into the active region. The front facet is typically left uncoated so that most of the light is emitted. By increasing the drive current, the diode becomes a laser.

At currents below the threshold current, LDs function as ELEDs. To optimize frequency response, laser diodes are often biased above this laser threshold. As a result, in an LD fiber optic system, light is modulated between a high power level and a lower power level, but never shut off. LDs typically can be modulated at frequencies up to over 2 gigahertz (GHz). Some lasers are capable of being modulated at frequencies over 20 GHz.

There are several important differences between LDs and LEDs. One is that LEDs usually lack reflective facets and in some cases are designed to suppress reflections back into the active region. Another is that lasers tend to operate at higher drive currents to produce light. A higher driver current results in more complicated drive circuits and more heat dissipation in the device.

LDs are also much more temperature sensitive than either SLEDs or ELEDs. Increases in the laser temperature significantly reduce laser output power. Increases in laser temperature beyond certain limits result in the loss of lasing. When lasers are used in many applications, the temperature of the laser must be controlled. Typically, electronic coolers, called thermo-electric (TE) coolers, are used to cool LDs in system applications.

SUPERLUMINESCENT DIODES

Superluminescence occurs when the spontaneous emissions of an ELED experience gain due to higher injected currents and reflections from facets. Superluminescent diodes (SLDs) are differentiated from both conventional LEDs and LDs. Although the output is not fully coherent, SLDs emit light that consists of amplified spontaneous emissions. The spectral width and beam angle of SLDs are narrower than that of conventional LEDs and wider than that of LDs.

An SLD is, in essence, a combination of a laser and an ELED. SLDs are similar in geometry to lasers but have no built-in optical feedback mechanism required by laser diodes for stimulated emission to achieve lasing. SLDs have structural features similar to those of ELEDs that suppress the lasing action by reducing the reflectivity of the facets. SLDs are essentially highly optimized ELEDs.

While SLDs operate like ELEDs at low current levels, their output power increases superlinearly and the spectral width narrows at high currents. Optical gain resulting from the higher injection currents causes the superlinear power increase and narrowing of the spectral width.

The advantages of SLDs over conventional LEDs include higher coupled power, narrower spectral width, and greater bandwidths. The disadvantages include nonlinear power-current characteristics, higher temperature sensitivity, and lower reliability.

Q11. What are the three basic LED types?

Q12. Which types of LEDs are the preferred optical sources for short-distance, low-data-rate fiber optic systems?

Q13. What are facets?

Q14. What is lowest current at which stimulated emission exceeds spontaneous emission in a semiconductor laser called?

Q15. Describe the output of a laser diode.

Q16. Which type of optical source usually lacks reflective facets and in some cases are designed to suppress reflections back into the active region?

Q17. Which type of optical source tends to operate at higher drive currents to produce light?

Q18. Are the effects of temperature changes on LDs more or less significant than for LEDs?

Q19. Specify the mechanism that SLDs lack that is required by laser diodes to achieve lasing.

FIBER OPTIC TRANSMITTERS

As stated previously, a fiber optic transmitter is a hybrid electro-optic device. It converts electrical signals into optical signals and launches the optical signals into an optical fiber. A fiber optic transmitter consists of an interface circuit, a source drive circuit, and an optical source. The interface circuit accepts the incoming electrical signal and processes it to make it compatible with the source drive circuit. The source drive circuit intensity modulates the optical source by varying the current through it. The optical signal is coupled into an optical fiber through the transmitter output interface.

Although semiconductor LEDs and LDs have many similarities, unique transmitter designs result from differences between LED and LD sources. Transmitter designs compensate for differences in optical output power, response time, linearity, and thermal behavior between LEDs and LDs to ensure proper system operation. Nonlinearities caused by junction heating in LEDs and mode instabilities in LDs necessitate the use of linearizing circuits within the transmitter in some cases.

Fiber optic transmitters using LDs require more complex circuitry than transmitters using LEDs. The basic requirement for digital systems is for drive circuitry to switch the optical output on and off at high speeds in response to logic voltage levels at the input of the source drive circuit. Because LDs are threshold devices, LDs are supplied with a bias just below the threshold in the off state. This bias is often referred to as prebias. One reason for prebiasing the LD is to reduce the turn-on delay in digital systems.

Most LD transmitters contain output power control circuitry to compensate for temperature sensitivity. This circuitry maintains the LD output at a constant average value by adjusting the bias current of the laser. In most cases LED transmitters do not contain output power control circuitry. LD and LED transmitters may also contain cooling devices to maintain the source at a relatively constant temperature. Most LD transmitters either have an internal thermo electric cooler or require a relatively controlled external temperature. Because LDs require more complex circuitry than LEDs, fiber optic transmitters using LDs are more expensive. For more information concerning fiber optic transmitters and their drive circuitry, refer to the reference material listed in appendix 2.

Transmitter output interfaces generally fall into two categories: optical connectors and optical fiber pigtails. Optical pigtails are attached to the transmitter optical source. This pigtail is generally routed out of the transmitter package as a coated fiber in a loose buffer tube or a single fiber cable. The pigtail is either soldered or epoxied to the transmitter package to provide fiber strain relief. The buffer tube or single fiber cable is also attached to the transmitter package to provide additional strain relief.

The transmitter output interface may consist of a fiber optical connector. The optical source may couple to the output optical connector through an intermediate optical fiber. One end of the optical fiber is attached to the source. The other end terminates in the transmitter optical output connector. The optical source may also couple to the output optical connector without an intermediate optical fiber. The optical source is placed within the transmitter package to launch power directly into the fiber of the mating optical connector. In some cases lenses are used to more efficiently couple light from the source into the mating optical connector.

Q20. How does the source drive circuit intensity modulate the source?

Q21. What is a prebias?

Q22. Is the drive circuitry generally more complex for an LED or a laser diode? Why?

Q23. What are the two types of output interfaces for fiber optic transmitters?

FIBER OPTIC TRANSMITTER PACKAGES

Fiber optic transmitters come in various sizes and shapes. The least complex fiber optic transmitters are typically packaged in transistor outline (TO) cans or hybrid microcircuit modules in dual inline packages (DIPs). These simple transmitters may require separate circuitry in the system equipment to provide an acceptable input signal to the transmitter. More complex fiber optic transmitters are available that have some or all of the signal conditioning circuitry integrated into the package. These transmitters typically are packaged in hybrid microcircuit modules in either DIP or butterfly lead packages, circuit cards, or complete stand-alone fiber optic converters. Stand-alone fiber optic converters and circuit cards generally contain sources in either TO cans or one of the hybrid microcircuit packages. For commercial applications, the most popular transmitter packages are the TO can and the DIP hybrid microcircuit.

FIBER OPTIC TRANSMITTER APPLICATIONS

Fiber optic transmitters can be classified into two categories: digital and analog. Digital transmitters produce two discrete optical power levels. These levels are essentially on and off with the exception that some light is emitted in the off state by some transmitters. Analog transmitters continuously vary the output optical power level as a function of the input electrical signal.

Digital Applications

Different types of fiber optic transmitters are used for different digital applications. For each specific application, the link data rate, transmission length, and operating environment influence the source type, center wavelength, spectral width, and package type chosen.

For low-data-rate applications, fiber optic transmitters generally use LEDs operating in either the 850-nm or 1300-nm window as their source. For the lowest data rates (0 to 20 megabits per second (Mbps)), sources tend to operate in the 850-nm window. For moderate data rates (50 to 200 Mbps), sources tend to operate in the 1300-nm window. Laser sources are almost never used in low-data-rate applications. Laser sources are only used when extremely high transmitter output powers are required in the application. The packages found in low-data-rate applications include all of the package types discussed earlier.

For high-data-rate applications, most fiber optic transmitters use laser diodes as sources. The sources typically operate in either the 1300-nm or 1550-nm windows. Most high-data-rate applications use LDs as the optical source and operate in the 1300-nm region. Almost all 1550-nm systems use an LD as the optical source. 1550-nm transmitters are usually only used in the extremely long distance high-data-rate applications (undersea links, etc.). High-data-rate transmitters are generally hybrid microcircuit modules or complete circuit cards. Almost all high-data-rate transmitters contain power control circuitry. Depending upon the application, high-data-rate transmitters may contain TE coolers.

Q24. List five common fiber optic transmitter packages.

Q25. What type of source is typically used in low-data-rate digital applications?

Q26. Why would a laser diode be used in a low-data-rate digital application?

Q27. What type of source is generally used in high-data-rate digital applications?

Analog Applications

Different types of fiber optic transmitters are also used for different analog applications. For each specific application, analog signal type, transmission length, and operating environment influence the source type, center wavelength, spectral width, and package type chosen.

For low-frequency applications, analog fiber optic transmitters generally use LEDs operating in either the 850-nm or 1300-nm window. Typical low frequency applications are analog audio and single channel video systems. For these systems, sources tend to operate in the 850-nm window. For moderate frequency applications, sources tend to operate in the 1300-nm window. These types of systems include multi-channel analog audio and video systems as well as frequency modulated (FM) systems. Laser sources are almost never used in low- or moderate-frequency analog applications. The main reason for this is the added circuit complexity that laser sources require. Laser sources are only used if extremely high transmitter output powers are required in the application. Most low-frequency analog transmitters are hybrid microcircuit modules, circuit cards, or stand-alone boxes.

For high-frequency applications, analog fiber optic transmitters use laser diodes as sources. Typical high frequency applications are cable television trunk line and raw radar remoting applications. The LDs typically operate in either the 1300-nm or 1550-nm windows. 1550-nm transmitters are typically used in cable television trunk line applications. Other applications may use either 1300-nm or 1550-nm LDs. High frequency transmitters are predominately circuit cards, but some hybrid microcircuit modules are also used. All high frequency analog transmitters contain TE coolers as well as linearization and power control circuitry.

Q28. Why are LEDs preferred over laser diodes for low- and moderate-frequency analog applications?

SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas that you have learned. You should have a thorough understanding of these principles before moving on to chapter 7.

A **FIBER OPTIC TRANSMITTER** is a hybrid electro-optic device. It converts electrical signals into optical signals and launches the optical signals into an optical fiber.

An **OPTICAL SOURCE** converts electrical energy (current) into optical energy (light).

The principal **LIGHT SOURCES** used in fiber optics are semiconductor light-emitting diodes (LEDs) and laser diodes (LDs).

SEMICONDUCTOR LD's emit coherent light. Light waves having a fixed-phase relationship are referred to as coherent light.

SEMICONDUCTOR LED'S emit incoherent light. Light waves that lack a fixed-phase relationship are referred to as incoherent light.

The **RELEVANT OPTICAL POWER** is the amount of optical power coupled into the fiber. It depends on the angle over which the light is emitted, the size of the source's light-emitting area relative to the fiber core size, the alignment of the source and fiber, and the coupling characteristics of the fiber (such as the NA and the refractive index profile).

SOURCE-TO-FIBER COUPLING EFFICIENCY is a measure of the relevant optical power.

SILICON (Si) and **GALLIUM ARSENIDE (GaAs)** are the two most common semiconductor materials used in electronic and electro-optic devices.

In a semiconductor device, **PHOTONS (LIGHT)** are emitted when current flows through the active area.

SPONTANEOUS EMISSION occurs when photons are emitted in a random manner. Spontaneous emission produces incoherent light.

STIMULATED EMISSION occurs when a photon interacts with the laser material to produce additional photons.

A **LIGHT-EMITTING DIODE (LED**) is a semiconductor device that emits incoherent light, through spontaneous emission, when a current is passed through it. The basic LED types used for fiber optic communication systems are the **SURFACE-EMITTING LED (SLED)**, the **EDGE-EMITTING LED (ELED)**, and **the SUPERLUMINESCENT DIODE (SLD)**.

In **SURFACE-EMITTING LED'S (SLEDs)**, the size of the primary active region is limited to a small circular area of 20 m to 50 m in diameter. The active region is the portion of the LED where photons are emitted. SLEDs usually emit more total power into the air gap at the fiber interface than an ELED, but they do not launch as much power into the fiber. SLEDS also tend to emit power over a wider spectral range than ELED.

EDGE-EMITTING LED'S (ELEDs) emit light in a narrow emission angle allowing for better source-to-fiber coupling. They couple more power into small NA fibers than SLEDs. The polished or cut surfaces at each end of the ELED active stripe are called FACETS.

SUPERLUMINESCENCE occurs when the spontaneous emissions of an ELED experience gain due to higher injected currents and reflections from facets.

SUPERLUMINESCENT DIODES (SLDs) are similar in geometry to lasers but have no built-in optical feedback mechanism required by laser diodes for stimulated emission to achieve lasing. Although the output is not fully coherent, superluminescent diodes (SLDs) emit light that consists of amplified spontaneous emissions. The spectral width and beam angle of SLDs are narrower than that of conventional LEDs and wider than that of LDs.

The **ADVANTAGES** of **SLDs** over conventional LEDs include higher coupled power, narrower spectral width, and greater bandwidths. The **DISADVANTAGES** include nonlinear power-current characteristics, higher temperature sensitivity, and lower reliability.

A **LASER** is a device that produces optical radiation using stimulated emission rather than spontaneous emission. Laser is an acronym for light amplification by the stimulated emission of radiation.

The **LASING THRESHOLD** is the lowest drive level at which the output of the laser results primarily from stimulated emission rather than spontaneous emission.

The **THRESHOLD CURRENT** is the lowest current at which stimulated emission exceeds spontaneous emission.

A **LASER DIODE** is a semiconductor diode that emits coherent light by lasing. The LD's output has a narrow spectral width and small output beam angle.

TRANSMITTER OUTPUT INTERFACES fall into two categories: optical connectors and optical fiber pigtails.

FIBER OPTIC TRANSMITTERS using LDs require more complex circuitry than transmitters using LEDs.

Because **LDs** are threshold devices, LDs are supplied with a bias just below the threshold in the off state. This bias is often referred to as a prebias.

The least complex **FIBER OPTIC TRANSMITTERS** are typically packaged in transistor outline (TO) cans or hybrid microcircuit modules in dual inline packages (DIPs).

More complex **FIBER OPTIC TRANSMITTERS** typically are packaged in hybrid microcircuit modules in either DIP or butterfly lead packages, circuit cards, or complete stand-alone fiber optic converters.

FIBER OPTIC TRANSMITTERS can be classified into two categories: digital and analog.

DIGITAL TRANSMITTERS modulate the fiber optic source between two discrete optical power levels. These levels are essentially on and off with the exception that some light is emitted in the off state by some transmitters.

ANALOG TRANSMITTERS continuously vary the output optical power level as a function of the input electrical signal.

For **LOW-DATA-RATE APPLICATIONS** (0 to 20 Mbps), fiber optic transmitters generally use LEDs operating in either the 850-nm or 1300-nm window.

For **MODERATE-DATA-RATE APPLICATIONS** (50 to 200 Mbps), fiber optic transmitters generally use LEDs operating in the 1300-nm window.

For **HIGH-DATA-RATE APPLICATIONS**, most fiber optic transmitters use laser diodes as sources.

LASER SOURCES are almost never used in low- or moderate-frequency analog applications because LED sources require much less complex circuitry.

ANSWERS TO QUESTIONS Q1. THROUGH Q28.

A1. *Interface circuit, source drive circuit, and an optical source.*

A2. *The optical source.*

A3. *Multimode fiber dispersion, the relatively high fiber attenuation, and the LED's relatively low optical output power.*

A4. *Longer distances and higher bandwidths are possible because fiber material losses and dispersion are significantly reduced at the 1300-nm region.*

A5. *Light waves that lack a fixed-phase relationship.*

A6. *LDs.*

A7. *(1) The angles over which the light is emitted. (2) The size of the source's light-emitting area relative to the fiber core size. (3) The alignment of the source and fiber. (4) The coupling characteristics of the fiber (such as the NA and the refractive index profile).*

A8. *Silicon and gallium arsenide.*

A9. *A laser is a device that produces optical radiation using stimulated emission rather than spontaneous emission.*

A10. *A photon initially produced by spontaneous emission in the active region interacts with the laser material to produce additional photons.*

A11. *Surface-emitting LEDs (SLEDs), edge-emitting LEDs (ELEDs), and superluminescent diodes (SLDs).*

A12. *SLEDs and ELEDs.*

A13. *Cut or polished surfaces at each end of the narrow active region of an ELED.*

A14. *Threshold current.*

A15. *The LD's output has a narrow spectral width and small output beam angle.*

A16. *LED.*

A17. *Laser.*

A18. *More.*

A19. *SLDs have no built-in optical feedback mechanism.*

A20. *By varying the current through the source.*

A21. *A current applied in the laser off state just less than the threshold current.*

A22. *For a laser diode. The laser diode transmitter generally contains output power control circuitry and may contain a TE cooler and some circuitry associated with the TE cooler.*

A23. *Optical connectors and optical fiber pigtails.*

A24. TO can, DIP, butterfly lead microcircuits, circuit cards, and stand-alone optical fiber converters.

A25. LED.

A26. When extremely high transmitter output powers are required.

A27. Laser diode.

A28. LEDs require less complex circuitry than lasers.

CHAPTER 7

OPTICAL DETECTORS AND FIBER OPTIC RECEIVERS

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to do the following:

1. Explain the principal properties of an optical detector and fiber optic receiver.
2. Detail semiconductor optical detector performance and capability requirements necessary for the successful implementation of fiber optic systems.
3. List the main components of a fiber optic receiver.
4. Discuss receiver sensitivity, dynamic range, and other key operational parameters used to define receiver performance.

INTRODUCTION TO OPTICAL DETECTORS AND FIBER OPTIC RECEIVERS

Chapter 6 taught you that a fiber optic transmitter is an electro-optic device capable of accepting electrical signals, converting them into optical signals, and launching the optical signals into an optical fiber. The optical signals propagating in the fiber become weakened and distorted because of scattering, absorption, and dispersion. The fiber optic device responsible for converting the weakened and distorted optical signal back to an electrical signal is a fiber optic receiver.

A **fiber optic receiver** is an electro-optic device that accepts optical signals from an optical fiber and converts them into electrical signals. A typical fiber optic receiver consists of an optical detector, a low-noise amplifier, and other circuitry used to produce the output electrical signal (see figure 7-1). The optical detector converts the incoming optical signal into an electrical signal. The amplifier then amplifies the electrical signal to a level suitable for further signal processing. The type of other circuitry contained within the receiver depends on what type of modulation is used and the receiver electrical output requirements.

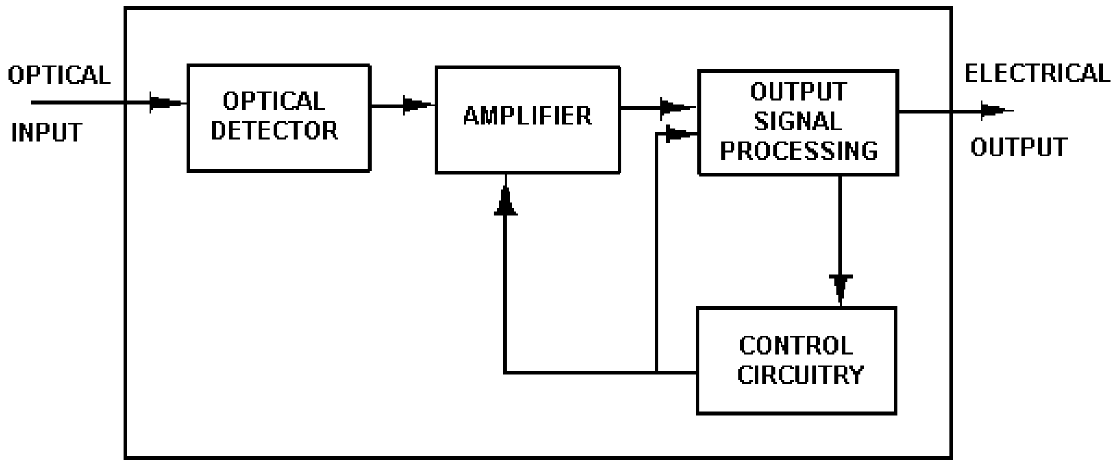

Figure 7-1.—Block diagram of a typical fiber optic receiver.

Receiver spectral response, sensitivity, frequency response, and dynamic range are key receiver performance parameters that can affect overall system operation. The choice of optical detector materials and structures determines the spectral response. Silicon (Si), gallium arsenide (GaAs), and gallium aluminum arsenide (GaAlAs) are typical detector materials used for receiver operation in the 850-nm wavelength region. germanium (Ge), indium phosphide (InP), and indium gallium arsenide (InGaAs) are examples of detector materials used for receiver operation in the 1300-nm and 1550-nm wavelength regions.

The **receiver sensitivity** is the minimum amount of optical power required to achieve a specific receiver performance. For digital transmission at a given data rate and coding, this performance is described by a maximum bit-error rate (BER). In analog systems, for a given modulation and bandwidth, it is described by a minimum signal-to-noise ratio (SNR). **Dynamic range** refers to the range of optical power levels over which the receiver operates within the specified values. It usually is described by the ratio of the maximum input power to the sensitivity. Before discussing receiver sensitivity, bandwidth, dynamic range, and frequency response in more detail, we discuss the main types of optical detectors used in fiber optics.

Q1. What is a fiber optic receiver?

Q2. Which part of the receiver amplifies the electrical signal to a level suitable for further signal processing?

Q3. Which performance parameter is the minimum amount of optical power required to achieve a specific bit-error rate (BER) in digital systems or a given signal-to-noise ratio (SNR) in analog systems?

Q4. Define receiver dynamic range.

OPTICAL DETECTORS

A **transducer** is a device that converts input energy of one form into output energy of another. An **optical detector** is a transducer that converts an optical signal into an electrical signal. It does this by generating an electrical current proportional to the intensity of incident optical radiation. The relationship between the input optical radiation and the output electrical current is given by the detector responsivity. Responsivity is discussed later in this chapter.

OPTICAL DETECTOR PROPERTIES

Fiber optic communications systems require that optical detectors meet specific performance and compatibility requirements. Many of the requirements are similar to those of an optical source. Fiber optic systems require that optical detectors:

- Be compatible in size to low-loss optical fibers to allow for efficient coupling and easy packaging.
- Have a high sensitivity at the operating wavelength of the optical source.
- Have a sufficiently short response time (sufficiently wide bandwidth) to handle the system's data rate.
- Contribute low amounts of noise to the system.
- Maintain stable operation in changing environmental conditions, such as temperature.

Optical detectors that meet many of these requirements and are suitable for fiber optic systems are semiconductor photodiodes. The principal optical detectors used in fiber optic systems include semiconductor positive-intrinsic-negative (PIN) photodiodes and avalanche photodiodes (APDs).

Q5. Describe the operation of an optical detector.

Q6. For efficient operation, should a detector have a high or low responsivity at the operating wavelength?

Q7. List the two principal optical detectors used in fiber optic systems.

SEMICONDUCTOR PHOTODIODES

Semiconductor photodiodes generate a current when they absorb photons (light). The amount of current generated depends on the following factors:

- The wavelengths of the incident light and the responsivity of the photodiode at those wavelengths
- The size of the photodiode active area relative to the fiber core size
- The alignment of the fiber and the photodiode

The optical fiber is coupled to semiconductor photodiodes similarly to the way optical sources are coupled to optical fibers. Fiber-to-photodiode coupling involves centering the flat fiber-end face over the photodiode active area. This is normally done directly by butt coupling the fiber up to the photodiode surface. As long as the photodiode active area is larger than that of the fiber core, fiber-to-detector coupling losses are very low. In some cases a lens may be used to couple the fiber end-face to the detector. However, this is not typically done.

SEMICONDUCTOR MATERIAL AND DEVICE PROPERTIES

The mechanism by which optical detectors convert optical power into electrical current requires knowledge of semiconductor material and device properties. As stated in chapter 6, providing a complete description of these properties is beyond the scope of this manual. In this chapter we only discuss the general properties of semiconductor PINs and APDs.

Semiconductor detectors are designed so that optical energy (photons) incident on the detector active area produces a current. This current is called a **photocurrent**. The particular properties of the semiconductor are determined by the materials used and the layering of the materials within the device. Silicon (Si), gallium arsenide (GaAs), germanium (Ge), and indium phosphide (InP) are the most common semiconductor materials used in optical detectors. In some cases aluminum (Al) and indium (In) are used as dopants in the base semiconductor material.

Responsivity

Responsivity is the ratio of the optical detector's output photocurrent in amperes to the incident optical power in watts. The responsivity of a detector is a function of the wavelength of the incident light and the efficiency of the device in responding to that wavelength. For a particular material, only photons of certain wavelengths will generate a photocurrent when they are absorbed. Additionally, the detector material absorbs some wavelengths better than others. These two properties cause the wavelength dependence in the detector responsivity. Responsivity is a useful parameter for characterizing detector performance because it relates the photocurrent generated to the incident optical power.

Q8. What are the four most common materials used in semiconductor detector fabrication?

Q9. What is a photocurrent?

Q10. Define responsivity.

PIN PHOTODIODES

A **PIN photodiode** is a semiconductor positive-negative (p-n) structure with an intrinsic region sandwiched between the other two regions (see figure 7-2). It is normally operated by applying a reverse-bias voltage. The magnitude of the reverse-bias voltage depends on the photodiode application, but typically is less than a few volts. When no light is incident on the photodiode, a current is still produced. This current is called the **dark current**. The dark current is the leakage current that flows when a reverse bias is applied and no light is incident on the photodiode. Dark current is dependent on temperature. While dark current may initially be low, it will increase as the device temperature increases.

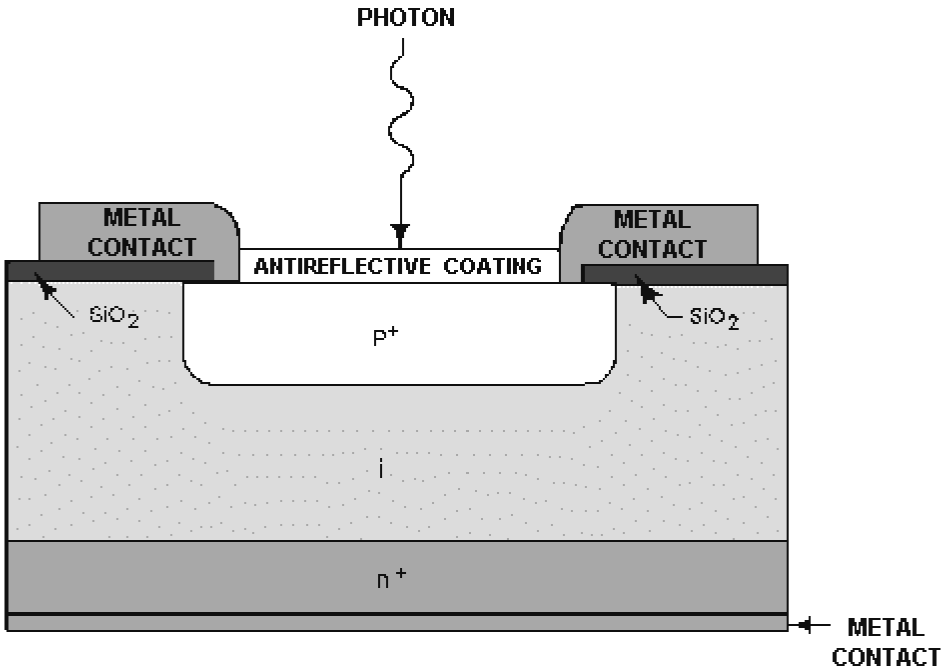

Figure 7-2.—The basic structure of a PIN photodiode.

Q11. How are PIN photodiodes usually biased?

Q12. What is the dark current?

Q13. Will dark current increase or decrease as the temperature of the photodiode increases?

Response Time

There are several factors that influence the response time of a photodiode and its output circuitry (see figure 7-3). The most important of these are the thickness of the detector active area and the detector RC time constant. The detector thickness is related to the amount of time required for the electrons generated to flow out of the detector active area. This time is referred to as the electron **transit time**. The thicker the detector active area, the longer the transit time will be.

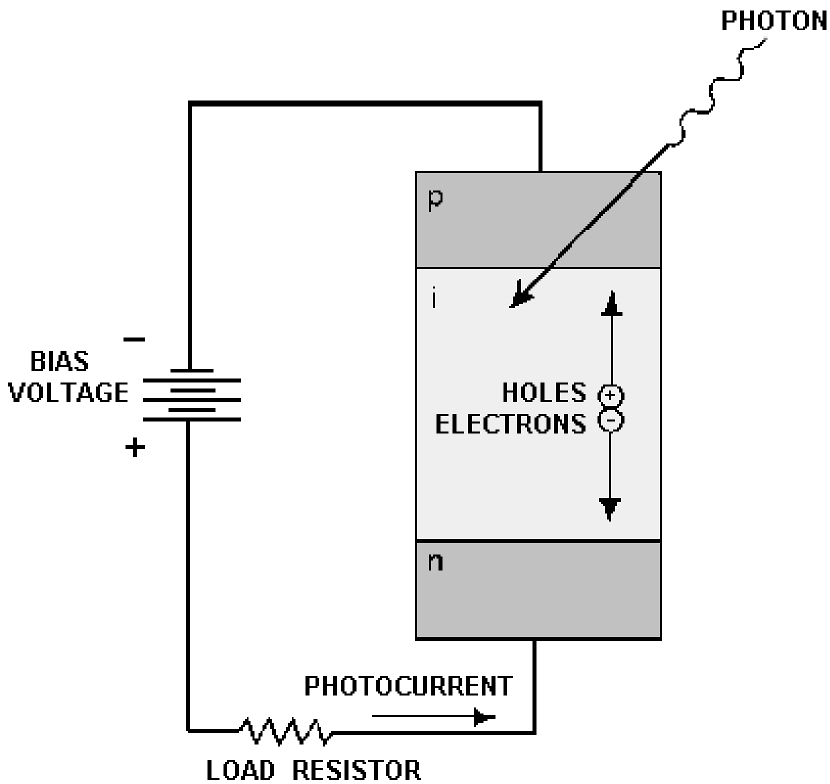

Figure 7-3.—A schematic representation of a photodiode.

The **capacitance** (**C**) of the photodiode and the **resistance** (**R**) of the load form the RC time constant. The capacitance of the photodetector must be kept small to prevent the RC time constant from limiting the response time. The photodiode capacitance consists mainly of the junction capacitance and any capacitance relating to packaging. The **RC time constant** is given by $t_{RC} = RC$.

Trade-offs between fast transit times and low capacitance are necessary for high-speed response. However, any change in photodiode parameters to optimize the transit time and capacitance can also affect responsivity, dark current, and coupling efficiency. A fast transit time requires a thin detector active area, while low capacitance and high responsivity require a thick active region. The diameter of the detector active area can also be minimized. This reduces the detector dark current and minimizes junction capacitance. However, a minimum limit on this active area exists to provide for efficient fiber-to-detector coupling.

Q14. Should the capacitance of the photodetector be kept small or large to prevent the RC time constant from limiting the response time?

Q15. Trade-offs between competing effects are necessary for high speed response. Which competing effect (fast transit time, low capacitance, or high quantum efficiency) requires a thin active area?

Linearity

Reverse-biased photodetectors are highly linear devices. Detector **linearity** means that the output electrical current (photocurrent) of the photodiode is linearly proportional to the input optical power. Reverse-biased photodetectors remain linear over an extended range (6 decades or more) of photocurrent before saturation occurs. Output saturation occurs at input optical power levels typically greater than 1 milliwatt (mW). Because fiber optic communications systems operate at low optical power levels, detector saturation is generally not a problem.

Q16. Why is detector saturation not generally a problem in fiber optic communications systems?

AVALANCHE PHOTODIODES

An **avalanche photodiode (APD)** is a photodiode that internally amplifies the photocurrent by an avalanche process. Figure 7-4 shows an example APD structure. In APDs, a large reverse-bias voltage, typically over 100 volts, is applied across the active region. This voltage causes the electrons initially generated by the incident photons to accelerate as they move through the APD active region. As these electrons collide with other electrons in the semiconductor material, they cause a fraction of them to become part of the photocurrent. This process is known as **avalanche multiplication**. Avalanche multiplication continues to occur until the electrons move out of the active area of the APD.

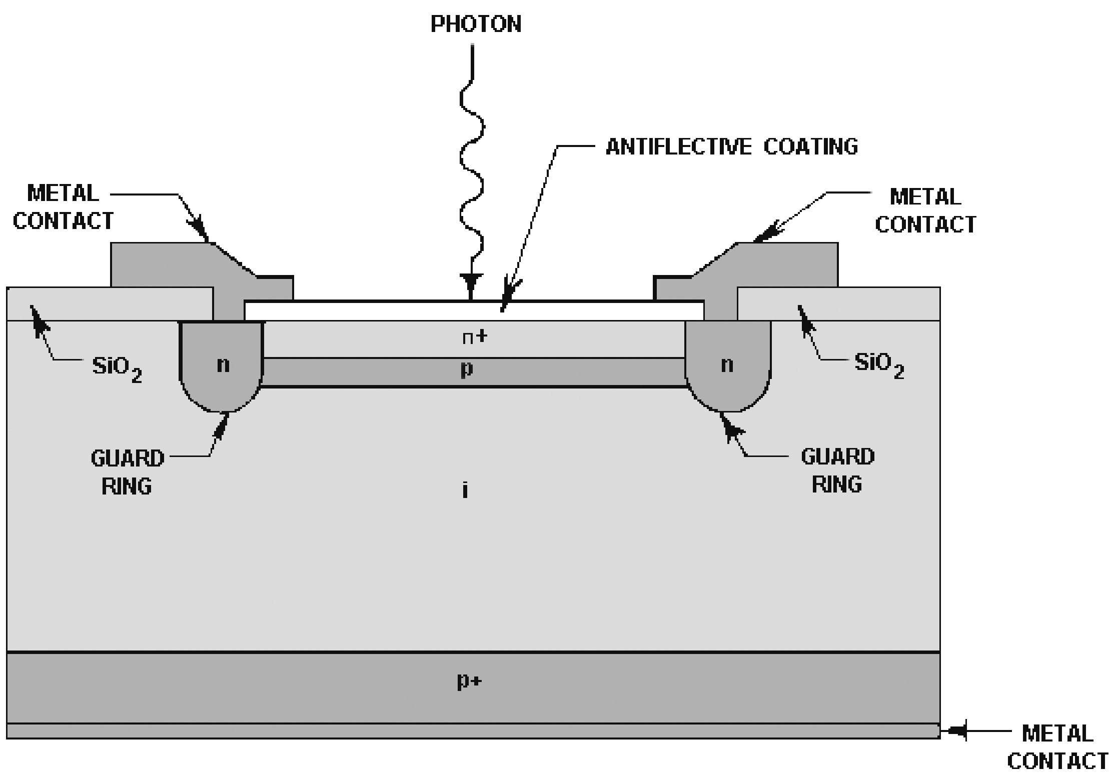

Figure 7-4.—The basic structure of an APD.

The gain of the APD can be changed by changing the reverse-bias voltage. A larger reverse-bias voltage results in a larger gain. However, a larger reverse-bias voltage also results in increased noise levels. Excess noise resulting from the avalanche multiplication process places a limit on the useful gain of the APD. The avalanche process introduces excess noise because every photogenerated carrier does not undergo the same multiplication. The noise properties of an APD are affected by the materials that the

APD is made of. Typical semiconductor materials used in the construction of low-noise APDs include silicon (Si), indium gallium arsenide (InGaAs), and germanium (Ge).

Trade-offs are made in APD design to optimize responsivity and gain, dark current, response time, and linearity. This chapter does not attempt to discuss trade-offs in APD design in more detail. Many aspects of the discussion provided on responsivity, dark current, and response time provided in the PIN photodiodes section also relate to APDs. The response time of an APD and its output circuitry depends on the same factors as PIN photodiodes. The only additional factor affecting the response time of an APD is the additional time required to complete the process of avalanche multiplication. To learn more about APD design trade-offs and performance parameters, refer to the reference material listed in appendix 2.

Q17. Describe avalanche multiplication.

Q18. How can the gain of an APD be increased?

FIBER OPTIC RECEIVERS

In fiber optic communications systems, optical signals that reach fiber optic receivers are generally attenuated and distorted (see figure 7-5). The fiber optic receiver must convert the input and amplify the resulting electrical signal without distorting it to a point that other circuitry cannot use it.

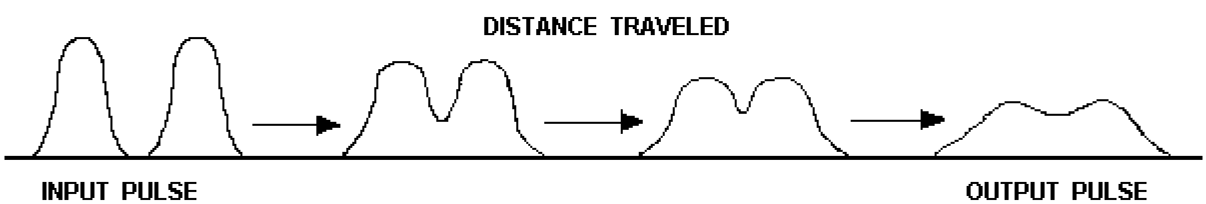

Figure 7-5.—Attenuated and distorted optical signals.

As stated previously, a fiber optic receiver consists of an optical detector, an amplifier, and other circuitry. In most fiber optic systems, the optical detector is a PIN photodiode or APD. Receiver performance varies depending on the type of detector used. The amplifier is generally described as having two stages: the preamplifier and the postamplifier. The **preamplifier** is defined as the first stage of amplification following the optical detector. The **postamplifier** is defined as the remaining stages of amplification required to raise the detector's electrical signal to a level suitable for further signal processing. The preamplifier is the dominant contributor of electrical noise in the receiver. Because of this, its design has a significant influence in determining the sensitivity of the receiver.

The output circuitry processes the amplified signal into a form suitable for the interfacing circuitry. For digital receivers, this circuitry may include low-pass filters and comparators. For analog receivers, this circuitry may also include low-pass filters.

Receiver sensitivity, bandwidth, and dynamic range are key operational parameters used to define receiver performance. One goal in designing fiber optic receivers is to optimize receiver sensitivity. To increase sensitivity, receiver noise resulting from signal-dependent shot noise and thermal noise must be kept at a minimum. A more detailed discussion of receiver shot and thermal noise is provided later in this chapter.

In addition to optimizing sensitivity, optical receiver design goals also include optimizing the bandwidth and the dynamic range. A receiver that has the ability to operate over a wide range of optical power levels can operate efficiently in both short- and long-distance applications. Because conflicts arise when attempting to meet each goal, trade-offs in receiver designs are made to optimize overall performance.

Q19. Which amplifier stage (the preamplifier or the postamplifier) is a dominant contributor of noise and significantly influences the sensitivity of the receiver?

Q20. List the key operational parameters used to define receiver performance.

RECEIVER NOISE

Noise corrupts the transmitted signal in a fiber optic system. This means that noise sets a lower limit on the amount of optical power required for proper receiver operation. There are many sources of noise in fiber optic systems. They include the following:

- Noise from the light source
- Noise from the interaction of light with the optical fiber
- Noise from the receiver itself

Because the intent of this chapter is to discuss optical detector and receiver properties, only noise associated with the photodetection process is discussed. **Receiver noise** includes thermal noise, dark current noise, and quantum noise. Noise is the main factor that limits receiver sensitivity.

Noise introduced by the receiver is either signal dependent or signal independent. Signal dependent noise results from the random generation of electrons by the incident optical power. Signal independent noise is independent of the incident optical power level.

Thermal noise is the noise resulting from the random motion of electrons in a conducting medium. Thermal noise arises from both the photodetector and the load resistor. Amplifier noise also contributes to thermal noise. A reduction in thermal noise is possible by increasing the value of the load resistor. However, increasing the value of the load resistor to reduce thermal noise reduces the receiver bandwidth. In APDs, the thermal noise is unaffected by the internal carrier multiplication.

Shot noise is noise caused by current fluctuations because of the discrete nature of charge carriers. Dark current and quantum noises are two types of noise that manifest themselves as shot noise. **Dark current noise** results from dark current that continues to flow in the photodiode when there is no incident light. Dark current noise is independent of the optical signal. In addition, the discrete nature of the photodetection process creates a signal dependent shot noise called quantum noise. **Quantum noise** results from the random generation of electrons by the incident optical radiation. In APDs, the random nature of the avalanche process introduces an additional shot noise called excess noise. For further information on the excess noise resulting from the avalanche process, refer to the avalanche photodiode section.

Q21. List the main types of receiver noise.

Q22. What is the main factor that determines receiver sensitivity?

Q23. For a reduction in thermal noise, should the value of the detector's load resistor be increased or decreased?

Q24. What are two types of noise that manifest themselves as shot noise?

RECEIVER DESIGN

The simplest fiber optic receivers consist of only the optical detector and a load resistor. However, the output signal of these simple receivers is not in a suitable form for most types of interfacing circuitry. To produce a suitable signal, a preamplifier, a post amplifier, and other circuitry are generally included in the receiver.

The choice of an optical detector and the design of the preamplifier help determine the operational characteristics of the receiver. Fiber optic receivers using APDs have greater sensitivity than those using PIN photodiodes. In addition, trade-offs are made in preamplifier designs to increase sensitivity while optimizing bandwidth and dynamic range. The two basic types of amplifiers used in fiber optic receivers are the **high-impedance amplifier** and the **transimpedance amplifier**.

The high-impedance preamplifier is generally used with a large load resistor to improve sensitivity. The large load resistor is used to reduce thermal noise. Although the high-impedance preamplifier achieves high sensitivity, receiver bandwidth and dynamic range are limited. The transimpedance preamplifier uses a low-noise, high-input impedance amplifier with negative feedback. This design provides improvements in bandwidth and dynamic range with some degradation in sensitivity from an increase in noise. For more information on receiver performance and design, refer to the reference material listed in appendix 2.

Q25. What are the two basic types of preamplifiers used in fiber optic receivers?

Q26. Which preamplifier design (high-impedance or transimpedance) provides improvements in bandwidth and greater dynamic range with some degradation in sensitivity from an increase in noise?

FIBER OPTIC RECEIVER PACKAGES

Fiber optic receivers come in packages similar to those for fiber optic transmitters. For information on fiber optic receiver packages, refer back to the fiber optic transmitter packages section of chapter 6.

FIBER OPTIC RECEIVER APPLICATIONS

Fiber optic receivers can be classified into two categories: **digital** and **analog**. Digital receivers detect the input optical signal, amplify the digital photocurrent, and reshape the signal to produce an undistorted output electrical signal. Analog receivers detect the input optical signal and amplify the generated photocurrent.

Digital Applications

For most digital applications the designs of the digital fiber optic receivers are similar. For **low-data-rate** applications, PIN diodes and high impedance amplifiers are generally used. Receiver sensitivities are maximized by using large load resistors in the photodiode circuit. For **moderate-data-rate** applications, PIN diodes and either high impedance amplifiers with smaller load resistances or transimpedance amplifiers are used. For **high-data-rate** applications, PINs or APDs are used with transimpedance amplifiers. APDs are rarely used in low- or moderate-data-rate applications unless receivers with extremely low sensitivities are required.

For each digital application, the receiver will generally contain a low-pass filter. The pass-band of the filter depends on the data rate of the application. The filter is used to smooth the amplified signal to remove some of the high frequency noise before the signal is further processed. The digital receiver generally contains a comparator, which reshapes the amplified electrical signal to remove any distortions introduced in the transmission process. In some cases the receiver may also contain clock recovery circuitry, which retimes the output electrical signal as well.

Q27. For what types of applications are APDs generally used?

Q28. Why is a low-pass filter generally part of a digital fiber optic receiver?

Analog Applications

Analog receivers are similar in design to digital receivers with the exception that digital signal restoring circuitry is not used. The preamplifier and postamplifiers are designed to be more linear than those used in digital receivers in some cases.

For **low-frequency** applications, PIN diodes and high impedance amplifiers are generally used. For **moderate-frequency** applications, PIN diodes and either high impedance amplifiers or transimpedance amplifiers are used. For **high-frequency** applications, PINs or APDs are used with transimpedance amplifiers. As in digital applications, APDs are rarely used in low- or moderate-frequency applications unless receivers with extremely low sensitivities are required.

SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas that you have learned. You should have a thorough understanding of these principles before moving on to chapter 8.

A **FIBER OPTIC RECEIVER** is an electro-optic device that accepts optical signals from an optical fiber and converts them into electrical signals. A typical fiber optic receiver consists of an optical detector, a low-noise amplifier, and other circuitry used to produce the output electrical signal.

RECEIVER SPECTRAL RESPONSE, SENSITIVITY, FREQUENCY RESPONSE, and **DYNAMIC RANGE** are key receiver performance parameters that can affect overall system operation.

RECEIVER SENSITIVITY is the minimum amount of optical power required to achieve a specific receiver performance. For digital transmission at a given data rate and coding, this performance is described by a maximum bit-error rate (BER). In analog systems, for a given modulation and bandwidth, it is described by a minimum signal-to-noise ratio (SNR).

DYNAMIC RANGE refers to the range of optical power levels over which the receiver operates within the specified values. It usually is described by the ratio of the maximum input power to the sensitivity.

A **TRANSDUCER** is a device that converts input energy of one form into output energy of another.

An **OPTICAL DETECTOR** is a transducer that converts an optical signal into an electrical signal. It does this by generating an electrical current proportional to the intensity of incident optical radiation.

The semiconductor **POSITIVE-INTRINSIC-NEGATIVE (PIN) PHOTODIODE** and **AVALANCHE PHOTODIODE (APD)** are the principal optical detectors used in fiber optic systems.

A **PHOTOCURRENT** is generated when photons are absorbed by a photodiode.

RESPONSIVITY is the ratio of the optical detector's output photocurrent in amperes to the incident optical power in watts.

DARK CURRENT, or reverse-leakage current, is the current that continues to flow in the photodetector when there is no incident light.

The **RESPONSE TIME** of a photodiode and its output circuitry depends primarily on the thickness of the detector active area and the detector RC time constant.

The **TRANSIT TIME** is the time it takes electrons to travel out of the detector active area.

The **RC TIME CONSTANT** is defined by the capacitance (C) of the photodiode and the resistance (R) of the load. The RC time constant is given by $t_{RC} = RC$.

A **HIGH-SPEED RESPONSE** requires short transit times and low capacitance. However, any change in photodiode parameters to optimize the transit time and capacitance can also affect quantum efficiency, dark current, and coupling efficiency.

Detector **LINEARITY** means that the output electrical current (photocurrent) of the photodiode is linearly proportional to the input optical power.

An **AVALANCHE PHOTODIODE (APD)** is a photodiode that internally amplifies the photocurrent by an avalanche process.

In **APDs**, a large **REVERSE-BIAS VOLTAGE**, typically over 100 volts, is applied across the active region.

AVALANCHE MULTIPLICATION occurs when accelerated electrons collide with other electrons in the semiconductor material, causing a fraction of them to become part of the photocurrent.

TRADE-OFFS are made in APD design to optimize responsivity and gain, dark current, response time, and linearity.

The **RESPONSE TIME** of APDs accounts for the avalanche build-up time in addition to transit time and RC time constant.

The **PREAMPLIFIER** is defined as the first stage of amplification following the optical detector.

The **POSTAMPLIFIER** is defined as the remaining stages of amplification required to raise the detectors electrical signal to a level suitable for further signal processing.

RECEIVER SENSITIVITY, BANDWIDTH, and **DYNAMIC RANGE** are key operational parameters used to define receiver performance.

NOISE is the main factor that determines receiver sensitivity.

RECEIVER NOISE includes thermal noise, dark current noise, and quantum noise.

THERMAL NOISE is the noise resulting from the random motion of electrons in a conducting medium.

SHOT NOISE is noise caused by current fluctuations due to the discrete nature of charge carriers.

DARK CURRENT NOISE results from dark current that continues to flow in the photodiode when there is no incident light.

QUANTUM NOISE results from the random generation of electrons by the incident optical radiation.

The **HIGH-IMPEDANCE AMPLIFIER** and the **TRANSIMPEDANCE AMPLIFIER** are the two basic types of amplifiers used in fiber optic receivers.

The **HIGH-IMPEDANCE PREAMPLIFIER** provides a high sensitivity, but limits receiver bandwidth and dynamic range.

The **TRANSIMPEDANCE PREAMPLIFIER** provides improvements in bandwidth and dynamic range with some degradation in sensitivity from an increase in noise.

PIN PHOTODIODES are used as the detector in most applications.

AVALANCHE PHOTODIODES are only used in high-speed applications and applications where detectors with extremely low sensitivities are required.

ANSWERS TO QUESTIONS Q1. THROUGH Q28.

A1. *An electro-optic device that accepts optical signals from an optical fiber and converts them into electrical signals.*

A2. *Amplifier.*

A3. *Receiver sensitivity.*

A4. *The range of optical power levels over which the receiver operates within the specified values. It usually is described by the ratio of the maximum input power to the sensitivity.*

A5. *It is a transducer that converts an optical signal into an electrical signal. It does this by generating an electrical current proportional to the intensity of incident optical radiation.*

A6. *High.*

A7. *The semiconductor positive-intrinsic-negative (PIN) photodiode and avalanche photodiode (APD).*

A8. *Silicon, gallium arsenide, germanium, and indium phosphide.*

A9. *The current produced when photons are incident on the detector active area.*

A10. *The ratio of the optical detector's output photocurrent in amperes to the incident optical power in watts.*

A11. *Reverse-biased.*

A12. *The leakage current that continues to flow through a photodetector when there is no incident light.*

A13. Increase.

A14. Small.

A15. Fast transit time.

A16. Because fiber optic communications systems operate at low optical power levels.

A17. The electrons initially generated by the incident photons accelerate as they move through the APD active region. As these electrons collide with electrons in the semiconductor material, they cause a fraction of them to become part of the photocurrent.

A18. By increasing the reverse-bias voltage.

A19. The preamplifier.

A20. Receiver sensitivity, bandwidth, and dynamic range.

A21. Thermal noise, dark current noise, and quantum noise.

A22. Noise.

A23. Increased.

A24. Dark current and quantum noises.

A25. The high-impedance amplifier and the transimpedance amplifier.

A26. Transimpedance.

A27. For high-data-rate applications and for low- or moderate-data-rate applications where receivers with extremely low sensitivities are required.

A28. To smooth the amplified signal to remove some of the high frequency noise before the signal is further processed.

CHAPTER 8

FIBER OPTIC LINKS

LEARNING OBJECTIVES

Upon completion of this chapter, you should be able to do the following:

1. Describe a basic point-to-point fiber optic data link.
2. Explain the difference between digital and analog fiber optic communications systems.
3. Discuss the most common types of line coding used in digital fiber optic communications including non-return-to-zero (NRZ), return-to-zero (RZ), and biphase (or Manchester).
4. Describe the main type of analog modulation.
5. State several precautions that need to be emphasized when installing fiber optic links on board ships.

FIBER OPTIC SYSTEM TOPOLOGY

Most of the discussion on fiber optic data links provided earlier in this training manual refers to simple point-to-point links. A **point-to-point** fiber optic data link consists of an optical transmitter, optical fiber, and an optical receiver. In addition, any splices or connectors used to join individual optical fiber sections to each other and to the transmitter and the receiver are included. Figure 8-1 provides a schematic diagram of a point-to-point fiber optic data link.

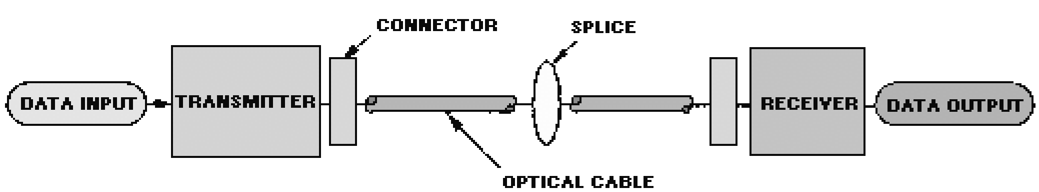

Figure 8-1.—A schematic diagram of a point-to-point fiber optic data link.

A common fiber optic application is the **full duplex link**. This link consists of two simple point-to-point links. The links transmit in opposite directions between the equipments. This application may be configured using only one fiber. If configured with one fiber, fiber optic splitters are used at each end to couple the transmit signal onto the fiber and receive signal to the detector.

All fiber optic systems are simply sets of point-to-point fiber optic links. Different system topologies arise from the different ways that point-to-point fiber optic links can be connected between equipments. The term **topology**, as used here, refers to the configuration of various equipments and the fiber optic components interconnecting them. This equipment may be computers, workstations, consoles, or other equipments. Point-to-point links are connected to produce systems with linear bus, ring, star, or tree topologies. Point-to-point fiber optic links are the basic building block of all fiber optic systems.

A **linear bus topology** consists of a single transmission line that is shared by a number of equipments (see figure 8-2). Generally the transmission line in a fiber optic linear bus consists of two optical lines, one for each direction of communication. Optical taps (optical splitters) are used by each equipment to connect to each line. For each line, the optical tap couples signals from the line to the equipment receiver and from the equipment transmitter onto the line. The connection between any two equipments is a simple point-to-point link that contains the optical tap for each equipment.

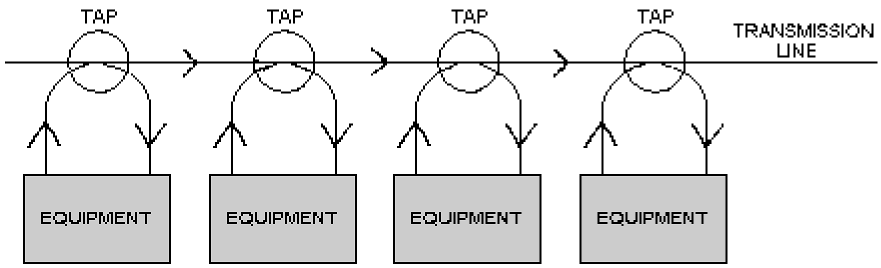

Figure 8-2.—Linear bus topology.

A **ring topology** consists of equipments attached to one another in a closed loop or ring (see figure 8-3). The connection between each equipment is a simple point-to-point link. In some systems each equipment may have an associated optical switch. In normal operation, the switch routes signals from the fiber connected to the previous equipment to the receiver. It also routes signals from the transmitter to the fiber connected to the next equipment. In bypass operation, the switch routes signals from the fiber connected to the previous equipment to the fiber connected to the next equipment. In each case, the connection between adjacent equipments on the ring is a simple point-to-point link through fiber, connectors, and switches.

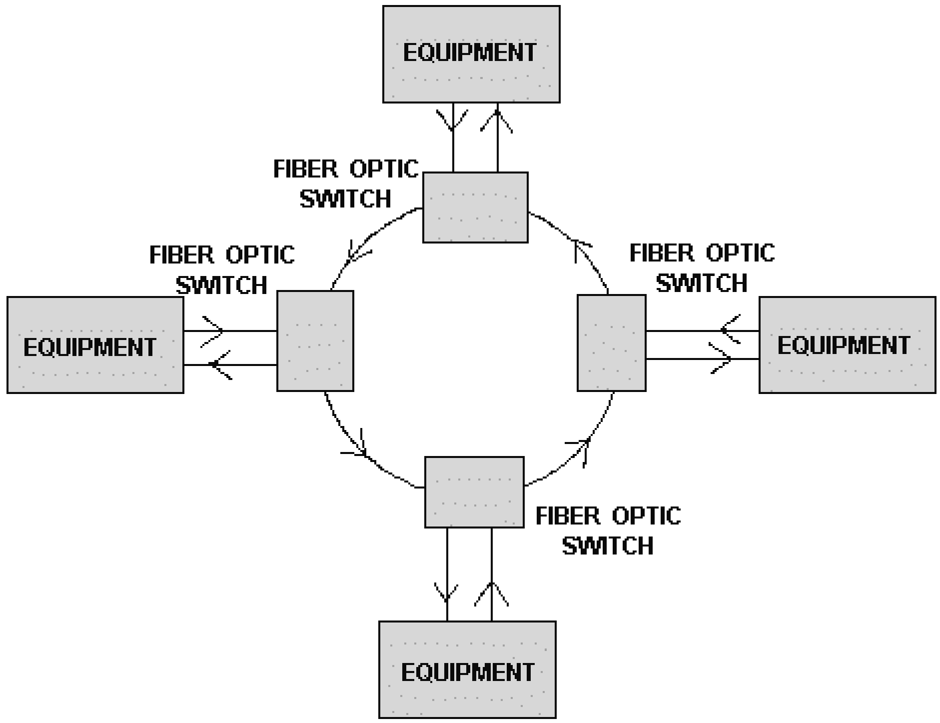

Figure 8-3.—Ring topology.

In the **star topology**, each equipment is connected to a common center hub (see figure 8-4). The center hub can be a passive fiber optic star coupler or an active equipment. If the center hub is a passive star coupler, each equipment transmitter is connected to an input port of the coupler and an output port of the coupler is connected to each equipment receiver. The connection between any two equipments is a simple point-to-point link through the star coupler. If the center hub is an active equipment, the connection between any two equipments consists of two point-to-point links. Each connection consists of one link from the first equipment to the center hub and a second link from the center hub to the second equipment.

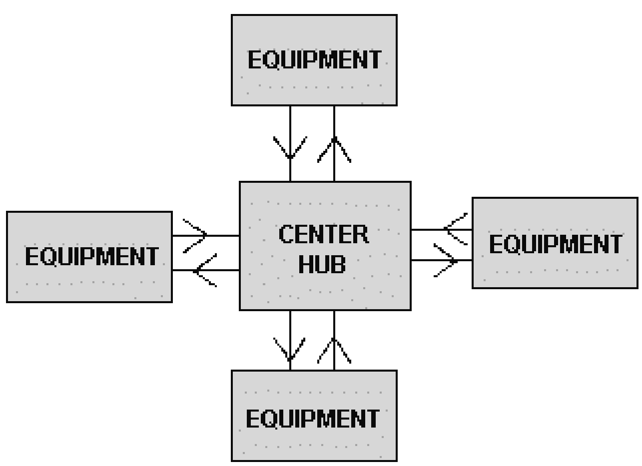

Figure 8-4.—Star topology.

A **tree topology** consists of a transmission line that branches, or splits (see figure 8-5). A tree topology may have many different branching points. At each branching point either a passive fiber optic splitter or an active branching device is used. In many cases both passive couplers and active branching devices are used within a particular system. Regardless of the branching method, each connection within the tree is a simple point-to-point link through splitters or multiple point-to-point links through active branching devices.

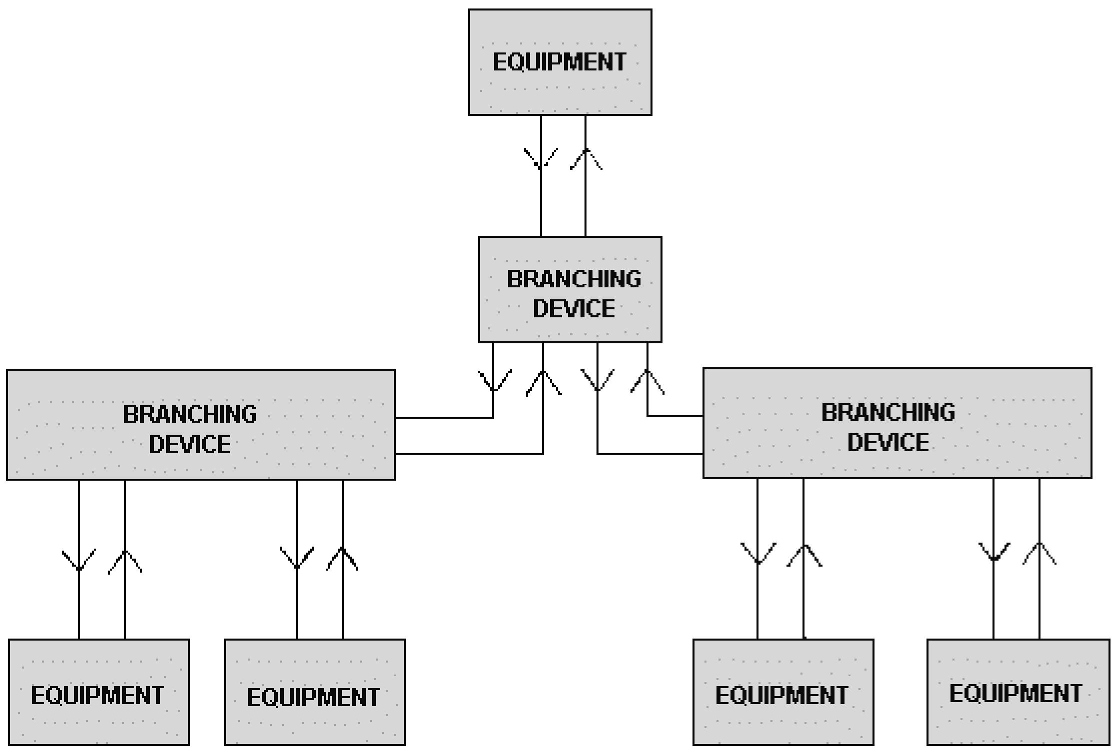

Figure 8-5.—Tree topology.

Q1. List four system topologies that can be constructed using point-to-point fiber optic links.

Q2. Which topology (linear bus, ring, star, or tree) consists of equipments attached to one another in a closed loop?

Q3. Which topology (bus, ring, star, or tree) has a center hub interconnecting the equipments?

LINK CLASSIFICATION

While there are several ways to classify fiber optic links, this chapter classifies links according to the modulation type: either digital or analog. **Modulation** is the process of varying one or more characteristics of an optical signal to encode and convey information. Generally, the intensity of the optical signal is modulated in fiber optic communications systems. Digital modulation implies that the optical signal consists of discrete levels. Analog modulation implies that the intensity of the optical signal is proportional to a continuously varying electrical input. Most fiber optic systems are digital because digital transmission systems generally provide superior performance over analog transmission systems.

Q4. Define modulation.

DIGITAL TRANSMISSION

A **digital signal** is a discontinuous signal that changes from one state to another in discrete steps. A popular form of digital modulation is **binary**, or two level, digital modulation. In binary modulation the optical signal is switched from a low-power level (usually off) to a high-power level. There are a number of modulation techniques used in digital systems, but these will not be discussed here. For more information on digital modulation techniques, refer to the references listed in appendix 2.

Line coding is the process of arranging symbols that represent binary data in a particular pattern for transmission. The most common types of line coding used in fiber optic communications include non-return-to-zero (NRZ), return-to-zero (RZ), and biphase, or Manchester. Figure 8-6 illustrates NRZ, RZ, and biphase (Manchester) encoding.

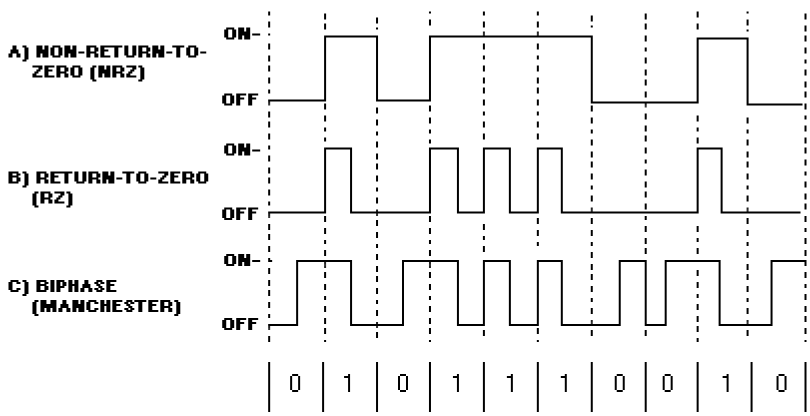

Figure 8-6.—NRZ, RZ, and biphase (Manchester) encoding.

NRZ code represents binary 1s and 0s by two different light levels that are constant during a bit duration. The presence of a high-light level in the bit duration represents a binary 1, while a low-light level represents a binary 0. NRZ codes make the most efficient use of system bandwidth. However, loss of timing may result if long strings of 1s and 0s are present causing a lack of level transitions.

RZ coding uses only half the bit duration for data transmission. In RZ encoding, a half period optical pulse present in the first half of the bit duration represents a binary 1. While an optical pulse is present in the first half of the bit duration, the light level returns to zero during the second half. A binary 0 is represented by the absence of an optical pulse during the entire bit duration. Because RZ coding uses only half the bit duration for data transmission, it requires twice the bandwidth of NRZ coding. Loss of timing can occur if long strings of 0s are present.

Biphase, or Manchester, encoding incorporates a transition into each bit period to maintain timing information. In Manchester encoding, a high-to-low light level transition occurring in the middle of the bit duration represents a binary 1. A low-to-high light level transition occurring in the middle of the bit duration represents a binary 0.

For further information on digital encoding schemes and modulation techniques, refer to the reference material listed in appendix 2.

Digital transmission offers an advantage with regard to the acceptable signal-to-noise ratio (SNR) at the optical receiver. Digital communications systems can tolerate large amounts of signal loss and dispersion without impairing the ability of the receiver to distinguish a binary 1 from a binary 0. Digital signalling also reduces the effects that optical source nonlinearities and temperature have on system performance. Source nonlinearities and temperature variations can severely affect analog transmission. Digital transmission provides superior performance in most complex systems (such as LANs) and long-haul communications systems. In short-haul systems, the cost and complexity of analog-to-digital and digital-to-analog conversion equipment, in some cases, outweigh the benefits of digital transmission.

Q5. What is a digital signal?

Q6. In NRZ code, does the presence of a high-light level in the bit duration represent a binary 1 or a binary 0?

Q7. How can the loss of timing occur in NRZ line coding?

Q8. How is a binary 1 encoded in RZ line coding?

Q9. In Manchester encoding, does a low-to-high light level transition occurring in the middle of the bit duration represent a binary 1 or a binary 0?

ANALOG TRANSMISSION

An **analog signal** is a continuous signal whose amplitude, phase, or some other property varies in a direct proportion to the instantaneous value of a physical variable. An example of an analog signal is the output power of an optical source whose intensity is a function of a continuous electrical input signal.

Most analog fiber optic communications systems intensity modulate the optical source. In **intensity modulation**, the intensity of the optical source's output signal is directly modulated by the incoming electrical analog baseband signal. A **baseband signal** is a signal that is in its original form and has not been changed by a modulation technique.

In some cases, the optical source may be directly modulated by a incoming electrical signal that is not a baseband signal. In these cases the original electrical signal generally modulates an electrical subcarrier frequency. The most common form of analog subcarrier modulation in fiber optic systems is frequency modulation (FM). The optical source is intensity modulated by the electrical subcarrier.

While most fiber optic systems employ digital modulation techniques, there are certain applications where analog modulation techniques are preferred. The transmission of video using analog techniques is very popular, especially for shorter distances, where costs can be minimized and complex multiplexing and timing equipment is unnecessary. The transmission of analog voice signals may also be attractive in small, short-haul systems. In addition, fiber optic sensor systems may incorporate analog transmission. Requirements that analog transmission places on applications include high signal-to-noise ratio and high source linearity. While analog transmission can be attractive for short-haul or medium-haul systems, it is unattractive for long-haul systems where digital techniques provide better performance.

Q10. What is an analog signal?

Q11. What type of modulation do most analog fiber optic communications systems use?

Q12. Why has the transmission of video using analog techniques been very popular, especially for shorter distances?

SYSTEM DESIGN

Fiber optic systems can be simple point-to-point data links or can involve more complex topologies. However, it is generally necessary only to refer to point-to-point data links when discussing the process of link design. Fiber optic systems that incorporate complex architectures can be simplified into a collection of point-to-point data links before beginning the design process.

Fiber optic system design is a complicated process that involves link definition and analysis. The design process begins by providing a complete description of the communication requirements. This information is used to develop the link architecture and define the communications links. System designers must decide on the operational wavelength and types of components to use in the system. These decisions affect numerous system and link design parameters, such as launched power, connection losses, bandwidth, cost, and reliability.

Once a system design has been formulated, each link is analyzed to determine its viability. Link analysis involves calculating each link's power budget and risetime budget. Calculating a **power budget** involves identifying all of the sources of loss in the fiber optic link. These losses and an additional safety margin are then compared to the difference between the transmitter output power and the receiver sensitivity. The difference between the transmitter output power and the receiver sensitivity is referred to as the **available power**. If the sources of loss plus the safety margin are less than the available power in the link, the design is viable.

Calculating the **risetime budget** involves calculating the risetimes of the link transmitter and the optical fiber. The composite optical transmitter/fiber risetime is referred to as the **fiber exit risetime**. If the fiber exit risetime is less than the maximum input risetime specified for the link receiver, then the link design is viable.

If a proposed link design is not viable, the system designer will reevaluate various decisions made earlier in the system design. These reevaluations may include using a different transmitter or receiver or may involve redesigning the physical configuration of the link. Because there are many variables involved in link design and analysis, it may take several iterations before the variables are combined in a manner that ensures link operation. For more information of fiber optic system design, refer to the *Navy Fiber Optic System Design Standard*.

Q13. Why is it generally only necessary to refer to point-to-point data links when discussing the process of fiber optic system design?

Q14. List five system design parameters considered when system designers choose the system operational wavelength and link components.

Q15. What two analyses are performed to determine if a link design is viable?

SYSTEM INSTALLATION

The Navy has a standard to provide detailed information and guidance to personnel concerned with the installation of fiber optic cable plants on naval surface ships and submarines. The **fiber optic cable**

plant consists of all the fiber optic cables and the fiber optic interconnection equipment within the ship, including connectors, splices, and interconnection boxes. The fiber optic cable plant installation standard consists of a basic standard and six numbered parts dealing with the following:

- Cables-provides detailed methods for cable storage and handling, end-sealing, repair, and splicing
- Equipment-provides detailed methods for fiber optic equipment installation and cable entrance to equipment
- Penetrations-provides detailed methods for cable penetrations within the ship's structure
- Cableways-provides detailed methods to install fiber optic cables in cableways
- Connectors and interconnections-provides detailed methods for installing fiber optic connectors and other interconnections, such as splices
- Tests-identifies and provides detailed methods for testing fiber optic cable plants before, during, and after installation and repair

There are other standards that discuss fiber optic system installation. Many of these standards incorporate procedures for repair, maintenance, and testing. The techniques developed for installing fiber optic hardware are not much different than for installing hardware for copper-based systems. However, the primary precautions that need to be emphasized when installing fiber optic systems on board ships are as follows:

- Optical fibers or cables should never be bent at a radius of curvature less than a certain value, called the **minimum bend radius**. Bending an optical fiber or cable at a radius smaller than the minimum bend radius causes additional fiber loss.
- Fiber optic cables should never be pulled tight or fastened over or through sharp corners or cutting edges. Extremely sharp bends increase the fiber loss and may lead to fiber breakage.
- Fiber optic connectors should always be cleaned before mating. Dirt in a fiber optic connection will significantly increase the connection loss and may damage the connector.
- Precautions must be taken so the cable does not become kinked or crushed during installation of the hardware. Extremely sharp kinks or bends increase the fiber loss and may lead to fiber breakage.
- Only trained, authorized personnel should be allowed to install or repair fiber optic systems.

Q16. Optical fibers or cables should never be bent at a radius of curvature smaller than a certain value. Identify this radius of curvature.

Q17. List five precautions to take when installing fiber optic systems on board naval ships.

SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas that you have learned. Understanding the basics of fiber optic system classification, design, and installation is recommended before you begin studying specific fiber optic system applications.

A basic **POINT-TO-POINT** fiber optic data link consists of an optical transmitter, optical fiber, and an optical receiver. In addition, any splices or connectors used to join individual optical fiber sections to each other and to the transmitter and the receiver are included.

The term **TOPOLOGY** refers to the configuration of various equipments and the fiber optic components interconnecting them.

A **LINEAR BUS TOPOLOGY** consists of a single transmission line that is shared by a number of equipments.

A **RING TOPOLOGY** consists of equipments attached to one another in a closed loop or ring.

In the **STAR TOPOLOGY**, each equipment is connected to a common center hub. The center hub can be a passive fiber optic star coupler or an active equipment.

A **TREE TOPOLOGY** consists of a transmission line that branches, or splits.

FIBER OPTIC LINKS are classified according to the modulation type: either digital or analog.

DIGITAL MODULATION implies that the optical signal consists of discrete levels.

ANALOG MODULATION implies that the intensity of the optical signal is proportional to a continuously varying electrical input.

MODULATION is the process of varying one or more characteristics of an optical signal to encode and convey information.

A **DIGITAL SIGNAL** is a discontinuous signal that changes from one state to another in discrete steps.

BINARY, or two level, digital modulation is a popular form of digital modulation.

LINE CODING is the process of arranging symbols that represent binary data in a particular pattern for transmission. The most common types of line coding used in fiber optic communications include non-return-to-zero (NRZ), return-to-zero (RZ), and biphase, or Manchester.

DIGITAL TRANSMISSION offers an advantage with regard to the acceptable SNR at the optical receiver.

An **ANALOG SIGNAL** is a continuous signal that varies in a direct proportion to the instantaneous value of a physical variable.

Most **ANALOG FIBER OPTIC COMMUNICATIONS SYSTEMS** intensity modulate the optical source.

In **INTENSITY MODULATION**, the intensity of the optical source's output signal is directly modulated by the incoming electrical analog baseband signal.

A **BASEBAND SIGNAL** is a signal that is in its original form and has not been changed by a modulation technique.

FIBER OPTIC SYSTEMS that have complex architectures can be simplified into a collection of point-to-point data links.

LINK ANALYSIS involves calculating each link's power budget and risetime budget.

Calculating a **POWER BUDGET** involves identifying all of the sources of loss in the fiber optic link. These losses and an additional safety margin are then compared to the difference between the transmitter output power and the receiver sensitivity.

Calculating the **RISETIME BUDGET** involves calculating the risetimes of the link transmitter and the optical fiber.

The **FIBER OPTIC CABLE PLANT** consists of all the fiber optic cables and the fiber optic interconnection equipment within the ship, including connectors, splices, and interconnection boxes.

OPTICAL FIBERS or **CABLES** should never be bent at a radius of curvature less than a certain value, called the minimum bend radius.

FIBER OPTIC CONNECTORS should always be cleaned before mating.

ANSWERS TO QUESTIONS Q1. THROUGH Q17.

A1. *Linear bus, ring, star, and tree topologies.*

A2. *Ring.*

A3. *Star.*

A4. *The process of varying one or more characteristics of an optical signal to encode and convey information.*

A5. *A discontinuous signal that changes from one state to another in discrete steps.*

A6. *Binary 1.*

A7. *If long strings of 1s or 0s are present causing a lack of level transitions.*

A8. *A half-period optical pulse present in the first half of the bit duration.*

A9. *Binary 0.*

A10. *A continuous signal that varies in a direct proportion to the instantaneous value of a physical variable.*

A11. *Intensity modulation.*

A12. *Because cost can be minimized and complex multiplexing and timing equipment is unnecessary.*

A13. *Because fiber optic systems that incorporate complex architectures can be simplified into a collection of point-to-point data links before beginning the design process.*

A14. Launch power, connection losses, bandwidth, cost, and reliability.

A15. Power budget and risetime budget.

A16. Minimum bend radius.

A17.

- *a. Never bend an optical fiber or cable at a radius of curvature less than the minimum bend radius.*
- *b. Never pull fiber optic cables tight or fasten them over or through sharp corners or cutting edges.*
- *c. Always clean fiber optic connectors before mating.*
- *d. Do not kink or crush fiber optic cable during installation of the hardware.*
- *e. Allow only trained, authorized personnel to install or repair fiber optic systems.*

APPENDIX I

ABBREVIATIONS AND ACRONYMS

Al—aluminum

APD—avalanche photodiode

As—arsenic

BER—bit-error rate

CATV—cable television

cm—centimeter

CO_2—carbon dioxide

dB—decibel

DH—double heterojunction

DIP—dual inline package

EIA—Electronics Industries Association

ELED—edge light-emitting diode

FDDI—fiber distributed data interface

FM—frequency modulation

FOTP—fiber optics test procedure

FWHM—full-width half-maximum

Ga—gallium

Ge—germanium

GHz—gigahertz

IM—intensity modulation

In—indium

IVPO—inside vapor phase oxidation

km—kilometer

LAN—local area network

LD—laser diode

LED—light-emitting diode

m—meter

Mb—megabyte/megabit

MCVD—modified chemical vapor deposition

MFD—mode field diameter

MHz—megahertz

μm—micrometer

μW—microwatt

mm—millimeter

mW—milliwatt

MPD—mode power distribution

NA—numerical aperture

nm—nanometer

NRZ—non-return-to zero

OFCC—optical fiber cable component

OH^-—hydroxyl ions

OLTS—optical loss test set

OTDR—optical time-domain reflectometer

OVPO—outside vapor phase oxidation

P—phosphorus

PC—physical contact

PCS—plastic clad silica

PIN—positive-intrinsic-negative

RC—resistance capacitance

RMS—root mean square

RZ—return-to-zero

s—second

Si—silicon

SiO_2—silica

SLD—superluminescent diode

SLED—surface light-emitting diode

SNR—signal-to-noise ratio

TE—transverse electric

TIA—Telecommunications Industries Association

TO—cans transistor outline cans

TM—transverse magnetic

VAD—vapor phase axial deposition

Assignment Questions

<u>Information</u>: The text pages that you are to study are provided at the beginning of the assignment questions.

ASSIGNMENT 1

Textbook assignment: Chapter 1, “Background on Fiber Optics,” pages 1-1 through 1-7. Chapter 2, “Fiber Optic Concepts,” pages 2-1 through 2-35.

1-1. Fiber optics uses what medium to send information?

1. Electrons
2. Phonons
3. Link 11
4. Light

1-2. What are the three parts of a fiber optic data link?

1. Transmitter, optical fiber, receiver
2. Transmitter, optical fiber, optical connectors
3. Optical fiber, optical connectors, receiver
4. Optical fiber, optical connectors, optical splices

1-3. The fiber optic transmitter has which of the following functions?

1. Amplifies the optical signal
2. Converts the electrical input signal to an optical signal
3. Converts the input optical signal to an electrical signal
4. Amplifies the output electrical signal

1-4. Fiber optic systems use what two types of optical sources?

1. LEDs and APDs
2. PIN diodes and LEDs
3. LEDs and laser diodes
4. Laser diodes and APDs

1-5. The optical source performs which of the following functions?

1. Amplifies the optical signal
2. Amplifies the electrical signal
3. Launches the optical signal into the fiber
4. Converts the optical signal to an electrical signal

1-6. What fiber mechanisms weaken and distort the optical signal launched into the fiber?

1. Scattering, absorption, and dispersion
2. Scattering, radiation, and absorption
3. Dispersion, radiation, and absorption
4. Scattering, reflection, and refraction

1-7. The fiber optic receiver performs which of the following functions?

1. Amplifies the optical signal
2. Amplifies the electrical signal
3. Converts the electrical signal back into an optical signal
4. Converts the optical signal back into an electrical signal

1-8. What are the two parts of a fiber optic receiver?

1. Fiber and case
2. Fiber and optical detector
3. Optical detector and PIN diode
4. Optical detector and signal-conditioning circuits

1-9. Noise has what effect, if any, on the quality of a signal?

1. Increases
2. Reduces
3. None; noise has no effect

1-10. What are the two types of optical detectors?

1. LEDs and APDs
2. PIN diodes and APDs
3. APDs and laser diodes
4. Laser diodes and PIN diodes

1-11. Besides the transmitter, the optical fiber, and the receiver, which of the following components may be found in a fiber optic link?

1. Splices only
2. Couplers only
3. Connectors only
4. Splices, couplers, and connectors

1-12. Extremely high losses occurred in early fibers because of which of the following conditions?

1. Cracks in the fibers
2. Holes in the fiber sides
3. Core areas too small in the fibers
4. Impurities in the fiber material

1-13. What was the first light source developed that could be easily coupled into a fiber?

1. LED
2. Lamp
3. YAG laser
4. PIN diode

1-14. Compared to multimode fibers, single mode fibers tend to have lower loss and produce less signal distortion.

1. True
2. False

1-15. What multimode fiber properties help reduce connection losses?

1. Larger core size and lower NA
2. Larger core size and higher NA
3. Smaller core size and lower NA
4. Smaller core size and higher NA

1-16. Fiber optics is being used in which of the following types of applications?

1. Long-haul communications
2. Subscriber-loop applications
3. Military applications
4. All of the above

1-17. Of the following advantages, which one does NOT apply to fiber optics?

1. Established standards
2. Increased bandwidth
3. Improved environmental
4. Improved signal security

1-18. Of the following factors, which ones are advantages of fiber optic systems?

1. Electrical isolation and low bandwidth
2. Immunity to noise and low bandwidth
3. Electrical isolation and immunity to noise
4. Signal security and high price

1-19. To describe the nature of light, which of the following ways can be used?

1. Electromagnetic wave only
2. Particles of energy only
3. Electromagnetic wave and particles of energy
4. Element

1-20. Light exhibits what kind of wave motion?

1. Longitudinal
2. Transverse
3. Turbulent
4. Aperiodic

1-21. Which of the following factors is a description of transverse wave motion?

1. The wave motion is not predictable
2. The wave magnitude varies parallel to the direction of propagation
3. The wave magnitude varies perpendicular to the direction of wave motion

1-22. What does a transparent substance do to light rays that fall on it?

1. Absorbs them
2. Reflects them
3. Refracts them
4. Transmits them

1-23. What does a translucent substance do to light rays that fall on it?

1. Reflects and absorbs them
2. Refracts and absorbs them
3. Transmits and diffuses them
4. Transmits and reflects them

1-24. Which of the following substances is a good example of a translucent substance?

1. Cardboard
2. Clear glass
3. Frosted glass
4. Aluminum foil

1-25. Which of the following substances is a good example of a transparent substance?

1. Cardboard
2. Clear glass
3. Frosted glass
4. Aluminum foil

1-26. What does an opaque substance do when light rays fall on it?

1. Refracts them
2. Reflects or absorbs them
3. Transmits them only
4. Transmits and diffuses them

1-27. Which of the following substances is an example of an opaque substance?

1. Cardboard
2. Clear glass
3. Oiled paper
4. Frosted glass

1-28. Which of the following objects is NOT an example of a luminous source?

1. Sun
2. Gas flame
3. Mirror
4. Flashlight

1-29. What are light waves called that strike a surface but are neither transmitted nor absorbed?

1. Diffused
2. Refracted
3. Reflected
4. Diffracted

1-30. What is the name of the law that states "The angle of incidence is equal to the angle of reflection"?

1. Snell's Law
2. Murphy's Law
3. Law of Entropy
4. Law of Reflection

1-31. A light wave is incident on a surface. The reflected power is the greatest in which of the following incidences?

1. 30º
2. 45º
3. Perpendicular
4. Almost parallel

1-32. A light wave passes from one medium into another medium with a different velocity. As the wave enters the second medium, the change of direction is known by which of the following terms?

1. Reflection
2. Refraction
3. Absorption
4. Diffusion

1-33. If a light wave passes from a less dense medium to a more dense medium, how does the angle of refraction compare to the angle of incidence?

1. Greater than the angle of incidence only
2. Equal to the angle of incidence only
3. Greater than or equal to the angle of incidence
4. Less than the angle of incidence

1-34. What is another word for diffused?

1. Absorbed
2. Refracted
3. Scattered
4. Attenuated

1-35. When light falls on a piece of black paper, what happens to most of the light?

1. It is absorbed
2. It is reflected
3. It is scattered
4. It is refracted

1-36. Light is transmitted along an optical fiber by what two methods?

1. Ray theory and mode theory
2. Ray theory and photon theory
3. Ray theory and quantum theory
4. Mode theory and photon theory

1-37. How does the speed of light in the fiber compare to the speed of light in the air?

1. It is slower in the fiber
2. It is faster in the fiber
3. It is the same in both the fiber and the air

1-38. The relationship between the incident rays and the refracted rays at a boundary between mediums with different indexes of refraction describes what law?

1. Bragg's Law
2. Snell's Law
3. Murphy's Law
4. Law of Reflection

1-39. Total internal reflection occurs at which of the following angles?

1. Obtuse angle
2. Fresnel angle
3. Right angle
4. Critical angle of incidence

1-40. What are the three basic parts of an optical fiber?

1. Core, cladding, and coating
2. Inside, middle, and outside
3. Fiber, kevlar, and jacket
4. Hole, shell, and coating

1-41. The cladding performs all except which of the following functions?

1. Reduces the loss of light from the core
2. Reduces the scattering loss at the surface of the core
3. Protects the fiber core from absorbing surface contaminants
4. Reduces mechanical strength

1-42. What is the definition of a bound ray?

1. A ray that cannot move
2. A ray that travels in the air
3. A ray that is refracted out of the fiber
4. A ray that propagates through the fiber by total internal reflection

1-43. The fiber NA relates to which of the following characteristics?

1. Physical size of the fiber
2. Tensile strength of the fiber
3. Maximum angle within the fiber acceptance cone
4. Speed of light within the fiber

1-44. A skew ray is which of the following types of rays?

1. An unbound ray
2. A meridional ray
3. An unbalanced ray
4. A ray that propagates without passing through the center axis of the fiber

1-45. Electromagnetic wave behavior is used to describe the propagation of light along the fiber in what theory?

1. Mode theory
2. Particle theory
3. Darwin's theory
4. Rayleigh's theory

1-46. High-order modes cross the axis of the fiber at steeper angles than low-order modes.

1. True
2. False

1-47. Compared to a low-order mode, the electrical and magnetic fields of a high-order mode are distributed more toward the center of a fiber.

1. True
2. False

1-48. What are the two basic types of fibers?

1. Small and large
2. Glass and plastic
3. Opaque and diffuse
4. Single mode and multimode

1-49. Compared to multimode fibers, single mode fibers have a larger core size.

1. True
2. False

1-50. The lowest signal loss and the highest bandwidth are characteristic of which of the following types of fibers?

1. Air core
2. Multimode
3. Single mode
4. Plastic core

1-51. Compared to single mode fibers, multimode fibers have which of the following advantages?

1. Ease of making connections only
2. Ease of launching light into them only
3. Ease of both making connections and launching light into them
4. Lower dispersion

1-52. System performance is affected most by which of the following fiber properties?

1. NA and delta
2. Core diameter and NA
3. Attenuation and dispersion
4. Core diameter and cladding

1-53. The loss of optical power as light travels along a fiber is called

1. attenuation
2. scattering
3. absorption
4. dispersion

1-54. Attenuation is specified in what units?

1. dB
2. dB/km
3. µm
4. µm/km

1-55. Glass optical fibers have low loss between the infrared and ultra- violet absorptive regions. The approximate wavelength of operation for glass optical fibers is in which of the following ranges?

1. 1 nm to 700 nm
2. 700 nm to 1600 nm
3. 1600 nm to 9000 nm
4. 9 µm to 20 µm

1-56. Increased extrinsic absorption at 950 nm, 1,250 nm, and 1,383 nm is caused by what impurity in glass optical fibers?

1. Phosphorus
2. Germanium
3. Titanium
4. Water

1-57. Which type of scattering loss is proportional to the reciprocal of the fourth power of the wavelength of the light?

1. Mie
2. Raman
3. Rayleigh
4. Brillouin

1-58. A radius of curvature is larger than the fiber diameter in which of the following types of fiber bends?

1. Macrobends
2. Microbends
3. Gentle bends
4. Serpentine bends

1-59. Only in multimode fibers does which of the following types of dispersion occur?

1. Modal
2. Material
3. Waveguide
4. Chromatic

1-60. When different colors of light travel through the fiber at different speeds, which of the following types of dispersion occurs?

1. Modal
2. Intramodal (chromatic)
3. Intermodal
4. Atmospheric

ASSIGNMENT 2

Textbook assignment: Chapter 3, "Optical Fibers and Cables," pages 3-1 through 3-26. Chapter 4, "Optical Splices, Connectors, and Couplers," pages 4-1 through 4-34.

2-1. In a step-index fiber, the refractive index profile of the fiber core has which of the following characteristics?

1. It is uniform over the fiber core
2. It linearly decreases from a maximum at the fiber center to a minimum at the core-cladding boundary
3. It is parabolic with a maximum index of refraction at the center and a minimum index of refraction at the core-cladding boundary
4. It linearly increases from a minimum at the fiber center to a maximum at the core cladding boundary

2-2. In a graded-index fiber, the refractive index profile of the fiber core is best described by which of the following statements?

1. It is uniform over the fiber core
2. It linearly decreases from a maximum at the fiber center to a minimum at the core-cladding boundary
3. It is parabolic with a maximum index of refraction at the center and a minimum index of refraction at the core-cladding boundary
4. It linearly increases from a minimum at the fiber center to a maximum at the core cladding boundary

2-3. Which of the following multimode fiber core sizes is NOT a standard commercial fiber size?

1. 50 μm
2. 5 μm
3. 76 μm
4. 100 μm

2-4. Elements other than silicon and oxygen are added to glass material by the fiber manufacturer to change its index of refraction. What are these elements called?

1. Spices
2. Dopants
3. Additives
4. Impurities

2-5. Compared to multimode step-index fibers, do multimode graded-index fibers have lower, higher, or approximately equal bandwidths?

1. Lower
2. Higher
3. Approximately equal

2-6. In multimode graded-index fibers, is the index of refraction of the glass at the center of the fiber core lower, higher, or approximately equal to the index of refraction of the cladding glass?

1. Lower
2. Higher
3. Approximately equal

2-7. For a multimode graded-index fiber, the numerical aperture is at its maximum value at which of the following locations?

1. At the fiber axis
2. At the core-cladding interface
3. Half way between the fiber center and the core-cladding interface
4. One-fourth of the way between the fiber center and the core- cladding interface

2-8. In multimode fiber, all light rays have to propagate all of the way to the core-cladding interface before they are reflected back toward the fiber axis.

1. True
2. False

2-9. A step-index multimode fiber and a graded-index multimode fiber have the same core and cladding sizes and the same refractive index difference. Which fiber type, if either, will accept light more easily and have more propagating modes?

1. Step-index fiber
2. Graded-index fiber
3. Neither; they will behave approximately the same

2-10. The multimode graded-index fiber that has the best bend performance and will show the least amount of optical degradation if mishandled is what size?

1. 50/125 μm
2. 5/125 μm
3. 85/125 μm
4. 100/140 μm

2-11. The attributes of the 62.5/125- μm fiber do NOT include which of the following factors?

1. Low loss
2. High bandwidth
3. Low bending sensitivity
4. Low source to fiber coupling efficiency

2-12. What are the two basic types of single mode step-index fibers?

1. Low NA and high NA
2. Solid core and air core
3. Enriched clad and depressed
4. Matched clad and depressed clad

2-13. For wavelengths greater than its cutoff wavelength, a typical single mode fiber is allowed to propagate a total of how many modes, if any?

1. 1 only
2. 10 only
3. 100
4. None

2-14. Fibers are single mode at a particular wavelength only when $V < 2.405$. Under what condition, if any, will the fiber cease to be single mode?

1. When the wavelength of the light is greater than the cutoff wavelength
2. When the wavelength of the light is less than the cutoff wavelength
3. None

2-15. The use of plastic-clad silica and all plastic fibers has what primary drawback?

1. Higher NA
2. Higher cost
3. Higher bandwidth
4. Limited optical performance

2-16. In the fabrication of silica optical fibers, which of the following processes may be used?

1. Outside vapor phase oxidation (OVPO)
2. Inside vapor phase oxidation (IVPO)
3. Vapor phase axial deposition (VAD)
4. All of the above

2-17. In making a preform, layers of glass powder are deposited on the inside or outside of a glass rod or tube. What is this glass powder called?

1. Soot
2. Smoke
3. Preform
4. Afterburn

2-18. The process used in drawing the fiber is best described by which of the following statements?

1. The preform is melted and the molten glass is molded, using special fiber molds
2. The preform is softened and the glass is pulled into a thin glass filament
3. The preform is softened and the glass is rolled into a thin glass filament
4. The preform is melted and the fiber is formed by blowing the molten glass through a small hole

2-19. To protect the fiber from contaminants in the drawing process, what substance is added over the fiber?

1. Water
2. Coating
3. Preform
4. Cladding

2-20. Most fiber optic cable structures contain which of the following items?

1. Buffers only
2. Jackets only
3. Buffers and jackets only
4. Buffers, jackets, and strength members

2-21. Properly designed optical cable structures perform which of the following functions?

1. Protect the optical fibers from mechanical stresses, damage, and breakage
2. Increase the tensile stress on the fiber
3. Decrease the attenuation of the fiber
4. All of the above

2-22. The fiber buffer performs which of the following functions?

1. Protects the fiber from micro-bends
2. Provides additional mechanical protection
3. Helps preserve the fiber's inherent strength
4. All of the above

2-23. Navy shipboard fiber optic cables should NOT contain which of the following materials as a strength member?

1. Steel wire
2. Arimid yarns
3. Carbon fibers
4. Glass-reinforced plastics

2-24. In the materials of a Navy shipboard fiber optic cable jacket, which of the following properties is NOT desirable?

1. High abrasion resistance
2. High flame retardance
3. High halogen content
4. Low toxicity

2-25. Most commercial fiber optic cable jacket materials are suitable for use in Navy shipboard applications.

1. True
2. False

2-26. For low-density fiber Navy ship- board applications, which cable designs, if any, are preferred?

1. Stranded cable
2. Ribbon cable
3. OFCC cable
4. None; they are all equally effective

2-27. When compared with other cable designs, the OFCC fiber optic cable has which of the following advantages?

1. Ruggedness only
2. Ease of handling only
3. Ruggedness and ease of handling
4. Relative small size

2-28. The only advantage of the stranded cable design over the OFCC cable design is

1. greater ruggedness
2. better fiber protection
3. smaller size for the same fiber count
4. better water-blocking performance

2-29. A particular fiber optic cable design has the highest fiber count possible in the smallest size. But it is difficult to use, shows susceptibility to fiber damage during fiber breakout, and has poor bending and water-blocking performance. Which of the following designs fits this description?

1. OFCC cable
2. Stranded cable
3. Ribbon cable

2-30. A fiber optic connection that is typically intended to be permanent is what type, if any?

1. Mechanical splice
2. Connector
3. Coupler
4. None; they are all intended to be removable

2-31. Easy coupling and uncoupling of optical fibers are allowed by what type of fiber optic connection, if any?

1. Splice
2. Coupler
3. Connector
4. None; all are equally difficult

2-32. The distribution or combination of optical signals among fibers uses which type of fiber optic connection, if any?

1. Splice
2. Coupler
3. Connector
4. None; it is not possible to distribute or combine optical signals

2-33. Coupling loss in a fiber optic connection may be caused by which of the following conditions?

1. Poor fiber alignment
2. Poor fiber end preparation
3. Differences in optical properties between connected fibers
4. All of the above

2-34. The loss in optical power through a connection is described by what relationship, if any?

1. Log relationship
2. Linear relationship
3. Exponential relationship
4. None; there is no way to describe the relationship

2-35. An intrinsic coupling loss may be caused by which of the following conditions?

1. Fiber separation
2. Angular misalignment
3. Fiber geometry mismatches
4. Poor fiber end preparation

2-36. In connections that have an air gap, the reflective losses can be minimized by taking which of the following actions?

1. Polishing the fiber ends more finely
2. Cleaning the fiber ends carefully with alcohol
3. Filling the air gap with an index matching gel
4. Heating the connection to an elevated temperature

2-37. A main source of extrinsic coupling loss in fiber to fiber connections is caused by which of the following conditions?

1. Fiber mismatches
2. Poor fiber alignment
3. Poor fiber end preparation

2-38. Which of the following conditions is NOT a form of poor fiber alignment?

1. NA mismatch
2. Fiber separation
3. Lateral misalignment
4. Angular misalignment

2-39. For mating fibers to touch when a connector is assembled, which of the following polishing techniques was developed?

1. Fresnel polish
2. Rayleigh polish
3. Circular polish
4. Physical contact polish

2-40. Single mode fibers are less sensitive to alignment errors than multimode fibers because of their small core size.

1. True
2. False

2-41. The fiber cleaving process includes which of the following actions?

1. Cutting the fiber with a cleaver
2. Bending the fiber until it breaks
3. Lightly nicking the fiber and applying tension until it breaks
4. Sawing the fiber with a special fiber saw

2-42. To remove most of the surface imperfections introduced in the fiber cleaving process in most fiber optic connections, what action should be taken?

1. Polish the fiber end
2. Cover the fiber end face with epoxy
3. Clean the fiber end face with alcohol
4. Cover the fiber end face with index matching gel

2-43. The connector end face should be inspected for scratches and shattered fiber ends by which of the following methods?

1. The naked eye
2. A 10_x eye loupe
3. An electron microscope
4. A 200_x-400_x microscope

2-44. In Navy fiber optic applications, losses from fiber mismatches are minimized by which of the following actions?

1. Polishing the fiber ends
2. Using index matching gels
3. Using index matching epoxies
4. Using Navy specification fibers with tightly specified parameters

2-45. Fiber optic splices are typically used in which of the following conditions?

1. When repeated connections or disconnections are desired only
2. When repeated connections or disconnections are unnecessary only
3. When low loss connections are required only
4. When repeated connections or disconnections are unnecessary and when low loss connections are required

2-46. What are the two basic categories of fiber splices?

1. Glass and plastic
2. Metal and ceramic
3. V-groove and rotary
4. Mechanical and fusion

2-47. For shipboard applications, which of the following types of splices is recommended?

1. Fusion
2. Rotary
3. V-groove
4. Ceramic alignment tube

2-48. The assembly of a rotary splice is which of the following actions?

1. Cleave fiber ends, insert into each end of a glass tube filled with adhesive, and cure with ultraviolet light
2. Cleave fiber ends, insert into each end of a glass tube filled with index matching gel, and twist on splice end caps
3. Break glass tube at center, fill each half with epoxy, insert fibers into each half, cure adhesive with ultraviolet light, and polish and place polished ends together with alignment sleeve
4. Cleave fiber ends, insert fibers into splice, and crimp in place

2-49. The basic process used in making fusion splices is which of the following methods?

1. Gluing the fiber ends together
2. Melting the fiber ends together
3. Polishing the fiber ends and placing them together
4. Cleaving the fiber ends and placing them together

2-50. Fusion splicing is not recommended for Navy use for all of the following reasons except which one?

1. Low splice yields
2. Low splice losses
3. Long splicing times
4. High level of expertise required for splicer operator

2-51. The total loss of a fiber optic connector should always remain below which of the following values?

1. 1 dB
2. 2 dB
3. 5 dB
4. 10 dB

2-52. What are the two basic types of fiber optic connectors?

1. V-groove and ribbon
2. Three rod and biconical
3. Ceramic and stainless steel
4. Butt-jointed and expanded-beam

2-53. Single fiber butt-jointed connections generally consist of which of the following parts?

1. Plug and receptacle
2. Ferrule and alignment clip
3. Two plugs and an adapter
4. One plug and two adapters

2-54. In ceramic ferrules, the center hole is created by which of the following processes?

1. With a microdrill
2. With a laser drill
3. By forming the ferrule around a precision wire
4. With a small water jet

2-55. The standard connector for Navy light-duty applications is of which of the following styles?

1. ST®
2. SMA
3. Array
4. Biconical

(NOTE: ST®; is a registered trademark of AT&T)

2-56. Light-duty connectors are intended for use in all but which of the following locations?

1. Junction boxes
2. Equipment enclosures
3. Environmentally protected locations
4. Exposed equipment interface connectors

2-57. A standard connector for Navy heavy-duty applications is of which of the following styles?

1. MIL-C-83526 connector
2. MIL-C-28876 connector
3. Biconical connector
4. Array connector

2-58. In a heavy-duty connector, what are the two types of terminals called?

1. Plugs and adapters
2. Type A and type B
3. Pins and sockets
4. Nuts and bolts

2-59. Fiber optic couplers attenuate the optical signal much more than a connector or a splice.

1. True
2. False

2-60. Active fiber optic couplers are called active fiber optic couplers for which of the following reasons?

1. Because they contain moving parts
2. Because they switch the optical signal between different parts
3. Because they contain active devices, including sources and detectors
4. Because they move through the system

2-61. An optical coupler has one input port and two output ports. Which of the following types of couplers is it?

1. Optical splitter
2. Optical combiner
3. Star coupler
4. Tree coupler

2-62. An optical coupler has two input ports and one output port. Which of the following types of couplers is it?

1. Optical splitter
2. Optical combiner
3. Star coupler
4. Tree coupler

2-63. An optical coupler has one input port and several output ports. Which of the following types of couplers is it?

1. T-coupler
2. Star coupler
3. Tree coupler
4. Optical splitter

2-64. An optical coupler has several input ports and several output ports. Which of the following types of couplers is it?

1. X-coupler
2. T-coupler
3. Star coupler
4. Tree coupler

ASSIGNMENT 3

Textbook assignment: Chapter 5, "Fiber Optic Measurement Techniques," pages 5-1 through 5-32. Chapter 6, "Optical Sources and Fiber Optic Transmitters," pages 6-1 through 6-16.

3-1. Manufacturers should measure some component parameters during and after component manufacture for which of the following reasons?

1. To characterize the component design
2. To verify the quality of the manufactured parts
3. To determine if the component has been damaged in the shipping process
4. To determine if the installation process has degraded the component performance beyond allowable limits

3-2. End users should measure some component parameters upon receipt before installing a component into a fiber optic system for which of the following reasons?

1. To characterize the component design
2. To verify the quality of the manufactured parts
3. To determine if the component has been damaged in the shipping process

3-3. End users should measure some component parameters after installation of the component in the fiber optic system for which of the following reasons?

1. To characterize the component design
2. To verify the quality of the manufactured parts
3. To determine if the component has been damaged in the shipping process
4. To determine if the installation process has degraded the component performance beyond allowable limits

3-4. Standard test methods used for testing fiber optic components or systems can be found in which of the following test documents?

1. EIA/TIA-455 only
2. EIA/TIA-526 only
3. EIA/TIA-455 and EIA/TIA 526
4. MIL-STD 2196

3-5. In laboratory fiber attenuation measurements, the output optical power of a long fiber is compared with the optical power launched into that same fiber two meters from the optical source. This method of measuring the optical attenuation is called the

1. OTDR method
2. fiber method
3. cutback method
4. two-point method

3-6. Which of the following are considered launch conditions?

1. The temperature at the time of measurement
2. The humidity at the time of measurement
3. The way power is launched into the optical fiber
4. The type of connector or splice used on the fiber

3-7. Launch conditions in an attenuation measurement are important to measurement personnel for which of the following reasons?

1. The attenuation measured for each different launch condition will be different
2. The use of the wrong launch condition will damage the optical power meter
3. The fibers will only transmit light launched in one particular manner
4. The use of the wrong launch condition will damage the fiber

3-8. For single mode fiber, what method is typically used to assure that power is launched into only the fundamental mode?

1. Only LEDs are used as test optical sources
2. Only lasers are used as test optical sources
3. The fiber is always placed at a 45º angle with respect to the plane of the source
4. A 30-mm diameter mandrel or free-form loop is applied at the launch end of the fiber

3-9. What does the term overfilled launch mean?

1. When too much power is launched into the fiber
2. When not enough power is launched into the fiber
3. When light is launched only into the low order mode
4. When the launch spot size and the angular distribution are larger than that of fiber core

3-10. In what part of the fiber does an underfilled launch concentrate most of the optical power?

1. In the center of the fiber
2. At the edge of the fiber
3. Over all of the fiber
4. In the cladding

3-11. What is a mode filter?

1. A device that converts cladding power to core power
2. A device that removes any cladding power from the fiber
3. A device that attenuates specific modes propagating in the core of the fiber
4. A device that attenuates specific wavelengths of light in the core of the fiber

3-12. To remove high-order modes in multimode fibers, which of the following mode filters is normally used?

1. Bessel filter
2. Bandpass filter
3. Mandrel wrap filter
4. Neutral density filter

3-13. What is the wavelength called over which the fiber will propagate only one mode?

1. Cutoff wavelength
2. Fresnel wavelength
3. Cutback wavelength
4. Rayleigh wavelength

3-14. Determining the cutoff wavelength of a single mode fiber involves finding the wavelength above which the power transmitted through the fiber decreases abruptly.

1. True
2. False

3-15. When the cutoff wavelength is reached, why does the transmitted power in a single mode fiber abruptly decrease?

1. The fiber absorption increases at the cutoff wavelength
2. The fiber scattering increases at the cutoff wavelength
3. The fiber diffusion increases at the cutoff wavelength
4. The second-order mode ceases to propagate at the cutoff wave- length

3-16. The spreading of a light pulse as it travels along the fiber is caused by what mechanism?

1. Diffraction
2. Attenuation
3. Absorption
4. Dispersion

3-17. In a fiber, the intermodal (modal) dispersion is greatest under what condition?

1. When the input pulse has a long rise time
2. When all fiber modes are excited
3. When the input pulse has an extremely high amount of power
4. When the source spectrum contains many different wave- lengths

3-18. The fiber bandwidth (−3 dB) is defined as the lowest frequency at which the magnitude of the fiber frequency response has decreased to what portion of its zero-frequency value?

1. One-tenth
2. One-fifth
3. One-half
4. Three-fourths

3-19. Modal bandwidth is normally given in what units?

1. GHz
2. MHz
3. MHz/km
4. MHz-km

3-20. Why does chromatic dispersion occur?

1. Because different fiber modes have different propagation speeds
2. Because different colors of light travel through the fiber at different speeds
3. Because different colors of light are attenuated differently in the fiber
4. Because different fiber modes are attenuated differently in the fiber

3-21. End users perform fiber geometry measurements for which of the following reasons?

1. To reduce system bandwidth limitations
2. To separate bigger fibers from smaller fibers
3. To reduce system attenuation and coupling losses from fiber mismatches
4. To determine which connector to use

3-22. Cladding diameter, cladding noncircularity, core-cladding concentricity error, and core noncircularity are measured by which of the following techniques?

1. Micrometer calipers
2. Electron microscopes
3. Video cameras attached to a computer for digital analysis
4. Ruler

3-23. The core diameter of a multimode fiber is defined by which of the following measurements?

1. The distance between the 50% points of the measured near-field distribution
2. The distance between the 50% points of the measured far-field distribution
3. The distance between the 2.5% points of the measured near-field distribution
4. The distance between the 2.5% points of the measured far-field distribution

3-24. The fiber near-field is which of the following regions?

1. The region close to the fiber-end face, within a few cm of the end face
2. The region within 3 to 5 cm of the fiber-end face
3. The region about one foot of the fiber-end face
4. The region far from the fiber- end face

3-25. The fiber far-field is which of the following regions?

1. The region close to the fiber-end face, within a few cm of the end face
2. The region far from the fiber-end face, greater than a few cm for multimode and mm for single mode
3. The region exactly next to the fiber-end face
4. Anywhere inside the acceptance cone of the fiber

3-26. The far-field power distribution describes the emitted power per unit as a function of the angle θ from the fiber axis some distance from the fiber-end face.

1. True
2. False

3-27. The numerical aperture of a multi- mode fiber is best described by which of the following definitions?

1. Half the difference between the 50% angles of the far-field distribution
2. Half the difference between the 50% angles of the near-field distribution
3. Half the difference between the 5% angles of the near-field distribution
4. Half the difference between the 5% angles of the far-field distribution

3-28. The mode field diameter of a single mode fiber relates to which of the following factors?

1. The cladding diameter of a multimode fiber
2. The cladding diameter of a single mode fiber
3. The spot size of the fundamental mode of a single mode fiber
4. The coating diameter of the single mode fiber

3-29. Insertion loss is determined by which of the following techniques?

1. The power transmitted through a component is compared to the power transmitted through the fiber or the cable before the component was inserted
2. The power transmitted through a component with a mandrel wrap on the fiber is compared to the power transmitted through the component without a mandrel wrap inserted
3. The power transmitted through a cable is compared to the power transmitted through a similar piece of cable
4. The power transmitted through a connector is compared to the power transmitted through a similar connector

3-30. The return loss of a fiber optic component is which of the following measurements?

1. The difference in the power loss when a component is measured in reverse directions
2. The amount of loss of the reflected light compared with the power of the incident beam at the interface
3. The amount of loss of the reflected light compared with the transmitted light at a component

3-31. Some properties may change during installation; therefore, they are typically measured in the field. All of the following measurements should be made in the field except which one?

1. Fiber loss
2. Connector/splice return loss
3. Connector/splice insertion loss
4. NA

3-32. Field loss measurements are made by using which of the following test equipments?

1. Low power calorimeters
2. Optical sources and power meters only
3. Optical time domain reflectometers only
4. Optical sources and power meters; and optical time domain reflectometers

3-33. Measurements made with an optical time domain reflectometer are more accurate than those made with an optical source and an optical power meter.

1. True
2. False

3-34. An OTDR should not be used to measure optical fibers or links that are less than a specific minimum length. What is that length?

1. 5 m
2. 50 m
3. 100 m
4. 250 m

3-35. The initial pulse (or spike) at the beginning and at most connections in a link on the OTDR trace is caused by which of the following processes?

1. Reflected power at each air gap in the link
2. Extremely high losses at the beginning of each piece of fiber
3. Amplification of the OTDR pulse at the beginning of each piece of fiber
4. Second harmonic generation at the beginning of each piece of fiber

3-36. When OTDR measurements are made, a dead zone fiber is used for what reason?

1. To compensate for the inaccuracy of the OTDR
2. To match the fiber types at the first connection
3. To maximize the reflectance at the first connection
4. To reduce the effect of the initial reflection at the OTDR on the measurement

3-37. When fiber attenuation is measured with an OTDR, the initial cursor, Z_1, should be placed at what point along the OTDR trace?

1. Just before the connector or the splice at the beginning of the fiber
2. On the gradual downward part of the trace just before the ending connector or splice
3. On the steep downward part of the trace just after the beginning connector or the splice
4. On the gradual downward part of the trace just after the reflective spike from the beginning connector or splice

3-38. When fiber attenuation is measured with an OTDR, the end cursor, Z_2, should be placed at what point along the OTDR trace?

1. Just before the connector or the splice at the beginning of the fiber
2. On the gradual downward part of the trace just before the ending connector or splice
3. On the steep downward part of the trace just after the beginning connector or splice
4. On the gradual downward part of the trace just after the reflective spike from the beginning connector or splice

3-39. When the distance between the ends of a fiber is measured with an OTDR, the initial cursor should be placed at what point along the OTDR trace?

1. Just before the connector or the splice at the beginning of the fiber
2. On the steep downward part of the trace just after the beginning connector or splice
3. On the gradual downward part of the trace just after the reflective spike from the beginning connector or splice
4. On the gradual downward part of the trace just before the ending connector or splice

3-40. OTDR measurements should be performed in each direction and averaged for which of the following reasons?

1. OTDRs are not consistent measurement tools; therefore, multiple measurements must be made
2. Variations in fiber properties (backscattering) change the OTDR measurement, depending on the direction of the measurement; bidirectional averaging eliminates these effects
3. Fibers transmit preferentially in one direction; therefore, measurements must be made to determine the preferential direction

3-41. When a point defect (a connector or a splice) exhibits an apparent gain in power in one direction, it exhibits which of the following properties in the other direction?

1. The same apparent gain in power
2. An exaggerated loss in power
3. A slight loss in power
4. No gain or loss in power

3-42. When using a light source and a power meter to make link loss measurements, which of the following steps should you perform first?

1. Connect the reference jumper between the source and the power meter
2. Connect the reference jumper and one test jumper between the source and the power meter
3. Connect the link directly between the source and the power meter
4. Connect the link directly between two power meters

3-43. During the measurement of the link's output optical power, the test setup is described by which of the following orders?

1. Source, test jumper, link, test jumper, power meter
2. Source, test jumper, link, power meter
3. Source, link, test jumper, power meter
4. Source, link, power meter

3-44. What is the function of a fiber optic transmitter?

1. To amplify optical signals and launch the amplified optical signals into an optical fiber
2. To convert electrical signals into optical signals and launch the optical signals into an optical fiber
3. To convert optical signals into electrical signals only
4. To convert electrical signals into optical signals and transmit the optical signals through the air

3-45. Which of the following items is/are part of a fiber optic transmitter?

1. An optical source only
2. A source drive circuit only
3. An optical source and a source drive circuit only
4. An optical source, a source drive circuit, and an interface circuit

3-46. An optical source has which of the following functions?

1. To convert light to electrical energy (current)
2. To amplify the electrical signal
3. To convert electrical energy into light
4. To convert light into sound

3-47. Which of the following properties are NOT desired properties of an optical source?

1. Be compatible in size to low-loss optical fibers
2. Emit light at wavelengths that maximize fiber loss and dispersion
3. Maintain stable operation in changing environmental conditions
4. Cost less and be more reliable than electrical devices

3-48. Fiber optic communication systems typically operate in what three wavelength windows?

1. 400 nm, 850 nm, and 1550 nm
2. 400 nm, 900 nm, and 1400 nm
3. 850 nm, 1300 nm, and 1550 nm
4. 1300 nm, 2000 nm, and 4000 nm

3-49. Incoherent light has what type of lightwaves?

1. Lightwaves that are produced by lasers
2. Lightwaves that lack a fixed-phase relationship
3. Lightwaves that have a fixed-phase relationship
4. Lightwaves that contain only one wavelength of light

3-50. Semiconductor LEDs emit which of the following kinds of light?

1. Incoherent
2. Coherent only
3. Monochromatic only
4. Coherent and monochromatic

3-51. Semiconductor lasers emit which of the following kinds of light?

1. Spontaneous
2. Incoherent
3. Coherent
4. All of the above

3-52. All of the light emitted by a semiconductor laser or LED is coupled into an optical fiber.

1. True
2. False

3-53. Relevant optical power does NOT depend on which of the following factors?

1. The angles over which the source emits light
2. The size of the source's light-emitting area relative to the fiber core size
3. The alignment of the source and the fiber
4. The dopants in the semiconductor material

3-54. What is it called when the fiber end face is directly placed over the source emitting region?

1. Butt coupling
2. Lensed coupling
3. Evanescent coupling
4. Fresnel coupling

3-55. What are the two most common semiconductor materials used in electronic and electro-optic devices?

1. Germanium and aluminum
2. Silicon and gallium arsenide
3. Indium and zirconium
4. Zinc and platinum

3-56. LEDs produce light by what process?

1. Combustion
2. Stimulated emission
3. Spontaneous emission
4. Photosynthesis

3-57. Lasers produce light by what process?

1. Combustion
2. Stimulated emission
3. Spontaneous emission
4. Photosynthesis

3-58. Stimulated emission is the random generation of photons within the active area of an LED.

1. True
2. False

3-59. In an optical source, the input electrical energy is converted to light and which of the following other forms of energy?

1. Gravitational
2. Sound
3. Heat
4. All of the above

ASSIGNMENT 4

Textbook assignment: Chapter 6, "Optical Sources and Fiber Optic Transmitters," pages 6-4 through 6-16. Chapter 7, "Optical Detectors and Fiber Optic Receivers," pages 7-1 through 7-14. Chapter 8, "Fiber Optic Links," pages 8-1 through 8-11.

4-1. Which of the following components is NOT one of the basic types of LEDs used for fiber optic communication systems?

1. Surface-emitting LED
2. Edge-emitting LED
3. Superluminescent diode
4. Avalanche photodiode

4-2. In low and moderate data rate applications, which of the following source types are typically used?

1. SLEDs only
2. ELEDs only
3. SLEDs and ELEDs
4. Lasers

4-3. Compared to SLEDs, ELEDs have all except which of the following properties?

1. Emit light in a narrower emission angle than SLEDs
2. Couple more power into small NA fibers than SLEDs
3. Emit power over a wider spectral range than SLEDs
4. Are more temperature sensitive than SLED

4-4. Which of the following definitions best describes the term laser mode?

1. The condition of the laser, either lasing or not lasing
2. The selected wavelengths that the laser emits
3. The maximum modulation frequency possible for the laser
4. The maximum angle of the emitted beam from the laser

4-5. What does the term lasing threshold mean?

1. The lowest drive current level at which the output of the laser results primarily from stimulated emission
2. The polished or cut surfaces at each end of the active stripe in the laser
3. The shortest wavelength that the laser emits
4. The front step of the laser chip

4-6. Transmitters containing what source type, if any, will typically require the most complex circuitry?

1. SLED
2. ELED
3. LD
4. None; all are roughly the same

4-7. Which of the following types of sources is typically the most temperature sensitive?

1. SLEDs
2. ELEDs
3. SLDs
4. LDs

4-8. Which of the following types of sources have very similar semi-conductor designs?

1. SLEDs, ELEDs, SLDs
2. SLEDs, ELEDs, lasers
3. SLEDs, SLDs, lasers
4. ELEDs, SLDs, lasers

4-9. What kind of circuitry do most lasers have that compensates for the sensitivity of the laser to its environment?

1. Linearization circuitry
2. Automatic overload protection circuitry
3. Power control circuitry
4. Low-pass filter circuitry

4-10. For lasers that are to be operated under widely changing thermal conditions, what device is normally included in the laser package?

1. Automatic overload protection circuitry
2. Thermo electric cooler
3. Variable attenuator
4. Low-pass filter

4-11. For fiber optic transmitters, which of the following are typical output interfaces?

1. Optical fiber pigtails
2. Single fiber cable pigtails
3. Optical connectors
4. All of the above

4-12. Which of the following types of transmitters are typically the most expensive?

1. SLEDs
2. ELEDs
3. SLDs
4. LDs

4-13. Which of the following are possible transmitter package types used in Navy shipboard applications?

1. Hybrid microcircuit dual inline packages (DIPs) only
2. Circuit cards only
3. Stand-alone fiber optic converters only
4. Hybrid microcircuit dual inline packages, circuit cards, and stand-alone fiber optic converters

4-14. In shipboard applications with moderate data rates (50 to 200 Mbps), which of the following source types will typically be used?

1. 850-nm LEDs only
2. 1300-nm LEDs only
3. 850-nm and 1300-nm LEDs
4. Lasers

4-15. In shipboard applications with low data rates (0 to 50 Mbps), which of the following source types will typically be used?

1. 850-nm LEDs only
2. 1300-nm LEDs only
3. Either 850-nm LEDs or 1300 nm LEDs depending on design
4. Lasers

4-16. Which of the following fiber optic components is responsible for converting the weakened and distorted optical signal back to an electrical signal?

1. Fiber optic transmitter
2. Fiber optic amplifier
3. Fiber optic receiver
4. Fiber optic coupler

4-17. Which of the following is NOT a typical part of a fiber optic receiver?

1. Optical detector
2. Thermo electric cooler
3. Low-noise amplifier
4. Output signal conditioning circuity

4-18. The term receiver sensitivity has which of the following meanings?

1. The minimum amount of optical power required to achieve a specific receiver performance
2. The range of optical power levels over which the receiver operates within specified values
3. The ratio of the output photocurrent to the incident optical power
4. The wavelengths over which the receiver will properly operate

4-19. The term dynamic range has which of the following meanings?

1. The minimum amount of optical power required to achieve a specific receiver performance
2. The range of optical power levels over which the receiver operates within specified values
3. The ratio of the output photocurrent to the incident optical power
4. The wavelengths over which the receiver will properly operate

4-20. An optical detector has which of the following purposes?

1. To convert an optical signal into an electrical signal
2. To convert an electrical signal to an optical signal
3. To amplify the optical output signal
4. To generate an optical pulse proportional to the input current

4-21. Which of the following attributes is NOT a desirable attribute of an optical detector?

1. Be compatible in size to low-loss optical fibers
2. Contribute high amounts of noise to the system
3. Have a high sensitivity at the operating wavelength of the optical source
4. Maintain stable operation in changing environmental conditions

4-22. In fiber optic systems, what are the principal types of detectors used?

1. Integrating spheres
2. Photon counters
3. Photomultiplier tubes
4. PIN photodiodes and APDs

4-23. Which of the following factors does NOT affect the amount of current generated by a photodiode?

1. The responsivity of the photodiode at the wavelength of the incident light
2. The data rate of the incoming optical signal
3. The size of the photodiode active area relative to the fiber core size
4. The alignment of the fiber and the photodiode

4-24. Which of the following terms is defined as the current produced by an optical detector because of the optical energy incident on its active area?

1. Photocurrent
2. Active current
3. Incident current
4. Threshold current

4-25. The term detector responsivity has which of the following meanings?

1. The minimum amount of optical power required to achieve a specific receiver performance
2. The range of optical power levels over which the receiver operates within specified values
3. The ratio of the output photocurrent to the incident optical power
4. The wavelengths over which the detector will convert light to electric current

4-26. The responsivity of an optical detector is constant over wavelength; that is, an optical detector does not absorb some wavelengths better than others.

1. True
2. False

4-27. A PIN photodiode usually operates in what way?

1. Reverse-bias voltage applied
2. Forward-bias voltage applied
3. No bias voltage applied

4-28. What is the name of the current produced by a photodiode when no light is incident on the device?

1. Threshold current
2. Spill current
3. Photocurrent
4. Dark current

4-29. Reverse-biased photodetectors are highly linear devices with respect to output photocurrent and input optical power.

1. True
2. False

4-30. When compared to the reverse-bias voltage of a PIN photodiode, the reverse-bias of an APD is which of the following sizes?

1. Much less than the PIN's
2. About the same as the PIN's
3. A little greater than the PIN's
4. Much greater than the PIN's

4-31. The gain of an APD can be changed in what way?

1. By changing the data rate of the incoming optical signal
2. By changing the reverse-bias voltage
3. By changing the modulation format of the incoming signal
4. By changing the input power of the optical signal

4-32. In a fiber optic receiver, what is the dominant contributor of electrical noise?

1. Optical detector
2. Preamplifier
3. Postamplifier
4. Output circuitry

4-33. What action, if any, will maximize the sensitivity of a fiber optic receiver?

1. Minimizing the receiver noise
2. Maximizing the receiver bandwidth
3. Maximizing the receiver dynamic range
4. None; no action will maximize sensitivity

4-34. In a fiber optic system, which of the following is NOT a typical source of noise?

1. Noise from the light source
2. Noise from the interaction of light with the optical fiber
3. Noise coupled in from adjacent optical fibers in a multifiber cable
4. Noise from the receiver itself

4-35. Which of the following types of noise are introduced by the fiber optic receiver?

1. Thermal noise only
2. Shot noise only
3. Quantum noise only
4. Thermal noise, shot noise, and quantum noise

4-36. Which of the following are basic types of preamplifiers used in typical fiber optic receivers?

1. High-impedance and high- fidelity amplifiers
2. High-impedance and trans- impedance amplifiers
3. High-fidelity and trans- impedance amplifiers
4. High-impedance, high-fidelity, and transimpedance amplifiers

4-37. Compared to a high-impedance amplifier, a transimpedance amplifier provides all but which of the following improvements?

1. Sensitivity
2. Dynamic range
3. Bandwidth

4-38. For which of the following applications would a transimpedance amplifier typically be used instead of a high-impedance amplifier?

1. Low-data-rate applications only
2. Moderate-data-rate applications only
3. Low- and moderate-data-rate applications
4. High-data-rate applications

4-39. For which of the following applications would an APD rarely be used?

1. Low- and moderate-data-rate applications
2. Low- and high-data-rate applications
3. Moderate- and high-data-rate applications

4-40. What type of fiber optic link consists of two simple point- to-point links transmitting in opposite directions?

1. Simplex link
2. Full duplex link
3. Composite link
4. Total link

4-41. What type of fiber optic link is the basic building block of all fiber optic systems?

1. Point-to-point
2. Point-to-central
3. Branch
4. Loop

4-42. What topology consists of a single transmission line that is shared by a number of equipments?

1. Linear bus topology
2. Ring topology
3. Star topology
4. Tree topology

4-43. What topology consists of a transmission line that branches or splits?

1. Linear bus topology
2. Ring topology
3. Star topology
4. Tree topology

4-44. What topology consists of equipments attached to one another in a closed loop?

1. Linear bus topology
2. Ring topology
3. Star topology
4. Tree topology

4-45. In what topology is each equipment connected to a common center hub?

1. Linear bus topology
2. Ring topology
3. Star topology
4. Tree topology

4-46. What are the two basic classifications of fiber optic links?

1. High power and low power
2. Return-to-zero and non-return- to-zero line coded
3. Digital and analog
4. Amplitude modulated and frequency modulated

4-47. A digital signal can be defined as which of the following signals?

1. A continuous signal whose amplitude or some other property varies in direct proportion to some physical variable
2. A discontinuous signal that changes from one state to another in discrete steps
3. A signal generated by an electrical circuit
4. A signal generated by a laser

4-48. Which of the following items is NOT an example of a digital line code?

1. Frequency modulation
2. Non-return-to-zero
3. Return-to-zero
4. Manchester

4-49. What line code, if any, makes the most efficient use of system bandwidth?

1. Non-return-to-zero
2. Return-to-zero
3. Manchester
4. None; all have the same efficiency

4-50. When compared to analog transmission, digital systems can tolerate which of the following conditions without affecting system performance?

1. Large amounts of signal loss and dispersion
2. Source nonlinearities
3. Effects of temperature on system components
4. All of the above

4-51. An analog signal is defined as which of the following signals?

1. A continuous signal whose amplitude or some other property varies in direct proportion to some physical variable
2. A discontinuous signal that changes from one state to another in discrete steps
3. A signal generated by an electrical control circuit
4. A signal generated by an LED

4-52. The typical method of source modulation for most analog fiber optic systems is what type of modulation?

1. Phase modulation
2. Wavelength modulation
3. Intensity modulation
4. Pulse position

4-53. Analog transmission would most likely be used in which of the following shipboard applications?

1. Video links
2. Local area networks
3. Computer interconnections
4. Long-haul communications

4-54. A fiber optic cable plant consists of which of the following parts?

1. The fiber optic cables associated with the combat system only
2. The fiber optic cables associated with noncombat systems only
3. The fiber optic interconnection equipment only
4. All of the fiber optic cables and the fiber optic interconnection equipment within the ship

4-55. When installing fiber optic cables aboard Navy ships, which of the following precautions should you take?

1. Never bend an optical cable in a bend smaller than the cable's minimum bend radius
2. Always clean fiber optic connectors before mating them
3. Never pull a fiber optic cable over or through sharp corners or cutting edges
4. All of the above
